These experiments show that there exists in flame an electric current, not of thermo-electric origin, and such that the platinum at the base of the flame plays the part of the positive metal in the circuit which it forms with the platinum at the apex. (Grove.)

Matteucci attributes the flame-current to the same mode of action as that which takes place in Grove's gas-battery. In fact, in the arrangements above described, one of the platinum wires is in contact with the combustible matter of the flame, viz. hydrogen or vapour of alcohol, the other with the oxygen of the air, and between them is a quantity of aqueous vapour, the particles of which become polarised, and suffer electrolytic decomposition just as those of the water in the gas battery; the direction of the current is in accordance with this view, the platinum immersed in the hydrogen or alcohol-vapour acting as the positive metal. A similar explanation is applicable to the development of electricity in the combustion of charcoal. Matteucci has shown that when pure charcoal burns in dry oxygen gas, no electricity is developed; but when the combustion takes place in moist air or oxygen, an electric current is produced, the vapour of water being as before the electrolyte, and being decomposed by the hot charcoal, just as the water in an ordinary voltaic couple is decomposed by the zinc; so that the charcoal becomes charged with $-E$, and the aqueous vapour and carbonic anhydride with $+E$.

CHEMICAL EFFECTS OF THE ELECTRIC CURRENT. ELECTROLYSIS.

The decomposition of chemical compounds by the electric current has been already considered in connection with the discharge of friction electricity (p. 397), and with the development of electricity by chemical action; but there are several important facts and laws relating to it which must now be more fully developed.

When an electric current passes through any compound liquid, the elements or radicles of that liquid (regarded as a binary compound) are separated and transferred in opposite directions, the one following the direction of the positive, the other that of the negative electricity, and the separation going on continuously as long as the current is kept up. The separation and transference of the elements takes place in the same manner, from whatever source the electricity may be derived; but they are exhibited most conspicuously by voltaic electricity.

This mode of decomposition is called *Electrolysis* ($\epsilon\lambda\epsilon\kappa\tau\rho\nu$ and $\lambda\upsilon\epsilon\iota\upsilon$); the compound decomposed is an *Electrolyte*; and the extremities of the metallic or other conductors by which the current enters the liquid are called *Electrodes* ($\epsilon\lambda\epsilon\kappa\tau\rho\nu$ and $\epsilon\delta\delta\omicron\varsigma$). They were formerly called *poles*, but the term *electrode* is preferable, because less theoretical, a pole being usually understood as a centre of force, as in fact the metallic terminals of the voltaic battery were regarded in the earlier days of the science.* The electrodes are in most cases surfaces of metal, but they may also be surfaces of liquid or even of air, as in the decompositions by friction-electricity described at p. 397.

Those elements or radicles which follow the direction of the current of positive electricity, and are evolved at the negative electrode, are called *electro-positive bodies*; such are for the most part hydrogen, the metals, and basic radicles in general: those which travel in the direction of the current of negative electricity and are eliminated at the positive electrode, are called *electro-negative bodies*; such are oxygen, chlorine, iodine, cyanogen, and acid radicles in general. It must be understood, however, that the electric relations of elements, like the purely chemical relations of acid and base, are not absolute, but vary according to the combination in which they exist; an element which is electro-positive in one combination may be electro-negative in another.

When two platinum plates or wires connected with the poles of a voltaic battery, of not less than three pairs, are plunged into water acidulated with sulphuric acid, to increase its conducting power, streams of gas are evolved from the liquid at the surfaces of both the platinum terminals—hydrogen from that which is connected with the negative, oxygen from that which is connected with the positive, pole; and if the gases are collected in separate tubes placed over the platinum terminals, the hydrogen is found to occupy twice the volume of the oxygen. The quantity of these gases

* The terms *electrolysis*, *electrolyte*, and *electrode* were introduced by Faraday, who further designates the surface of the electrolyte in contact with the positive electrode as the *anode*, and that which is in contact with the negative electrode as the *cathode*; he also applies the terms *anions* and *cations* to the elements evolved at the anode and cathode respectively, and includes both sets of elements under the general term, *ions*. For the derivation of these terms, see *Faraday's Experimental Researches*, series vii., also the article *ANION* in this Dictionary.

evolved in a given time serves as a measure of the chemical power of the battery: hence an apparatus arranged for decomposing water in this manner and measuring the quantities of gas obtained is called a *Voltameter*. *Fig. 420* represents a voltameter for

Fig. 420.*Fig. 421.**Fig. 422.*

collecting the gases in separate tubes; *figs. 421, 422*, voltameters in which they are collected in the same tube: the latter is generally the more convenient form of measurement, because a larger quantity of gas is collected in a given time; but when particular accuracy is required, it is best to collect the gases separately, and measure only the hydrogen, because the oxygen is somewhat more rapidly absorbed by the water.

When hydrochloric acid is subjected to the action of the battery with platinum electrodes, hydrogen is evolved at the negative, and chlorine at the positive electrode; but with copper electrodes chloride of copper is formed at the latter. Iodide of potassium in aqueous solution, with platinum electrodes, yields iodine at the positive, and potassium at the negative electrode, the potassium not however being separated in the metallic state, but decomposing the water; so that hydrogen is evolved and a solution of potash is formed. Aqueous sulphate of sodium (Na_2SO_4) yields in like manner sodium at the negative, SO_4 at the positive electrode, the sodium being converted into soda, with elimination of hydrogen, the SO_4 into sulphuric acid (H_2SO_4) with elimination of oxygen. Aqueous sulphate of copper (Cu_2SO_4) yields metallic copper at the negative, and sulphuric acid at the positive electrode.

Fused iodide of lead yields iodine at the positive, lead at the negative electrode; other fused chlorides, bromides, and iodides, yield similar results.

It is only at the surface of the electrodes that any signs of decomposition are apparent; the intermediate portion of the liquid appears perfectly quiescent; nevertheless this portion forms part of the circuit along which the current passes, and must therefore be subject to its influence; indeed, if we regard the current as a succession of molecular charges and discharges, taking place throughout the circuit (p. 404), every molecule of liquid between the electrodes must experience a succession of these actions. The non-appearance of any change, except at the electrodes, is explained as follows:—

Suppose the electrolyte to be hydrochloric acid. A row of its molecules situated between the electrodes *p n* (*fig. 423*) becomes polarised by the action of the battery, the chlorine-atoms (denoted by the dark half-circles in the figure) taking a negative charge and turning towards the positive electrode, while the hydrogen-atoms (the light half-circles) take a positive charge and turn towards the negative electrode. When this state of tension has reached a certain limit, discharge takes place along the whole row of particles, the chlorine of each molecule passing on to the hydrogen of the one on its left: whence it follows that an atom of chlorine is left free at the positive, and an atom of hydrogen at the negative electrode, and the remaining atoms arrange themselves as shown in the second line of the diagram. The same process is then repeated; these molecules become polarised like those of the first row, turning their chlorine-atoms to *p*, and their hydrogen-atoms to *n*, and when the tension has reached a certain height, discharge again takes place, a second atom of chlorine being evolved at *p*, and a hydrogen atom at *n*; and in this manner the action is continued, no change

being apparent in the intermediate molecules, because one molecule of hydrochloric acid is exactly like another. The decomposition which goes on in a liquid subjected

Fig. 423.

to the action of the battery is, in fact, exactly the same as that which takes place in the cells of the battery itself, as already explained (p. 419).

A similar explanation applies to every case of the decomposition of a single electrolyte. Moreover, the same interchange of atoms may take place between two or more liquids, placed between the same electrodes and connected together by columns of liquid, as by siphon-tubes filled with water, or by moistened bundles of cotton or asbestos, as shown in *figs. 424, 425, 426*, or separated by porous diaphragms. Suppose,

Fig. 424.

Fig. 426.

Fig. 425.

for example, the positive electrode to be immersed in a solution of nitrate of potassium, and the negative in a solution of chloride of sodium, the two liquids being separated by a partition of bladder, vegetable parchment, or porous earthenware. A series of molecules between the electrodes may be thus represented :

The atoms are then transferred in opposite directions in the manner above described, the atom NO^3 in 1 being in the first instance evolved at p , and the atom of Na in 6 at n . At the same time, the K in 1 is transferred to the NO^3 in 2, the K in 2 to the NO^3 in 3, the K in 3 to the Cl in 4, the Na in 4 and 5 to the Cl in 5 and 6, respectively: so that the new arrangement is —

The action is then continued in the same manner, the successive steps of the decomposition being represented as follows:

In this manner, both the acid radicles are transferred to the positive and both the basic radicles (metals) to the negative electrode.

The same transference of atoms in opposite directions takes place with any number of solutions, all the acids ultimately reaching the positive, and all the bases the negative electrode, provided all the compounds formed by the several interchanges of molecules are soluble: but if an insoluble compound is formed, it falls to the bottom, is removed from the sphere of action, and its elements are not carried any further.

Thus when a solution of sulphate of potassium is placed in contact with the negative electrode, distilled water at the positive electrode, and a solution of caustic baryta between them (*fig. 425*), no sulphuric acid is transferred to the positive electrode, but a precipitate of sulphate of barium is formed in the middle liquid. Similarly with chloride of barium in the positive vessel, water in the negative, and sulphate of potassium in the middle, potash soon appears in the negative vessel, and a precipitate of sulphate of barium is formed in the middle vessel; but no baryta is transferred to the negative, or sulphuric acid to the positive electrode. When chloride of barium is placed in the negative vessel, sulphate of silver in the middle, and water in the positive vessel, thus

sulphuric acid makes its appearance after a while in the positive vessel, and a precipitate of chloride of silver is formed in the middle.

Relation between Decomposition and Conduction.—From the manner in which electrolytic decomposition takes place, it is manifestly dependent on that freedom of motion among the molecules of a body which is found only in the liquid state. On the other hand, the transference of atoms in opposite directions is an essential condition of the passage of electricity through compound liquids; the series of discharges between contiguous molecules, which in solid conductors takes place without permanent dislodgement of the atoms, is in the electrolyte essentially connected with the interchange of the constituent atoms. Many oxides, chlorides, and salts of various kinds, *e.g.* potash, protoxide of lead, the chlorides of the alkali- and earth-metals, sulphide of antimony, sulphide of potassium, chlorate and nitrate of potassium, borate of lead, &c. &c., which resist the passage of the voltaic current while in the solid state, conduct and suffer decomposition when fused; whereas other compounds, *e.g.* iodide of sulphur, stannic iodide, orpiment, realgar, glacial acetic acid, caffeine, spermaceti, camphor, &c., neither conduct nor are decomposed when melted. The same is true of stannic chloride, chloride of arsenic, and hydrated chloride of arsenic, which are liquid at common temperatures. (Faraday.)

There is an apparent exception to this law, with regard to water and certain other liquids, which appear to conduct feeble currents of electricity without undergoing decomposition. Thus Faraday found that when acidulated water, solution of sulphate of sodium, fused nitre, fused chloride of lead, fused chloride of silver, or fused iodide of lead, was placed, together with solution of iodide of potassium, in the circuit of a single pair of zinc and platinum plates excited by dilute acid, the iodide of potassium was decomposed, but not the other electrolyte, which therefore appeared to conduct without decomposing. According to Jacobi also, the current of a single pair does not decompose water, and yet produces deflection of the galvanometer. If the current of a ten-pair battery be weakened, by the interposition of a long thin wire, to such a degree, that it produces the same deflection of the galvanometer needle as the current of a single pair, it likewise appears to pass through water without producing decomposition.

This passage of feeble currents through electrolytes without decomposing them, appears at first sight to be at variance with the law of definite electrolytic action (*p. 438*). The anomaly, however, is only apparent. It is true that no gas is obtained when a feeble current is passed into acidulated water by means of platinum plates; nevertheless the water is decomposed, but so slowly that the oxygen and hydrogen gases liberated on so large a surface, partly surround it as an envelope, and are partly absorbed by the water. The decomposition may, however, be made apparent by placing the apparatus under an exhausted receiver, the gases then making their appearance on the surface of the plates. Another mode of rendering decomposition by feeble currents visible is to reduce the surface of one of the electrodes. Thus, if one of the electrodes consists of a platinum plate and the other of a fine platinum wire covered with glass up to its very point, gas is evolved from the surface of this wire, partly because there is no surface to which it can attach itself, and partly perhaps because the large surface of the other electrode intensifies the polarisation of the metal point, and of the particles of electrolyte in contact with it, just as a metal plate or the extended hand does, when held before a pointed rod inserted into the conductor of an electrical machine (*p. 389*). The evolution of gas from the wire ceases, however, after a short time, but may be renewed by increasing the surface of the other electrode, or by reversing the current, which destroys the polarisation of the electrodes (*p. 429*).

Secondary products of Electrolysis. It is but rarely that both elements of an electrolyte are separated at the electrodes in the free state, one or both of them frequently entering into some new combination, either with substances contained in the solution,

or with the electrodes themselves. Instances of this secondary action have been already noticed in speaking of the electrolysis of sulphate of sodium and other salts, and many others may be given. In a mixture of hydrochloric and hydriodic acids nothing but iodine would be evolved at the positive electrode, because, though both acids might be decomposed at once by the current, the chlorine, as soon as liberated, would decompose another portion of the hydriodic acid, combining with the hydrogen and liberating an equivalent quantity of iodine.

When an aqueous solution of acetate or nitrate of lead is electrolysed, metallic lead is deposited on the negative, and peroxide of lead on the positive electrode, the latter being formed by the action of oxygen separated from the water on the lead in the solution; accordingly the quantity of oxygen gas evolved at the positive electrode is considerably less than in a voltameter included in the same circuit.

Aqueous ammonia yields, by electrolysis with platinum electrodes, pure nitrogen at the positive and hydrogen at the negative electrode, the volume of the latter being three or four times greater than that of the former. The gases are not, however, evolved by the direct action of the current; for the proportion of nitrogen is not constant, but varies with the strength of the solution, whereas the volume of hydrogen evolved is exactly equal to that in a voltameter included in the same circuit: whence it appears that the water of the aqueous ammonia is decomposed by the current, and the nitrogen evolved at the positive electrode results from the decomposition of the ammonia by nascent oxygen, with which indeed it is often mixed to a small amount.

Nitric acid yields oxygen at the positive electrode, in quantity equal to that in a voltameter in the same circuit; no gas is evolved at the negative electrode, but the nitric acid is there reduced to nitrous acid and nitric oxide, which colour the liquid yellow or red. This result is due, partly to the electrolysis of the water, the hydrogen from which reduces the nitric acid at the negative electrode, partly to the direct decomposition of the nitric acid itself, into NO^2 and H , the NO^2 being transferred to the positive electrode, where it decomposes water, reproducing nitric acid and eliminating oxygen. In consequence of this action, the strength of the acid increases around the positive electrode.

The substances eliminated from a solution by the action of the current sometimes enter into combination with the electrodes. This is especially the case when the positive electrode is formed of an oxidable metal; thus, when acidulated water is decomposed with a plate of copper or iron for the positive electrode, no oxygen is evolved, but the metal dissolves in the acid. On the other hand, when the negative electrode is coated with a metallic oxide, especially with a peroxide (such as MnO or PbO), the hydrogen reduces this oxide and forms water. Actions of this kind taking place at the electrodes greatly assist the decomposition, by inducing a polarisation of the molecules of the electrolyte in the same direction as that induced by the action of the battery.

Becquerel (*Traité de l'Electricité et du Magnétisme*, 1835, tom. iii. pp. 294—330), by exposing different solutions to the action of feeble electric currents with electrodes of various nature, has obtained many metallic compounds, viz. oxides, sulphides, iodides, &c., and even the sulphate and carbonate of barium, in regular crystals.

Organic compounds subjected to electrolysis yield numerous secondary products. A solution of acetate of potassium divided into two parts by a porous diaphragm, to prevent the mixing of the gases evolved at the two electrodes, yields pure hydrogen, together with potash, at the negative electrode, and at the positive (if of platinum) a mixture of carbonic anhydride and methyl-gas, with a small quantity of oxide of methyl:

We may suppose that the acetic acid is resolved by the current into H and $\text{C}^2\text{H}^4\text{O}^2$, the latter then splitting up into CO^2 and CH^4 . Other acids of the adipic series, $\text{C}^n\text{H}^{2n}\text{O}^2$, are decomposed in a similar manner, the general formula of the decomposition being

An aqueous solution of ethylsulphate of potassium yields, at the negative electrode potash and hydrogen, and at the positive, ethylsulphuric acid, which, if the positive electrode is formed of amalgamated zinc, forms ethylsulphate of zinc, but if the positive electrode is of platinum, is resolved, partly by oxidation, into carbonic anhydride, aldehyde, and sulphuric acid. Amylsulphate of potassium with platinum electrodes yields potash and hydrogen at the negative electrode, and at the positive, free sulphuric acid and oxygen, with an odour of valeric acid. Amylphosphate of potassium

yields in like manner, at the positive electrode, oxygen, carbonic acid, and phosphoric acid, with an odour of valeric or butyric acid. (Guthrie, Chem. Soc. Qu. J. ix. 131.)

Electrolytic reduction of Metals. All metals may be reduced by electrolysis from one or other of their compounds, either in the fused state or in aqueous solution. Several examples of these reductions have already been mentioned. The less oxidizable metals, such as copper, lead, tin, and other noble metals, are reduced from the solutions of their salts with the utmost ease, even by the current of a single pair. Indeed, as explained at page 420, every precipitation of one metal by another, such as that of copper by iron, lead and tin by zinc, silver by copper, &c., is an example of electrolytic decomposition. The electrotype process and the processes of electro-silvering and electro-gilding also belong to the same order of phenomena. For the details of these processes we must refer to *Ure's Dictionary of Arts, Manufactures, and Mines*, article **ELECTRO-METALLURGY**.

The electrolytic process is also used for the detection of metals in toxicological investigations, &c. It has long been applied to the detection of small quantities of mercury, a thin plate of gold being used as the negative electrode, so that the mercury may form an amalgam with it. In 1850, Gaultier de Claubry (*J. Pharm.* [3] xvii. 125; *Chem. Soc. J.* ii. 167) proposed its application to the detection of other metals, *e.g.* arsenic, antimony, lead, copper, zinc, &c., and more recently Bloxam (*ibid.* xiii. 14) has applied it to the detection of arsenic, a solution of arsenious acid acidulated with sulphuric or hydrochloric acid and decomposed by the electric current, giving off the greater part of its arsenic as arsenetted hydrogen (i. 362).

The reduction of the more oxidizable metals requires, for the most part, more powerful currents and peculiar arrangements, to prevent the recombination of the metal with the oxygen, chlorine, or other element, from which it has been separated, and at the same time to concentrate the force of the current at the point of reduction. The latter object may be effected by reducing the negative electrode to a fine point, and giving the positive electrode a considerable surface, as already described with reference to the decomposition of water by feeble currents. Bunsen finds that, with a given battery power, the reducing force of the current varies nearly in the inverse ratio of the transverse section of the electrode at which the reduction takes place. Thus, a current of constant strength passed through an aqueous solution of sesquichloride of chromium, eliminates, as the cross section of the negative electrode is diminished, hydrogen, chromic oxide, chromous oxide, and finally metallic chromium. (*Pogg. Ann.* xci. 619.)

It was by an arrangement based on this principle, and with the aid of a powerful battery, that Davy succeeded in isolating the metallic bases of the alkalis. Thus, to reduce *potassium*, hydrate of potassium contained in a platinum capsule was moistened with a small quantity of water, and brought in contact with the end of a platinum wire connected with the negative pole of a powerful voltaic battery, the positive pole of which was connected with the capsule. Potassium then collected round the wire in small metallic globules, most of which, however, took fire in the air, and were reconverted into caustic potash. By making a hole in the lump of hydrate of potassium, filling it with mercury, and dipping the negative wire into the mercury, the reduction is much more easily effected, the potassium forming an amalgam, from which the mercury may afterwards be removed by distillation. The reduction of *sodium* is effected by similar methods.

Barium may be obtained by subjecting the chloride mixed up to a paste with water and a little hydrochloric acid, at the temperature of 100° C., to the action of the electric current, using for the negative electrode an amalgamated platinum wire. A crystalline amalgam is thus obtained, from which the mercury may be distilled off in a stream of hydrogen. *Strontium* may be obtained in a similar manner; also *calcium*, though less easily, because the point of the wire becomes covered with a crust of lime, which interrupts the current. (Bunsen, *Pogg. Ann.* xci. 619.)

Some of the alkali- and alkaline-earth-metals form fusible chlorides, from which the metals are easily obtained by electrolysis.

Lithium may be reduced by subjecting its chloride, fused over a spirit-lamp in a small porcelain crucible, to the action of a Bunsen's battery of four to six cells. The positive electrode is formed of a small splinter of gas-coke, and the negative of an iron wire, about as thick as a knitting-needle. After a few seconds, a small, silver-white regulus is formed round the wire, under the fused chloride. It may be lifted out of the fused mass, together with the wire electrode, by means of a small flat iron spatula, the wire withdrawn with the still melted metal, which is protected from oxidation by a coating of chloride of lithium, and the metal removed from the spatula by a pen-knife, after having been cooled under rock-oil. These operations may be repeated every two or three minutes, and thus an ounce of the chloride reduced in a very short time. (Bunsen, *loc. cit.*)

Strontium is likewise obtained from the fused chloride. A small porcelain crucible, having a porous cell in the middle, is filled with anhydrous chloride of strontium, mixed with a little sal-ammoniac, the level of the salt within the cell being considerably higher than in the crucible. The negative electrode, which is placed within the porous cell, consists of a very thin iron wire, wound round a thicker one, and then covered with a piece of tobacco-pipe stem, so that only $\frac{1}{8}$ of an inch of it appears below; the positive electrode is an iron cylinder, placed in the crucible round the porous cell. The heat is regulated during the experiment, so that a crust may form in the cell. The metal then collects under this crust, without coming in contact with the sides of the crucible. By this method, pieces of the metal weighing half a gramme are sometimes obtained. (Matthiessen, Chem. Soc. Qu. J. viii. 107.)

Barium may be reduced, in like manner, from the chloride, but only as a metallic powder; and *calcium* from a mixture of 2 at. chloride of calcium, 1 at. chloride of strontium, and a little sal-ammoniac. (Matthiessen.)

Magnesium is separated from the fused chloride as follows:—A porcelain crucible (fig. 427) is divided in half in its upper part by a vertical diaphragm (made out of a

Fig. 427.

thin porcelain crucible-cover, and fitted with a lid filed from a tile), through which the extremities of the electrodes, made of gas-coke or Bunsen's charcoal (i. 760), are introduced into the two halves of the crucible. The crucible is then heated to redness, together with the cover and the electrodes, filled with fused chloride of magnesium, and subjected to the action of a 10-pair Bunsen's battery. The negative electrode is cut like a saw, so that the magnesium, as it separates, may lodge in the cavities, and not float on the surface of the specifically heavier liquid. (Bunsen, Ann. Ch. Pharm. lxxxii. 137.) According to Matthiessen (Chem. Soc. Qu. J. viii. 107), the metal may be much

more easily obtained from a fused mixture of 4 at. chloride of magnesium and 3 at. chloride of potassium, with a little sal-ammoniac; the cutting of the negative electrode may then be dispensed with, as the metal is heavier than the fused salt. A simple mode of effecting the reduction is to fuse the mixture in a common clay tobacco-pipe over a lamp, the negative electrode being formed of an iron wire passed up the pipe-stem, and the positive of a piece of gas-coke, just touching the surface of the fused chlorides. (Matthiessen.)

Aluminium may be obtained by similar methods from the fused chloride of aluminium and sodium. But as this salt fuses at a very moderate heat, at which the aluminium does not fuse, but separates as a powder, pulverised chloride of sodium should be gradually added during the reduction, in sufficient quantity to raise the temperature nearly to the melting point of silver. The aluminium then separates in large metallic globules. (Bunsen; Deville.)

For the reduction of certain metals from solutions, Bunsen arranges the decomposing cell as follows:—The positive electrode is formed of the inner concave surface of a charcoal crucible, filled with hydrochloric acid and standing within a porcelain crucible. The liquid to be decomposed is contained in a small porous cell standing in the carbon crucible, and the negative electrode is formed of a wire or narrow strip of platinum dipping into the liquid. The whole is heated over the water-bath. A concentrated solution of chromic or manganous chloride, subjected in this manner to the action of a 4-pair Bunsen's battery, quickly yields large lumps of the metal chemically pure.

Law of Definite Electrolytic Action.

Faraday first demonstrated the important law that: *The quantity of any electrolyte decomposed by the electric current is constant for a given quantity of electricity.* Suppose a number of voltmeters with platinum electrodes (p. 433) to be traversed by the same electric current, not divided between them, but passing through them all in succession; then it is found that the quantities of oxygen and hydrogen gases collected in a given time, are the same in all the voltmeters, even though the water contained in them may be acidulated in different degrees, and the electrodes may be of different sizes. The quantity of electricity which passes is determined by the resistance of the liquid which possesses least conducting power, and this quantity of electricity decomposes the same amount of water in all parts of the circuit. As, however both the gases are slightly soluble in water, and the oxygen more so than

the hydrogen, it is necessary to guard against errors thence arising, by placing the electrodes very close to one another, and at equal distances in all the voltameters, so that the gases may have only a short column of liquid to traverse, and not to leave the gases long in contact with the liquid, especially if the electrodes have large surfaces. As oxygen is more soluble in water than hydrogen, more exact results are obtained by collecting the hydrogen alone than the two gases together.

If the same current be divided between two voltameters (by means of a branching conductor), and then made to pass wholly through a third voltameter, the quantities of hydrogen evolved in the first two are together equal to that evolved in the third; and if the current is equally divided between the first two (as measured by the galvanometer) the quantities of hydrogen collected in them are equal to one another.

When the same current passes successively through different electrolytes, the quantities of these compounds decomposed, and of the several elements eliminated, are chemically equivalent to each other.

Faraday decomposed fused stannous chloride (SnCl_2) by a current which also traversed a voltameter containing acidulated water. Into the chloride contained in a bent glass tube, and kept in a state of fusion by a spirit-lamp, two platinum wires were inserted, one connected with the negative pole of a voltaic battery, the other with one of the electrodes of the voltameter, the second electrode of which was connected with the positive pole of the battery. Tin was then deposited on the negative electrode in the fused chloride, and at the same time the water in the voltameter was decomposed.

The experiment having been continued till the quantity of mixed oxygen and hydrogen gases collected in the voltameter amounted to 3.85 cubic inches, or 0.497 grains, the metallic tin deposited in the same time was found to weigh 3.2 grains. Now, these two quantities are very nearly in the ratio of the atomic weights of water and tin: for $0.497 : 3.2 = 18 : 115.8$. The difference between the number thus obtained and 118, the true atomic weight of tin, probably arose from the action of the chlorine evolved at the positive electrode on the tin, whereby a certain quantity of chloride was reproduced, the arrangement adopted not being capable of effecting a very complete separation. Four experiments made in a similar manner gave for the atomic weight of tin, as determined by electrolysis, the number 117.16.

The decomposition of chloride of lead in a similar manner, the positive electrode being formed of plumbago, gave for lead the number 100.85, the true atomic weight being 103.5. An experiment with borate of lead gave 101.20.

Faraday, in his "Experimental Researches" (ser. vii.), supposes that it is only compounds which, according to the atomic weights at that time generally adopted, are composed of 1 at. of each of their components, *e.g.* water = HO , hydrochloric acid HCl , sulphate of copper, CuSO_4 , &c., that can be decomposed by the electric current. Subsequent experiments by Matteucci and E. Becquerel have shown, however, that this is not the case; for trichloride of antimony, and cuprous as well as cupric chloride, also several basic nitrates and nitrites of lead, and other salts of various composition, must be ranged among electrolytes. E. Becquerel finds that when trichloride of antimony is electrolysed in the same circuit with a voltameter, for each atom of hydrogen evolved in the latter, 1 at. chlorine and $\frac{1}{3}$ at. antimony are separated (or for 3 at. hydrogen 3 at. chlorine and 1 at. antimony). With trichloride of iron, Fe^3Cl_3 , 1 at. chlorine and $\frac{1}{3}$ at. iron are separated for each atom of hydrogen in the voltameter. Cuprous chloride, Cu^+Cl_2 , gives 1 at. chlorine and 1 at. copper for 1 at. hydrogen.

The general result may be thus stated:—*The quantities of any number of electrolytes decomposed by the same electric current passing through them in succession, are such as contain equal numbers of atoms of hydrogen, or equivalent quantities of any other radicals, positive or negative.* Thus the quantities of the several electrolytes in the following table, which would be decomposed by the same current, are such as are expressed symbolically in the second column, and by their equivalent weights in the third.

	Formula.	Equivalent Weight.
Water	H^2O	18
Hydrochloric acid	H^2Cl^2	73
Cupric chloride	Cu^+Cl_2	134.2
Cuprous chloride	$(\text{Cu}^+)\text{Cl}_2$	197.4
Stannous chloride	Sn^+Cl_2	189
Antimonious chloride	$\frac{2}{3}(\text{Sb}^+)\text{Cl}_3$	152.3
Ferric chloride	$\frac{1}{3}\text{Fe}^3\text{Cl}^3$	108.3
Sulphuric acid	H^2SO^4	98
Cupric sulphate	Cu^+SO^4	159.2

When an aqueous solution, or a mixture of different electrolytes, is subjected to the action of the current, secondary actions intervene, leading to results which, at first sight, appear inconsistent with the law of definite electrolytic action. Thus, when a solution of sulphate of sodium is electrolysed, sulphuric acid and free oxygen are eliminated at the positive electrode, soda and hydrogen at the negative; and Daniell has shown that, if a voltameter containing acidulated water is interposed in the same circuit, the quantities of oxygen and hydrogen evolved from the saline solution are equal to those evolved from the water in the voltameter; and at the same time, if the saline solution is strong, quantities of sulphuric acid and soda exactly equivalent to these quantities of oxygen and hydrogen are separated from the salt. Here, then, the same current appears to do twice as much chemical work in the solution of sodic sulphate as in the voltameter. This anomaly is, however, only apparent; the fact being that, in a solution of a certain strength, only the sodic sulphate, Na_2SO_4 , is directly decomposed by the current, the sodium going to the negative, the oxysulphione (SO^4) to the positive electrode. Neither of these radicals is, however, eliminated in the free state: for the sodium decomposes the water near the negative electrode, forming soda and eliminating hydrogen; and the oxysulphione decomposes the water near the positive electrode, forming sulphuric acid, H_2SO_4 , and eliminating oxygen; and as the quantities of sodium and oxysulphione directly eliminated by the current are equivalent to the hydrogen and oxygen evolved in the voltameter (Na^2 and SO^4 in the one, H^2 and O in the other), it follows—1. That the quantities of hydrogen and oxygen evolved from the saline solution are equal to those evolved in the voltameter.—2. That equivalent quantities of sulphuric acid and soda are afterwards found at the two electrodes.

If the solution contains a salt of any metal not capable of decomposing water, such as sulphate of copper, the metal is deposited on the negative electrode, in quantity equivalent to the hydrogen evolved in the voltameter, and no hydrogen is separated at the negative electrode; while at the positive electrode sulphuric acid is formed, and oxygen evolved as above. In dilute solutions, the water and the salt are decomposed simultaneously by the current, in quantities which are together equivalent to the quantity of water decomposed in the voltameter. Thus, suppose that a dilute solution of sulphate of copper yields 2 grains of hydrogen, while 3 grains of that gas are collected in the voltameter; then the quantity of copper reduced at the negative electrode will be the equivalent of the remaining 1 grain of hydrogen in the voltameter, that is to say, 31.6 grains.

When water acidulated with sulphuric acid is decomposed by the current, the sulphuric acid, H_2SO_4 , is decomposed as well as the water—the SO^4 going to the positive electrode, where it eliminates oxygen and forms sulphuric acid; consequently, that acid accumulates about the positive electrode. The quantities of hydrogen and oxygen evolved are clearly the same as if the water alone were decomposed.

In the electrolysis of dilute hydrochloric acid, both the acid and the water are decomposed—the chlorine and oxygen evolved at the positive electrode being together equivalent to the hydrogen set free at the negative electrode.

An aqueous solution of peroxide of hydrogen (H_2O_2) yields, by electrolysis, a quantity of hydrogen equal to that evolved from water in the same circuit, and consequently a double quantity of oxygen. This apparent anomaly may be explained by regarding peroxide of hydrogen as a compound of water and oxygen; and supposing that the water is resolved by the current into H^2 and O , its decomposition necessarily involving the elimination of the second atom of oxygen which had been united with it.

In all cases of mixtures of two or more electrolytes, the sum of the quantities decomposed is the equivalent of the quantity of any one of them that would be decomposed by the same current acting for the same time—or, which comes to the same thing, of the quantity of water simultaneously decomposed in a voltameter. The proportion of each compound decomposed depends upon the nature of the electrolytes, and the proportions in which they are mixed. In concentrated aqueous solutions of the chlorides, bromides, and iodides of hydrogen and the metals, it is only these compounds that are directly decomposed by the current; but in dilute solutions, the water is decomposed at the same time.

Relations between the Quantity and Intensity of the Current and its Decomposing Power.

The chemical action which takes place in the cells of the battery is likewise equivalent to that which is produced in the decomposing cells, provided there is no local action (p. 418) on the surface of the positive metal. If a battery could be so constructed that there should be no local action, this relation would be strictly true; that is to say, in a battery composed of amalgamated zinc, dilute sulphuric acid, and

platinum, the volume of hydrogen evolved from the surface of each platinum plate would be equal to that evolved in a voltameter placed in the same circuit, and the quantity of zinc dissolved in each cell would be the exact equivalent of this, viz. 32.5 pts. of zinc dissolved in each battery-cell for every 1 pt. of hydrogen evolved in the voltameter. As, however, it is impossible to prevent local action altogether, the quantity of zinc dissolved in each cell is always somewhat greater than this proportion would indicate; thus Jacobi found that in a Daniell's battery with amalgamated zinc plates, 33.6 pts. of zinc were dissolved in each cell for every 9 pts. of water decomposed in the voltameter.

Hence it follows that, with a given intensity of chemical action in the battery-cells, and a given conducting power throughout the circuit, the amount of electrical or chemical power developed by the battery, as measured by the voltameter, is proportional to the surface of each plate exposed to the action of the liquid, in other words, to the area of the transverse section of that liquid, supposing the action in all the cells to be uniform. If, however, the chemical action in any one of the cells should be weaker than in the rest, then that cell presents, to a certain extent, an obstacle to the passage of the electricity developed by the rest, and the whole force of the battery is lowered; or, again, if the conducting power of the circuit is lessened by the interposition of a long wire, or of another decomposing cell, or of an electrolyte more difficult of decomposition, the quantity of electricity which can pass through the circuit in a given time, and therefore also the amount of chemical work which the battery is capable of performing in that time, is also lessened, and cannot be increased by augmenting the size of the plates, without, at the same time, increasing their number, which, as already explained, determines the intensity of the current, that is to say, its power of overcoming resistance. If, however, by increasing the number of pairs, or otherwise, the tension has been raised to such a degree that all the electricity evolved from the source in a given time is able to enter the liquid—so that the galvanometer shows the same deflection whether the circuit be closed by a metallic conductor or by a liquid—a further rise of intensity does not accelerate the decomposition.

The following experiments were made by Matteucci to determine the proportion in which the decomposition of different liquids, and therefore also the quantity of the current, increases with the number of pairs.

In A, a pile was constructed of zinc and copper with solution of sal-ammoniac; in B, with water containing nitro-sulphuric acid; and in C with spring-water; in D a battery of zinc and platinum in dilute sulphuric acid was employed. The liquid in the decomposing cell was water = Aq., or a solution of 1, 4, 8, or 10 pts. of sal-ammoniac in 100 pts. of water = Sm 1, Sm 4, Sm 8, Sm 10; or saturated solution of sal-ammoniac = Sm s; or dilute sulphuric acid = Sf; or a solution of 1 pt. of sulphate of zinc (zinc-vitriol) in 100 pts. of water = ZV; or solution of iodide of potassium = IK. PZ denotes the number of pairs employed. The degrees under A, B, C give the deflection of the galvanometer; the numbers under D denote the relative quantity of hydrogen gas evolved from the solution of iodide of potassium.

In the following experiments of Jacobi and Walker, Daniell's constant battery was used. The quantity of detonating gas developed in the decomposing cell in a given time, according as a greater or lesser number of plates were connected together, was determined in measures. In Jacobi's experiments, and in those of Walker, given under a and b, the decomposing cell contained water acidulated with sulphuric acid; in c it contained distilled water.

The more readily the atoms of a liquid are transposed—whether from its peculiar nature or from the thinness of the film of liquid between the electrodes,—the smaller is the tension which the electric current requires in order to penetrate it, the greater the quantity of electricity which flows into the liquid from a given source, and the greater the quantity of liquid decomposed in a given time.

Aqueous solution of iodide of potassium may be decomposed by a current of the smallest tension; next in order of facility come fused chloride of silver, fused protochloride of tin, fused chloride of lead, fused iodide of lead, water containing hydrochloric acid, water containing sulphuric acid. That the chloride of lead is more easily decomposed than the iodide, perhaps arises from the platinum electrode having a greater affinity for chlorine than for iodine. (Faraday, see page 417.)

Thermo-electric currents, weak both in quantity and intensity, decompose nitrate of silver, when the electrodes consist of platinum, but not salts of copper, lead, tin, or zinc; in these also electrodes of gold or silver produce no effect. But when the electrodes consist of the same metal as that in the solution, decomposition is easily effected, e.g. nitrate of silver with silver electrodes, sulphate of copper with copper, stannous chloride with tin, acetate of lead with leaden electrodes. Platinum wires produce no effect in solutions of platinum. A thermo-electric current is best conducted into a solution of common salt by means of wires of zinc, tin, lead, or iron—less readily by copper, with difficulty by silver, and not at all by platinum.

The current of the electrical machine, which is of very high intensity, is capable of passing through any electrolyte whatever; but the amount of decomposition which it produces is extremely small compared with that of the smallest voltaic apparatus (see p. 397): hence we may conclude that the quantity of electricity developed by the electrical machine, or any other friction apparatus, is very small as compared with that developed by chemical action.

MAGNETIC ACTION OF THE ELECTRIC CURRENT—ELECTRO-MAGNETISM.

A magnetic needle, balanced on its centre and placed in the neighbourhood of a wire, or other conductor, along which a current of electricity is passing, tends to place itself at right angles to the line of the current. This effect, which we have already had frequent occasion to notice, is produced by the electric current, from whatever source it may be derived; but it depends on the quantity of electricity in the current, not on its intensity, and is therefore exhibited by voltaic, and even by thermo-electric currents, in a much higher degree than by those resulting from friction electricity (p. 399). Very small wires of zinc and copper excited by dilute acid will produce a stronger deflection of the magnet than the most powerful electrical machine. The deflection of the magnet is exclusively an effect of electricity in the state of motion or discharge; the highest charges, either of the voltaic battery or of the electrical machine in the state of tension, have no effect whatever on the magnet.

The direction assumed by a magnetic needle under the influence of the current may be determined by either of the following empirical rules:—

1. Let the observer fancy himself extended in the direction of the current, looking towards the needle, and with the current of positive electricity flowing from his head to his feet: then the north pole of the needle will move towards his right hand.
2. The north pole of the needle tends to revolve round the conducting wire in the direction of the hands of a watch, the face of which is turned towards that end of the wire from which the positive electricity proceeds.

Either of these rules will determine the direction taken by the needle in any case whatever; the second is perhaps the more convenient of the two. As a particular example, we may mention, that if the conducting wire is horizontal, and in the direction of the magnetic meridian, the current of + *E* running from north to south, the needle turns its north pole to the west if placed above the wire, and to the east if placed below.

When the magnet is freely suspended by its centre, it tends to place itself at right angles to the current, its actual position of equilibrium being intermediate between this and the direction imparted to it by the earth's magnetism; *e. g.* if placed above a horizontal conducting wire in the magnetic meridian, with the current running from south to north, the north pole points in a direction between north and east, inclining to the one or the other, according as the earth's magnetism or the current acts more strongly upon it.

As the direction of the needle under the influence of the current is reversed, either by reversing the direction of the current itself, or by moving the needle to the opposite side of the wire—*e. g.* below if it was previously above—it follows that, if the conducting wire be bent back upon itself, and the needle placed between the two arms, as in *fig. 428*,* the two portions of the current above and below the needle will tend to give it the same direction, so that the force with which the current acts upon it will be doubled; it is even more than doubled, because the vertical parts of the wire likewise tend to turn the needle in the same direction, as may be easily seen by the rules

Fig. 428.

Fig. 429.

above given (p. 412). Hence also, if the needle is placed in the centre of a circular or of a square conductor (*fig. 428*) round which the current is passing, it will be moved in one direction by the joint action of all parts of this conductor. Further, if the wire be coiled several times upon itself always in the same direction, and a current sent through it from end to end, a needle placed in the centre of the coil, as in *fig. 429*, will be deflected in one direction by the joint action of all parts of the coil.

An instrument thus constructed is called a *galvanometer* or *multiplier*; it serves to indicate the existence of very feeble currents, and by the magnitude of the angle through which the needle is deflected by different currents, an approximate indication of their relative strength may be obtained. The angle of deflection is not, however, exactly proportionate to the strength of the current, so that the instrument constructed as above is not properly speaking a galvanometer, but only a *galvanoscope*; the former term is, however, in common use. Galvanometers constructed for exact measurement will be described hereafter.

The delicacy of the instrument is greatly increased by making use of an *astatic needle*—that is to say, of a magnetic needle so mounted that the action of the earth's magnetism upon it is neutralised. This is effected by joining two magnetic needles of equal powers, parallel to each other, but with their poles in contrary directions, by a small piece of straw or copper wire passing through their centres of gravity. One of these needles is placed within the coil, and the other above, in which position it is easy to see that they will both be deflected by the current in the same direction: if their similar poles pointed the same way, the upper part of the coil would turn them in opposite directions, inasmuch as one of them is above and the other below it.

With a given length of coil, the instrument is more delicate in proportion as the magnetic power of the two needles is more nearly equal; if exactly equal, they will place themselves at right angles to the coil under the influence of the feeblest current; but it is generally desirable to leave a certain difference between them, in order that the amount of deflection may give some idea of the comparative strength of the current.

Fig. 430 represents a galvanometer fitted up with an astatic needle, moving over a graduated arc. The needle is suspended by a thread of unspun silk, and the whole is covered with a glass case to protect the needle from the agitation of the air. The

* The arrows in the figure indicate the direction of the current of + *E*; and in all that follows, the expression "direction of the current" is to be understood as applying to the positive current.

wire is coiled round a wooden frame, and is covered with silk to insulate the several turns of the coil, so that the current may not pass from one to the other, instead of going through the entire length of the wire.

Fig. 430.

The length and thickness of the galvanometer wire vary according to the kind of current which the instrument is intended to indicate. For voltaic currents, a wire about 1 millimetre in diameter, and making about 800 turns round the frame, is generally well adapted. Thermo-electric currents, which are of very low intensity, require a much thicker and shorter wire, *e.g.* $\frac{1}{4}$ millimetre in diameter, and coiled thirty times round the frame. On the other hand, currents small in quantity, but of high intensity, are best indicated by a coil of very fine wire, making from 1,000 to 2,000 turns.

The insulation of the several turns of the coil, one from the other, is of very great importance, especially for currents of high intensity, such as those from the electrical machine (p. 399). M. Colladon of Geneva, who first observed the deflection of the needle by the machine current, used a galvanometer of 500 to 1,000 turns, having a wire twice covered with silk, and each series of turns separated from that below it by a sheet of oiled silk.

The direction of the current which deflects the galvanometer needle in a particular way is easily determined by the rules given on p. 442, when the direction in which the wire is coiled round the frame is known. For this purpose it is necessary to distinguish between right-handed and left-handed coils or helices. Suppose the wire to be coiled round a cylinder beginning at the left hand; then if the turns in front of the cylinder proceed from below upwards, as in *fig. 431*, the coil is left-handed; if, on

Fig. 431.

Fig. 432.

the contrary, they proceed in front from above downwards, as in *fig. 432*, it is right-handed.

A magnetic needle placed with its centre in the axis of such a coil, turns its north or south pole towards that end of the coil at which the current enters, according as the coil is left or right-handed.

The direction given to the needle is the same, whether the coil is elongated, as in *figs. 431, 432*, or compressed, as in the galvanometer. As, however, in the galvanometer when complete, it is not easy to see whether the coil is right or left-handed, it is best to determine by experiment, once for all, the direction taken by the needle when the current enters at one particular end of the coil.

Action of the Magnet on the Electric Current.

The action between the current and the magnet is mutual, so that if the conductor conveying the current is free to move, it is deflected in the direction opposite to that which the magnet takes under its influence: in short, if the magnet and conducting wire are both free to move, they place themselves at right angles to each other, the magnet moving in the manner pointed out at p. 442, the conductor in the contrary direction.

The action of the magnet on the current may be shown by means of Ampère's apparatus (*fig. 433*). On holding a bar-magnet below the rectangular wire and parallel to its lower horizontal arm, the wire turns round and places itself at right angles to the magnet, the position of equilibrium being determined by the rules given on p. 442.

Fig. 433.

Fig. 434.

A simpler apparatus for the same purpose is the *floating battery* (fig. 434) contrived by G. De la Rive. It consists of a pair of zinc and copper plates attached to a cork, and connected together by a coil of covered wire placed above the cork; the whole is floated on water slightly acidulated, whereby a current is made to pass round the coil. On the approach of a magnet, the coil takes up a position indicated by the law just cited.

The action of the floating battery thus constructed is rather weak, and consequently a coil of considerable length is required to make it sensitive. A better construction is that shown in figs. 435, 436, in which the extremities of the coil are connected with

Fig. 435.

Fig. 436.

a small Daniell's cell contained in a wide glass tube attached to the cork float. With this arrangement, stronger acid may be used and a more energetic current obtained, so that a thinner coil, or even a single circular or rectangular wire, is sufficient to exhibit strong deflection under the influence of a magnet.

A movable electric current is deflected by the earth's magnetism as well as by an ordinary magnet. This may be shown either with Ampère's apparatus or with the floating battery, the wire of either of which, when left to itself, takes up a position at right angles to the magnetic meridian. If it be remembered that the north magnetic pole of the earth is analogous to the south pole of an ordinary magnet, it will be seen that, in the position of stable equilibrium, the direction of the current is from east to west in the lower horizontal branch, and from below upwards on the western vertical side.

The action of the earth on the current is much less energetic than that of a bar-magnet held near the wire; nevertheless it may sometimes interfere with the results of this latter action. This source of complication may be obviated by giving to the movable wire the form of a double rectangle, fig. 437, so arranged that the earth's action on the one half shall be neutralised by that on the other. Such an arrangement is called an *astatic conductor*.

Fig. 437.

MUTUAL ACTION OF ELECTRIC CURRENTS.

Electric currents moving in parallel lines attract one another if they move in the same direction, and repel one another if they move in opposite directions.

This law may be demonstrated by bringing a conducting wire connecting the poles

Fig. 438.

of a rather powerful voltaic battery near the wire of the floating battery, as shown in fig. 438, or the wire of Ampère's apparatus (figs. 433, 437).

The mutual attraction and repulsion of currents is not, however, confined to the case of parallelism; for if two currents, A and B , are moving in directions inclined to each other in the same plane, A may be resolved into two component currents, one perpendicular and the other parallel to B ; the former produces no effect, because it is equally inclined to B both ways, and the latter attracts or repels B , according as it is moving in the same or the opposite direction. If the currents are in different planes, two such resolutions will show how much of the force of one may be considered as acting parallel to the other. The general result is, that *two inclined currents attract each other if they both tend towards or both from the summit of the angle formed between them, and repel one another if one is approaching that summit and the other receding from it*. The different cases of this action are shown in fig. 439. If a horizontal conducting wire be

Fig. 439.

Fig. 440.

held over the horizontal branch of the wire of a floating battery (fig. 440), and inclined to it at any angle whatever, then if the two currents both approach the summit of that angle on one side and recede from it on the other, the floating battery will turn round, till the upper horizontal branch of its wire has placed itself parallel to the

other wire, and as near to it as possible, the two currents moving in the same direction, this being their position of stable equilibrium. If, on the other hand, the original position of the currents is such, that one approaches the summit of their angle of intersection and the other recedes from it, the wire of the floating battery is at first repelled and turns round, making a larger and larger angle with the fixed wire, till it ultimately settles itself in the position of equilibrium shown in the preceding figure.

Suppose now the wire of the floating battery to have the form of a helix, as in *fig. 441*, and that another helix also conveying an electric current is held over it. The floating helix will place itself parallel to the other, and in such a position that the currents in the nearest parts of the two run in the same direction; and a little consideration will show that if the helices are both right or both left-handed (*p. 444*), their similar ends, *i. e.* those by which the current enters or leaves the helix, will be placed in contrary positions, the positive end of one over the negative end of the other. Moreover, if the positive end of the one (that by which the current makes its exit) be presented to the negative end of the other, attraction takes place; whereas the two positive or two negative extremities or poles repel each other. In short, the two helices act upon one another just like two bar-magnets; and indeed if a magnet be substituted for the fixed helix, the floating helix will be attracted and repelled by it, and will place itself parallel to it, just as it behaves to the other helix. Moreover, if the floating helix be left to itself, it will take up a position in which the current runs from east to west, and the axis of the helix therefore points north and south, just like a magnet.

Fig. 441.

This striking resemblance between the mutual action of electric currents and that of magnets has led to the idea, suggested and developed by Ampère, that magnetism is actually produced by electric currents, circulating round the magnet in planes perpendicular to its axis, and such, that on looking along the axis of the magnet with its south pole turned towards the observer, the current moves in the direction of the hands of a watch, that is, from the left side through the top and down by the right through the bottom to the left again. Thus in the bar-magnet represented in *fig. 442*, the south pole is at the lower end. Whether such currents actually exist is more than we are at present prepared to say. No direct proof of their existence has yet been given; but the theory affords a simple and perfectly satisfactory explanation of all cases of the action of magnets on each other, and of the mutual action between the magnet and the electric current. The fundamental fact of electro-magnetism, *viz.* that a magnet tends to place itself at right angles to an electric current, is, according to this theory, a direct consequence of the tendency of electric currents to place themselves parallel to one another (see *fig. 442*).

Fig. 442.

The action of the currents circulating round the axis of a magnet is well illustrated by the following experiment:—Present a bar-magnet to a floating battery, with a flat circular coil (*fig. 435*), in such a manner that the currents of the magnet shall coincide in direction with that in the coil. The coil will be attracted by the magnet and move on to it, fixing itself exactly in the middle, where it is equally attracted both ways. Now take hold of the coil, withdraw the magnet, and insert it the contrary way. The coil, if exactly in the middle of the bar, will remain there in a position of unstable equilibrium; but if ever so little nearer to the free end of the magnet, it will shoot off, turn itself round, and then return to its position in the middle of the magnet.

There are, however, certain phenomena into which we cannot here enter, relating to the mutual action of magnets and electric currents, which render it necessary to suppose that the currents which give rise to the polarity of magnets are molecular, that is to say, that they circulate round each individual particle of the magnet. These currents may be supposed to pre-exist in all magnetic bodies, even before the development of magnetic polarity, but disposed without regularity, so that they neutralise one another. Magnetisation is the process by which these molecular currents are made to move in one direction, so that those situated at the surface of the magnet yield as their resultant a finite current circulating round the magnet, while the currents in the interior are neutralised by those in the next external layer, the contiguous portions of which move in the direction opposite to their own. *Fig. 444* is a section of a cylindrical magnet showing the external layer of molecular currents, the observer looking

Fig. 443.*Fig. 444.*

towards the north pole; and *fig. 443* shows the finite superficial currents produced by their joint action.

Magnetisation by the Electric Current.

A bar of iron, steel, or other magnetic body placed at right angles to an electric current, becomes magnetised, its poles being situated in the same direction as those of a magnetic needle subjected to the influence of the same current and in the same relative position, this direction being such that the currents which, in Ampère's theory, are supposed to circulate round the magnet, coincide in direction with the acting current on that side of the bar which is nearest to it.

Soft iron is easily magnetised by the electric current, but returns to its ordinary unmagnetised state as soon as the current ceases to act upon it; it therefore requires the action of a continuous current, like that of the voltaic battery. Steel, cast iron, and nickel, on the other hand, are more difficult to magnetise, but retain their magnetic power when removed from the influence of the current; the resistance which these bodies offer to any force tending to polarise them, is best overcome by electricity of high tension; — indeed hard steel never acquires its full magnetic polarity under the influence of currents of low tension, but only when subjected to the sudden discharge of a Leyden jar or battery (p. 398).

Magnetisation of Soft Iron.—A short bar of soft iron placed at right angles to a wire joining the poles of a voltaic battery becomes magnetic; and on bringing the same wire in contact with a mass of iron filings, a number of them will adhere to it as long as the circuit is complete, falling off as soon as it is broken. This attraction, according to Ampère's theory, is merely a case of mutual attraction between electric currents running in the same direction.

In longer bars of soft iron, the magnetic influence of a straight current is scarcely, if at all, perceptible; but by causing the current to act simultaneously all along the bar, which may be effected by coiling the wire round it in the form of a helix, very strong magnetic polarity may be developed, even by the current of a small voltaic couple. The wire, if covered with silk, may be coiled directly round the bar; if uncovered, it must be coiled round a paper or wooden tube within which the bar is inserted; but covered wires are generally used, because the turns of the coil may then be kept very close together, and the wire may be coiled round the bar in several layers. The direction of the polarity depends of course on the kind of helix used. With a left-handed helix (p. 444), the north pole of the bar is at that end of the coil at which the current enters.

A bar of soft iron bent in the form of a horse-shoe, and having a long coil of wire round it, becomes a very powerful magnet, when its poles are joined by a keeper of soft iron and a current is sent through the coil; such an electro-magnet will support a very great weight. If the soft iron is of good quality, and has been several times tempered by slow cooling, the development of the magnetism follows instantaneously on the closing of the circuit; by far the greater part of the magnetism disappears also on breaking the circuit, but a small amount is retained for a time, depending on the length of the bar—long bars, and more especially horse-shoes, retaining a portion of their magnetism for a longer time than short ones. In horse-shoes the retention of the polarity is greatly promoted by joining the poles with a soft iron keeper. A horse-shoe electro-magnet, which supported a weight of 120 lbs. while under the influence of the current, was found to carry 50 lbs. when the circuit was interrupted, and retained this power for a long time, while the keeper remained in position; but on forcibly separating the keeper, the whole of the magnetism was destroyed. The cause of this effect is that the keeper, by contact with the poles of the magnet, becomes itself a magnet, each of its extremities becoming a pole of opposite name to that of the magnet with which it is in contact; and these poles intensify the polarity of the magnet, just as a body electrified by induction intensifies the electric polarity of the inducing body (p. 386), the whole forming a kind of closed magnetic circuit, the different parts of which tend to keep one another in equilibrium; on removing the keeper, this equilibrium is destroyed, and the bar of iron returns to its ordinary state.

Magnetisation of Steel.—Steel bars or wires are permanently magnetised when placed within a helix through which a voltaic current or an electric discharge is passed. For the latter mode of operation, the helix must be coiled round a glass tube and the steel bar placed within the tube (p. 398); for the former, either this method may be adopted, or helices of covered wire without the glass tube may be used. With a simple helix, that is, one in which all the turns of the coil go the same way, the resulting magnet will have only two poles, like an ordinary bar-magnet, the north being turned towards the positive or negative end of the helix, according as the latter is right or left-handed; but if one half of the helix is right and the other left-handed, a kind of double magnet will be formed, having two similar poles at each end, and a contrary pole in the middle; and with a triple helix, *e.g.* consisting of a right-handed portion placed between two left-handed portions, a magnet will be formed with four consecutive poles, arranged thus, N, S, N, S; and similarly for any number of alternations.

By the discharge of a large Leyden jar or battery, steel wires may be magnetised when simply laid at right angles to a straight conducting wire, either in contact with it, or at the distance of several inches. The intensity of the magnetism thus developed increases with the intensity of the discharge, other things being equal; but when needles of hard steel are placed at different distances from the conducting wire, the intensity, and even the direction, of the magnetic polarity induced by the same electric discharge, are found to vary in a very remarkable manner, according to the distance. From the experiments of Savary (Ann. Ch. Phys. [2] xxxiv. 5), and Abria (*ibid.* [3] i. 385), it appears that the intensity of the magnetism produced by the electric discharge does not diminish constantly as the distance becomes greater, but increases with the distance beyond a certain point, where it is at a minimum; and that, on the same side of the conducting wire, and with the same direction of the discharge, the situation of the magnetic poles with regard to the wire changes more than once at different distances. In contact with the conducting wire, or at very short distances from it, the poles are disposed according to the general law (pp. 442, 444). The table on p. 450 contains the results obtained by Savary with a platinum wire 2 metres long and $\frac{1}{4}$ millimetre in diameter, hard-tempered steel needles 15 mm. long and $\frac{1}{2}$ mm. in diameter, and an electrical battery having a coated surface of 22 square feet. The strength of the magnetism acquired by the needles was estimated by the time in which they performed a given number of oscillations under the influence of terrestrial magnetism. To avoid any errors that might arise from the mutual action of the steel needles, they were not placed vertically one over the other, but over different parts of the conducting wire. The polarity of a needle is called *positive* when its direction coincides with the general law, *negative* in the contrary case.

It appears from the table that, for the positively magnetised needles, there was a maximum of intensity at contact, and another at the height of 30 mm. above the wire, the second maximum being somewhat greater than the first. For the negatively magnetised needles, there was a maximum at 5 mm. The minima of intensity corresponded with the changes of sign. In another experiment, in which the conducting wire was only 1 metre in length, four changes of direction in the polarity were observed, and the last maximum was at the height of 40 mm. instead of 30.

No. of Needle.	Distance from the Wire in Millimetres.	Time of 60 Oscillations.	Direction of the Poles.
1	0.0	52".4	Positive

The diameter of the conducting wire likewise affects the distances at which the changes of sign in the magnetic polarity take place; with a very fine wire, $\frac{1}{8}$ mm. in diameter, no such changes of sign were observed, and the maximum of intensity was at the distance of 11 mm., that is to say, five times less than with a wire of three times the diameter.

The intensity of the magnetisation is, *ceteris paribus*, greater as the length of the wire is less in proportion to its diameter. This increase, however, has a limit: a wire 1 metre long, for example, gives the highest maximum of magnetisation when its diameter is $\frac{1}{8}$ mm.; at the distance at which this maximum effect is produced, the needle is magnetised to saturation; with greater lengths of wire the intensity is less. The relative maxima are nearer to the wire in proportion as the wire is longer.

The influence exerted by the length and diameter of the conducting wire, appears to depend upon the amount of retardation which it produces on the discharge: for in a circuit formed of three wires of unequal diameters, joined end to end, the magnetising effect of the discharge is the same, in whatever part of the circuit the needle is placed, the velocity of the discharge being, of course, the same in every part of the circuit.

The dimensions and hardness of the needles have likewise a very decided influence on the results: needles of unhardened steel exhibit no change of sign, whereas those of hard-tempered steel exhibit at least three such changes. If the diameter of the needle is somewhat considerable, the strongest magnetisation takes place in contact with the conducting wire, and the intensity continually diminishes with increase of distance. A hardened needle of considerable thickness is magnetised by the discharge like an unhardened needle of smaller diameter, a fact which may be explained by observing that the hardening affects only the surface, and that, in a thick needle, the surface bears a smaller proportion to the mass than in a thin one.

With helices, also, several changes of sign were obtained in the polarity of hard-tempered steel needles placed at different distances; but when the total length of the wire was increased without changing that of the coiled portion, the changes of sign became less frequent, till finally the polarity was no longer reversed at different distances, but only became less intense as the distance increased. The length of a needle placed within the helix has no influence on the direction of its polarity, but only on the intensity.

Non-conducting bodies, such as dry paper, wood, or glass, interposed between the steel bars and the conducting wire, have no influence, either on the direction or on the intensity of the magnetism produced, but conducting bodies modify the effect to a considerable extent; thus, if two similar needles are placed within a helix, one un-

covered, the other enclosed in a thick copper cylinder kept out of contact with the helix, a discharge which magnetises the former strongly, produces no effect on the latter. By gradually diminishing the thickness of the metallic envelope, the needle is more and more magnetised by a discharge of given strength. In some cases, the envelope changes the direction of the polarity induced. It is only by continuous envelopes that these effects are produced; metallic powders, which conduct but slowly, have no effect.

These effects, and others produced by the interposition of metallic discs, are due to momentary electric currents, excited in the conducting disc or envelope by the discharge. The remarkable variations of intensity and inversion of the polarity at different distances from the wire, are probably due to a similar cause, namely, the polarisation of the molecules of the intervening medium.

Savary has also shown that similar results may be obtained with the continuous voltaic current, and that the magnetising effects of the current approach more nearly to those of the sudden discharge, in proportion as the current has a higher intensity, and the battery is charged with a liquid of less conducting power. Altogether, the effects are less distinct with the current than with the sudden discharge, especially with regard to the change of direction of the polarity at different distances from the conducting wire. Steel needles are not strongly magnetised by the current unless they are placed within a helix.

ELECTRO-DYNAMIC INDUCTION.—MAGNETO-ELECTRICITY.

An electric current produces no perceptible disturbance in the electric state of a neighbouring conductor, so long as it remains of constant strength, and the relative positions of the two remain unaltered; but if the current undergoes any variation of strength—especially, therefore, at the moments of its commencement and cessation,—or if it be made to approach or recede from the other conductor, it then produces an electrical disturbance in that body, and if the latter forms a closed circuit, develops in it a current of electricity. This mode of action, discovered by Faraday in 1832, is called Electro-dynamic Induction. Its effects may be studied by means of the apparatus, represented in *fig. 445*.

Two copper wires covered with silk are coiled round a hollow wooden cylinder, so as to form two perfectly similar but separate helices, the turns of which are parallel, and as close to each other as possible. The ends of one of these helices A, are connected with a galvanic battery; those of the other, B, with a galvanometer. At the moment of completing the battery circuit, the galvanometer needle moves, its motion indicating a current in the wire B, in the direction opposite to that of the battery current in A. This induced current, however, is only momentary, the needle immediately returning to its ordinary position of equilibrium, and remaining there as long as the battery circuit remains closed; but on breaking the circuit, the needle again moves, and in the direction opposite to that of its first movement, indicating, therefore, a current in the wire B, in the same direction as that in A; this last also is only momentary.

Any variation in the strength of the battery current produces effects similar in kind, though less in degree, to those resulting from its commencement or cessation: for an increase in the strength of a current is equivalent to the production of a fresh current; and a decrease, to the cessation of a current of less strength.

If only a single helix is wound round the hollow wooden cylinder in the last figure, its ends connected with a galvanometer, and another helix through which a current is passing is quickly thrust into the tube: a momentary current is also induced in the first helix in a direction opposite to that in the second; so long as the latter remains within the tube, no current passes through the galvanometer, but on quickly withdrawing the inner helix, a momentary current passes through the galvanometer, in the direction opposite to the former, that is to say, in the same direction as that in the movable helix. This experiment is, indeed, only another form of the first; in both

Fig. 445.

cases an electric current is suddenly brought into the neighbourhood of a conducting wire forming a closed circuit, and as suddenly withdrawn; but the making and breaking contact with the battery in the first experiment, admits of a much quicker introduction and removal of the current, than the mechanical movement of the helix in the second: hence the induced currents are more powerful in the first instance.

All these effects are greatly intensified, but not altered in direction, by the introduction of a bar of soft iron or a bundle of iron wires within the inducing helix. Thus with the double helix (*fig. 445*), on making contact with the battery, the iron becomes strongly magnetised, and we may suppose that a number of molecular currents are made to circulate round its particles in the same direction as the current of the helix A (*p. 447*); these, at the moment of their formation, induce a strong momentary current in the contrary direction in the helix B; and on breaking contact, the magnetism is destroyed, and an equally strong current is induced in B, in the same direction as that in A.

The same effects are produced by magnetising the iron bar within the helix in any other way; thus on bringing the opposite poles of two bar magnets in contact with the extremities of the bar, a current is developed in the helix B; and on removing the magnets and thereby unmagnetising the bar, a momentary current is formed in the contrary direction.

Again, in the second form of the experiment, if a bar of soft iron is introduced into the movable helix, a current is developed in the fixed helix in the same direction as when the iron is not there, but of greater intensity; and if, instead of the helix, a permanent magnet be thrust into the tube with its poles in the same direction as those of the temporary magnet formed by the helix, the same momentary current will be produced as before, and a contrary current on withdrawing the magnet.

The direction of a current developed by the action of a magnet, is determined by the following law:—*The development of magnetism in a bar of iron in the neighbourhood of, and at right angles to a closed conducting wire, or the movement of a permanent magnet in the neighbourhood of such a wire, induces in it a current of electricity, the direction of which is opposite to that which would develop the same magnetic polarity in the iron, or impress the same motion on the magnet; and on destroying the magnetism in the iron, or moving the permanent magnet the contrary way, an opposite current is developed in the wire.*

The intensity of the induced currents varies with the length and diameter of the wire in which they are developed, also on the energy of the inducing currents, or the power of the magnet. In general, it is advantageous to use very long wires, and even to join several helices end to end; but in that case, if the induction is not effected by the action of a magnet, it is necessary to employ an inducing current proceeding from a battery of a considerable number of pairs. These conditions vary, however, according to the effects to be produced, and consequently with the nature of the conductors through which the induced current is to pass.

An electric current, at the moments of its commencement and cessation, develops momentary currents, not only in neighbouring wires, but likewise in the wire through which itself is passing. When a copper wire is made to dip into two mercury cups attached to the plates of a simple voltaic battery, the spark produced on breaking contact is much brighter than that formed on making contact, especially if the wire is long and formed into a coil, and still more if it is coiled round a bar or horse-shoe of soft iron. The cause of this difference is that the battery current, at the moment of its commencement, induces an opposite current in the conducting wire, whereby its own force is partly neutralised, whereas at the moment of cessation, it induces a secondary current in the same direction as itself, whereby its force is augmented and a stronger spark produced.

These secondary currents, which, like those induced by the current in neighbouring wires, are of considerable intensity, may be rendered evident by attaching to the wire, near its extremities, two thinner wires connected with a galvanometer; the needle will then be deflected on completing and breaking the battery circuit. If the extremities of these thinner wires are brought close together, a spark will pass between them at each completion and interruption of the circuit; and if copper cylinders are attached to them and held in the moistened hands, a shock will be felt. When the secondary current is diverted in either of these ways, the brightness of the spark which appears on breaking the battery circuit is much diminished.

The formation of these secondary currents, called extra-currents, will be easily understood if we remember that a wire may be regarded as a number of smaller wires, or rows of particles laid parallel to one another.

Induced currents are also developed by the influence of the earth's magnetism.

e.g. when a rectangular wire whose extremities are connected with a galvanometer is made to move round its lower side at right angles to the magnetic meridian. The direction of the current, in all varieties of the movement and form of the conductor, may be easily made out from the preceding general rules, remembering that the north magnetic pole of the earth is analogous to the south pole of an ordinary magnet.

Induced currents of higher orders. — An induced current is capable of developing other induced currents in neighbouring conductors; and these again develope others, the series being continued through several terms. These phenomena were first observed by Dr. Henry, of Princeton (Ann. Ch. Phys. [3] iii. 394), who made use of the apparatus represented in *fig. 446*, consisting of a number of flat spirals of covered

Fig. 446.

copper riband. The first spiral *a*, is connected with the poles of a voltaic battery; above this, and very close to it, is placed another spiral *b*, the ends of which are connected with those of a third spiral *c*, above which, and very close to it, is a fourth spiral *d*, connected with a fifth *e*, and so on. At the moment of *interrupting* the battery current in *a*, an induced current is developed in *b* in the same direction as in *a*; this induced current passes on to *c*, and there develops in *d* a momentary current in the contrary direction; this current passes on to *e*, where it develops in *f* a current whose direction is opposite to that of *d*, and therefore the same as that of *a* and *b*. The direction of the current in any one of the spirals may be determined by interposing in its circuit a galvanometer, or a chemical voltameter, or, as in the figure, a helix containing a steel wire, which becomes magnetised, and indicates the direction of the current by the positions of its poles.

Of the induced currents developed on *interrupting* the primary or battery current, the secondary, quaternary, and all of even order, have the same direction as the primary current, while the tertiary, and others of uneven order, move in the contrary direction.

Similar phenomena are observed at the instant of *closing* the battery circuit, excepting that as the secondary current (in the helix *b* above) is of contrary direction to the primary, all the induced currents of even order also move in the direction contrary to that of the primary, and those of uneven order in the same direction as the primary current.

The phenomenon is, however, more complicated than the preceding description would imply: for every current, however developed, induces in a neighbouring conductor two other currents, one at the moment of its commencement, in the opposite direction to itself, the other at the moment of its cessation, in its own direction. Hence there are in reality, two secondary, four tertiary currents, eight of the fourth order, 2^{n-1} of the n^{th} order. It is only, however, the secondary currents that are separated from each other by a finite interval, that namely between the closing and interruption of the battery circuit, which may be made as long as we please; but each of the secondary currents has but a momentary duration: consequently, of the two tertiary currents which it produces, the second follows instantly upon the first, and the current actually observed is merely the difference between the two. Similarly with regard to the currents of higher orders. If then the two currents developed in a conductor at the same instant by the action of a current of the next lower order, were always equal in quantity and intensity, no currents of higher order than the second could ever be observed. This, however, is not the case; the two secondary currents formed at the commencement and cessation of the primary current are equal in quantity, producing equal and opposite deflections of the galvanometer; but they differ in intensity, that is to say, in their power of overcoming resistances, the direct current having a greater intensity than the inverse. Similar differences of intensity appear also to exist in the two simultaneous currents of any higher order, excepting that in these the inverse currents possess the higher intensity, so that the current actually produced

moves in the direction contrary to that to which it owes its origin. That the induced currents of orders higher than the second are really the resultants of opposite induced currents of different intensity, is in accordance with the fact, that they are all capable of producing chemical, calorific, and physiological effects, that is, of traversing circuits which offer considerable resistance, but that the galvanometer is scarcely deflected by any induced current of higher order than the second.

Induced currents of several orders are likewise produced by the sudden discharge of electricity, as by the discharge of an electrical battery. The effects are somewhat complicated, but the general laws of the action are the same as when the primary current is continuous. As, however, the primary discharge is instantaneous, or nearly so, the two opposite secondary currents which it induces on a neighbouring conductor, succeed one another at an imperceptibly short interval, and therefore nearly neutralise each other, if the circuit does not present much resistance; but if the circuit is interrupted, either by a thin wire which becomes heated, or by an interval which gives rise to the passage of a spark, one of the induced currents, generally the second, or that which has the same direction as the primary, predominates over the other. (Riess, *Reibungs-electricität*, ii. 266-355.—Matteucci, *Ann. Ch. Phys.* [3] iv. 153.—Dove, *ibid.* iv. 336.—Marianini, *ibid.* x. 491; xi. 385.—Knochenhauer, *ibid.* xvii. 130.—Verdet, *ibid.* xxiv. 377.—Dela Rive, *Traité* i. 406.)

Theory of Electro-dynamic Induction.—The following explanation of the development of induced currents is given by Dela Rive (*Traité* i. 445). Electro-dynamic induction may be regarded as the result of the decomposition by influence of the natural electricity belonging to each particle of the conductor subjected to the action of the current, by the already separated electricities of each particle of the conductor conveying that current.

Considering the current as a series of decompositions and recompositions of the electricities of contiguous molecules, suppose AB (*fig.* 447) to be a conductor through

Fig. 447.

which a current is passing from A to B. The particles which compose this conductor have their natural electricity decomposed, the $-E$ of each turning towards A, which is the positive pole of the apparatus generating the current, and the $+E$ to B, which is the negative pole. These opposite electricities, as soon as they are separated, recombine from particle to particle, the $-E$ of a with the $+E$ of the pole A, the $-E$ of b with the $+E$ of a , and so on up to h , the $+E$ of which unites with the $-E$ of the pole B. This recombination, which is instantaneous, is immediately followed by a new decomposition, then follows another recombination, &c. this series of actions going on so rapidly that, as experiment shows, the whole of the conductor is kept in a constant state of tension.

Now let there be a second conductor, A' B', as near as possible to the first, but insulated from it by silk or wax. At the moment when the current begins to pass through A B, and its particles are polarised, as in the figure, those of A' B' become polarised in the opposite way, the $+E$ of each particle of A' B' being opposite to the $-E$ of the corresponding particle of A B; whence it follows that, if at the moment when the current begins to pass through A B, the two extremities of A' B' are united by a conductor, such as a galvanometer-wire, the $+E$ of the particle a' unites through that conductor with the $-E$ of the particle h' , producing therefore a momentary current whose direction is from A' to B' in that conductor, and from B' to A' in the wire A' B.

itself, that is to say, in the direction contrary to that of the inducing current. In like manner, if the ends $A'B'$, instead of being joined by a conductor, are made to communicate severally with the two plates of a condenser, A' imparts to it a charge of $+E$, B' a charge of $-E$. As soon as a' has lost its positive and b' its negative electricity, the $-E$ of a' is disguised by the $+E$ of b' , and so on to g' , the $-E$ of which is disguised by the $+E$ of h' . These opposite electricities attached to the contiguous particles do not at once recombine and neutralise one another, because they are retained in their places by the opposite electricities of the particles of AB ; but as soon as the current ceases to pass along AB , the $-E$ of a' unites with the $+E$ of h' through the medium of the conductor which connects the ends A' , B' , and at the same time, the opposite electricities of the particles a' , b' , c' , d' , e' , f' , and g' recombine, producing a current from B' to A' in the conductor, and from A' to B' in the wire itself, that is to say, in the same direction as the primary current in AB . The state of tension of the wire $A'B'$ during the time that the current is passing through AB , is that which Faraday calls the *electrotonic state*; its creation produces the first induced current, and its cessation, the second.

This mode of explanation is not however very satisfactory, and it does not show clearly why the secondary currents are produced only at the commencement and cessation of the primary current, and not during its continuance. Supposing a molecular polarisation, like that represented in *fig. 447*, to be produced in the two wires, a discharge ought to occur in $A'B'$ at the same instant as in AB , then a second decomposition of electricities, then a second discharge, and so on, as long as the current in AB continues. In short, all the changes of state in AB ought to be reproduced in $A'B'$, inversely and with less intensity. More complete theories of electro-dynamic induction have been given by Weber (*Pogg. Ann.* lxxiii. 193), and Neumann, (*Abhandl. d. Berl. Acad.* 1845, 1, and 1847, 1); but they are not of a nature to be introduced into this work. (See Wiedemann, *Galvanismus*, &c. ii. 675; Müller, *Lehrbuch*, ii. 378.)

Magneto-electric Machines.—The preceding principles have been applied to the construction of machines for the rapid and continuous development of induction currents. All these machines depend upon the rapid magnetisation and demagnetisation of a bar of soft iron round which a continuous wire is coiled, the development and destruction of the magnetism being effected, either by giving the bar of iron a continuous motion, which causes it to pass at short intervals before a magnetic pole,—or by subjecting it to the influence of an electric current, the circuit of which is completed and broken at very short intervals.

Saxton's magneto-electric machine (*fig. 448*) consists of a strong horse-shoe magnet, fixed horizontally, and a soft iron keeper in the form of a horse-shoe, each arm of which is encircled by a silk-covered wire. The keeper is made to revolve on a horizontal axis by an endless cord passing round a wheel, whereby the two extremities of the keeper are brought in front of the poles of the magnet twice at each turn of the wheel. By this motion, the keeper is alternately magnetised and unmagnetised. When it is in the *axial* position, that is to say, when its ends face the poles of the magnet, as in the figure, it is magnetised; when it has got a quarter round, or into the *equatorial* position, it is unmagnetised; when half round, it is again a magnet, but with its poles in the reverse of their former direction; when three-quarters round, it has again lost its magnetism, and so on. Now, as the loss of one kind of magnetic polarity is the same as the gain of the opposite kind, it is easy to see that, at each complete turn of the wheel, there will be two currents in opposite directions developed in each of the coils of wire. Further, on comparing each of the induced currents in one of the wires, with that which is induced at the same instant in the other wire, it is clear that these two currents must move in contrary directions, since the magnetic poles to which they owe their origin are of opposite kinds. Hence, to enable these currents to unite their forces instead of neutralising each other, it is necessary to join together the two ends of each of the wires from which the current appears to issue, and the two by which it appears to enter at the same time; these four ends thus joined two and two, present but two extremities or poles, which may be connected with the body through which the induced

Fig. 448.

currents are to be sent. Another mode of connection is to join the extremity of one wire from which the current issues, with that extremity of the other at which it enters, at the same instant leaving the other ends free to form the poles. These two arrangements differ in this respect, that in the former there are two parallel circuits, the effects of which are added together, whereas in the second, there is only one circuit twice as long as the former. The second circuit has evidently much less conducting power than the first, which consists of two wires only half as long as the single wire of the second; it is therefore the arrangement to be preferred when the induced currents are intended to pass through imperfect conductors, or interruptions in the circuit.

To establish the connections between the two extremities or poles of the wire, one of them is brought in contact with a metal rod fixed on the prolongation of the axis in the middle of the keeper, and moving with it, — the other with a vertical metal disc fixed by its centre to the same rod, which passes through it, but is well insulated from it by a glass tube enveloping the rod. The disc dips constantly by its lower part into a little trough of mercury, which also receives in succession the two points of a little brass needle attached to the end of the rod, and in metallic communication with it. Every time, therefore, that one of the points of the needle is brought by the rotation into such a position as to dip into the mercury, a metallic communication is established between the extremities or poles of the two coils of wire. If the needle is adjusted so that each of its points shall dip into the mercury just as the keeper arrives in front of the poles of the magnet, and emerge as it quits them, the first induction current is developed at the moment of immersion, the second at the moment of emersion. Both the immersion and the emersion are therefore accompanied by an electric spark, so that a constant succession of bright sparks is produced as long as the rotation of the wheel is continued.

To send the induced currents through any required conductor, the needle is removed, and the pointed end of a small metallic rod, firmly fixed to the frame of the apparatus, is pressed against the extremity of the axis of rotation, which is hollowed out for the purpose, the other end of the rod dipping into a cup of mercury. When the mercury in this cup and that in the basin, into which the disc above mentioned constantly dips, are connected by any conductor, the induced currents must necessarily pass through that conductor. To render the connection perfect, the bottom of the cavity at the end of the axis is amalgamated.

Magneto-electric currents are similar in most of their effects to voltaic currents; they heat thin wires to redness, decompose acidulated water, and give powerful shocks. To produce this last effect, two wires attached to metal cylinders (*fig. 449*) are connected, one into the mercury in the little cup, the other with that into which the disc dips; the cylinders are held in the hands, previously slightly moistened with salt water.

Magneto-electric currents differ however from voltaic currents in being discontinuous, and when produced by the machine above described, in moving in two opposite directions alternately. This discontinuity is the cause of the powerful shocks which they give; a voltaic current, the circuit of which is rapidly completed and broken, likewise produces much more powerful shocks than a continuous current from the same battery. The alternate movement of the magneto-electric currents in opposite directions has a considerable effect on its power of chemical decomposition: for this repeated change of direction necessarily causes a mixture of oxygen and hydrogen gases to be evolved from each electrode; and if the surface of the electrodes is rather large, considerable quantities of these mixed gases recombine and form water, especially when the alternate currents succeed each other very rapidly, so that the two gases are presented to each other almost in the nascent state. Hence it may happen that the quantity of gas collected in the voltameter is very small, although the currents may be very powerful, and produce great heat in metallic wires interposed in the circuit. These alternate currents produce no deflection of a galvanometer needle: whence we may conclude that they are equal in quantity.

It is possible, however, to arrange the interruptions of the circuit in such a manner as to produce a series of currents all in one direction. This is effected in Clarke's magneto-electric machine (*fig. 449*). The magnet *A* is vertical, and the connections are made without mercury, by means of a small steel spring *O*, pressing against a metal cylinder *K*, fixed upon the axis in place of the vertical disc in Saxton's machine, and insulated by a glass or wooden tube. Near the extremity of the axis is fixed another cylinder *H*, serving as a contact-breaker, for which purpose its surface is formed half of metal and half of wood, so that a second spring *Q*, which presses constantly against it, is brought in contact, as the axis revolves, sometimes with the metal, sometimes with the wood, and consequently is sometimes in, sometimes out of communication with one of the extremities of the coil, whilst the other spring, pressing constantly against the other cylinder *K*, which has a continuous metallic surface, is always in contact with the other end of the coil. To obtain a

succession of currents all in the same direction, it is only necessary to fix the disc H in such a manner that the spring may press against the metal part of its surface, while the keeper is passing from one axial position to the other half of the revolution. By this arrangement, one of the opposing currents is cut off at every turn of the wheel, and a rapid succession of currents is sent through the wire, all in one direction, and capable of producing all the effects of the continuous current of a voltaic battery of high tension, the resemblance between the two being greater as the momentary currents succeed one another with greater rapidity. When, however, the length and tenuity of the wire exceed a certain limit, the induced currents are no longer capable of heating wires or decomposing electrolytes, but their physiological effects become more intense. These differences depend upon the relative conducting power of different parts of the circuit, and on the quantity of electricity in the currents. When the wire is very long and thin, and consequently offers considerable resistance to the passage of electricity, the currents are small in quantity but of high intensity.

The Induction-coil.—The most powerful of all magneto-electric machines are those in which the soft iron is magnetised and unmagnetised, not by moving in front of a permanent magnet, but by the action of an electric current, the circuit of which is completed and broken in rapid succession. These instruments, called induction-coils, offer considerable variety in the details of their construction, but they all consist essentially of a hollow cylinder containing a bar of soft iron or a bundle of iron wires, and having two helices of wire coiled round it, as in *fig. 445*, one connected with the poles of a voltaic battery, the other serving for the development of the induced currents. The alternate interruption and closing of the battery-circuit may be effected by means of a metal spring connected with one end of the battery-coil, and pressing against the circumference of a toothed wheel, the axis of which is connected with the other end of the same coil, so that, as the wheel is turned round, the end of the spring is sometimes in contact with the teeth and completes the circuit, sometimes passes between them and interrupts it; but it is generally better to adopt a self-acting arrangement, as in the apparatus of Bonijol represented in *fig. 450*. In this machine, a fixed curved rod of metal, A B, and an elastic riband, C D, are interposed in the circuit of the inducing or battery current. The riband, by its elasticity, presses against the end B of the metal rod, and the two surfaces of contact are covered with discs of platinum to prevent oxidation. The elastic riband is pierced at E by a rod which can be raised or lowered, so as to bring its lower extremity, to which is attached a horizontal disc of iron, to a convenient distance from the bundle of wires in the axis of the cylinder. On making contact with

Fig. 449.

Fig. 450.

the battery, the soft iron core of the cylinder becomes magnetised, and attracts the little disc of iron, which pulls the elastic riband along with it, and separates the surfaces B, D, thereby breaking the circuit. As soon as this takes place, the iron wires lose their magnetism, the iron disc is no longer attracted, and the elasticity of the riband C D forces it up again, bringing the surfaces B, D in contact and completing the circuit: and this series of actions being repeated with great rapidity, an equally rapid series of induced currents is produced in the other helix, the ends of which communicate with the wires F, G. Consequently, any conductor, metallic, electrolytic, &c. interposed between F and G receives these induction currents. One of the poles of the battery is connected with the end H of the inducing coil, and the other with the end C of the elastic riband, the rod A B being connected by a wire with the other end K of the inducing coil.

The apparatus is also provided with another kind of current-breaker, consisting of a spring, M, and a toothed wheel, N, which is used when the self-acting current-breaker above described cannot be made available, as for example when the inducing coil is required to act on the other coil without the aid of the soft iron core.

The most powerful form of induction-coil, that of Ruhmkorff (*fig. 451*), acts by means of a self-acting current-breaker, like that just described. The cylinder of this

Fig. 451.

machine is a foot or eighteen inches long, and is surrounded by a coil of thick wire to convey the inducing current, and a much longer coil of thin wire for the development of the induced currents. The wires are insulated with resin, and the direction of the inducing current can be changed at pleasure by a commutator. To increase its power, M. Fizeau has added to it a condenser, consisting of two metallic ribands bent one round the other, and separated by oiled silk; these ribands communicate with the two extremities of the inducing wire, and thus become charged when the circuit is broken, and discharged when it is completed; this discharge, being in the same direction as the current, greatly increases its power.

In all these induction apparatus, a bundle of wires is much more effective in developing the induced currents than a solid cylinder of iron, apparently because, in the latter, superficial currents are developed by the action of the inducing current, which interfere with the principal effect. See De la Rive (*Traité*, i. 422).

The currents developed by the induction-coil, especially of Ruhmkorff's construction, are of very high intensity, capable of giving long sparks, and shocks of unendurable force. They are also capable of igniting gunpowder and other inflammable substances, and the apparatus has been used for exploding charges of gunpowder for mining, engineering, and military purposes. For military purposes, however, especially for operations in the open field, the use of the voltaic battery is attended with some inconvenience; and Messrs. Wheatstone and A bel have succeeded in producing the same effects by means of a magneto-electric machine, in which the currents are developed by mechanical movement, as in Saxton's and Clarke's machines. The apparatus contrived by Mr. Wheatstone for this purpose, consists of six small magnets, the poles of which are fixed soft iron bars, surrounded by coils of insulated wire. The coils of all the magnets are united together, so as to form, with an external conducting wire and the earth, a single circuit. An axis carries six soft iron armatures in succession before each of the coils. By this arrangement, all the magnets charge the wire simultaneously, and produce the effect of a single magnet of more than six times

the dimensions; and six currents are generated during a single revolution of the axis, so that with the aid of a multiplying motion applied to the axis, a very rapid succession of currents is produced.

Gunpowder alone may be fired by the magneto-electric discharge, especially when its conducting power is increased by the presence of a small quantity of moisture. Better results are, however, obtained by the use of fuses containing more inflammable substances, such as fulminating mercury. But the best mixture for the purpose is that invented by Mr. Abel, consisting of a mixture of phosphide of copper (p. 73) with chlorate of potassium, and a small quantity of cuprous sulphide, to increase its conducting power. For the description of the fuses used, and other details of the apparatus and manipulations, see Abel (Chem. Soc. J. xiv. 180).

MEASUREMENT OF THE FORCE OF ELECTRIC CURRENTS.

Ohm's Formulae.—The amount of electric or chemical power developed in the voltaic circuit, or, in other words, the quantity of electricity which passes through a transverse section of the circuit, in a unit of time, evidently depends upon two conditions; viz., the power, or electromotive force of the battery, and the resistance offered to the passage of the current by the conductors, liquid or solid, which it has to traverse. With a given amount of resistance, the power of the battery is proportional to the quantity of electricity developed in a given time; and by a double or treble resistance, we mean simply that which, with a given amount of exciting power in the battery, reduces the quantity of electricity developed, or work done, to one-half or one-third. If, then, the electromotive force of the battery be denoted by E , and the resistance by R , we have, for the quantity of electricity passing through the circuit in a unit of time, the expression:

$$q = \frac{E}{R} \dots \dots (1)$$

This is called Ohm's law, from the name of the distinguished mathematician who first announced it.

By means of the formula (1), we may estimate the effect produced on the strength of the current by increasing the number and size of the plates of the battery. The resistance R consists of two parts; viz. that which the current experiences in passing through the cells of the battery itself, and that which is offered by the external conductor which joins the poles; this conductor may consist either wholly of metal, or partly of metal and partly of electrolytic liquids. Let the resistance within the battery be r , and the external resistance r' ; then, in the one-celled battery, we have

$$q = \frac{E}{r + r'} \dots \dots (2)$$

Now suppose the battery to consist of n cells perfectly similar; then the electromotive force becomes nE , the resistance within the battery nr ; if, then, the external resistance remains the same, the strength of the current will be denoted by

$$q = \frac{nE}{nr + r'} = \frac{E}{r + \frac{r'}{n}} \dots \dots (3)$$

If r be small, this expression has nearly the same value as $\frac{E}{r + r'}$; that is to say, if the circuit be closed by a good conductor, such as a short thick wire, the quantity of electricity developed by the compound battery of n cells, is sensibly the same as that evolved by a single cell of the same dimensions. But if r' is of considerable amount, as when the circuit is closed by a long thin wire, or when an electrolyte is interposed, the strength of the current increases considerably with the number of plates. In fact, the expression (3) is always greater than (2); for:—

$$\frac{nE}{nr + r'} - \frac{E}{r + r'} = \frac{(n - 1)Er'}{(nr + r')(r + r')}$$

a quantity which is necessarily positive when n is greater than unity.

Suppose, in the next place, that the size of the plates is increased, while their number remains the same. Then, according to the chemical theory, an increase in the surface of metal acted upon must produce a proportionate increase in the quantity of electricity developed, provided the conducting power of the circuit is sufficient to give it passage. According to the theory which attributes the development of the electricity to the contact of dissimilar metals, an increase in the size of the plates does not

increase the electromotive force, but it diminishes the resistance within the cells of the battery by offering a wider passage to the electricity. Hence in the single cell, if the surface of the plates, and therefore the transverse section of the liquid, be increased m times, the expression for the strength of the current becomes:

$$\frac{E}{\frac{r}{m} + r'} = \frac{mE}{r + mr'}$$

If r' be small, this expression is nearly the same as $\frac{mE}{r + r'}$, that is to say, the quantity of electricity in the current increases very nearly in the same ratio as the size of the plates; but when the external resistance is considerable, the advantage gained by increasing the size of the plates is much less.

We may conclude, then, that when the resistance in the circuit is small, as in electro-magnetic experiments, a small number of large plates is the most advantageous form of battery; but in overcoming great resistances, power is gained by increasing the number rather than the size of the plates.

We have seen that the chemical or electrolytic power of a voltaic current is proportional to the amount of chemical action which goes on in the battery, and that the quantities of different electrolytes decomposed by the same current, are to one another as the weights of their comparable molecules (p. 439). Hence the chemical power of any current may be measured by the quantity of gas collected in a given time in a voltmeter placed in the circuit.

But it is by no means evident that the magnetic, calorific, and other effects of the electric current are proportional to its chemical power, and even if they were, the voltmeter would not afford a convenient measure of them, since, besides being somewhat uncertain in its indications, in consequence of the absorption and partial recombination of the oxygen and hydrogen evolved, it requires a certain time to elapse before a sufficient quantity of gas is collected for measurement, and cannot therefore give notice of any momentary variations in the power of the current. Hence to obtain exact measurements of the magnetic force of a current, it is necessary to resort to the magnetic action itself; instruments for this purpose are called Galvanometers or Rheometers. The so-called galvanometers, already described (p. 443), are really only galvanoscopes or multipliers; they indicate with great delicacy the existence and direction of a current, but are not adapted for quantitative measurement.

The Tangent Galvanometer or Tangent Compass.—In the true galvanometer (fig. 452) the current, instead of passing through a long coil of wire placed close to the needle, is made to pass through a broad circular band of brass or copper P Q, of considerable dimensions, in the centre of which is placed a magnetic needle n , the length of which is very small in comparison with the diameter of the circular conductor (it should not exceed $\frac{1}{10}$), so that the distance of the extremity of the needle from the conductor P Q, and consequently the force exerted upon it by the current, may be sensibly the same at all angles of deflection. The instrument is placed so that the plane of the circle P Q coincides with the magnetic meridian.

To determine the relation which exists under these circumstances between the deflection of the needle and the force of the current, let NS (fig. 453) represent a long horizontal wire stretched in the direction of the magnetic meridian, and suppose a magnetic needle, placed with its centre vertically under the wire, to be deflected by a current passing along the wire in the direction ns , making an angle ϕ with the wire. The current impels the pole s in the direction sf , perpendicular to NS, while the earth's magnetism acts upon it in the direction sg parallel to NS. Let the lines sf , sg be taken proportional to the magnitudes of these two forces; draw asb perpendicular to ns , and $f'bh, g'u$ parallel to it. Then the lines sa, sb represented the components of the forces sf, sg acting at right angles to the needle, and tending to move it one way or the other; hence, to keep the needle at rest, sa must be equal to sb . Now $sa = sg \sin \phi$ and $sb = sf \cos \phi$; therefore the condition of equilibrium is:

$$sf \cos \phi = sg \sin \phi;$$

$$\text{therefore, } sf = sg \frac{\sin \phi}{\cos \phi} = sg \tan \phi$$

In like manner, for another angle of deflection ϕ' , we should have $sf' = sg \tan \phi'$, therefore:

$$sf : sf' = \tan \phi : \tan \phi';$$

that is to say, the magnetic force of the current is proportional to the tangent of the angle of deflection.

Fig. 452.

Fig. 453.

Fig. 454.

The Sine-Galvanometer or Sine-Compass.—To avoid any error that may arise from the different relative positions of the needle and conducting wire at different inclinations, the construction of the galvanometer is sometimes modified in such a manner as to keep the needle always in the plane of the circular conductor. For this purpose, the needle is placed in the middle of a horizontal divided circle (fig. 454), which is itself placed within a vertical circle, the two being movable together round a vertical axis, and the amount of this rotation being measured on another horizontal circle below. The conducting wire, which is of copper covered with silk, is wound several times round the vertical circle. The instrument is first placed with the vertical circle in the plane of the magnetic meridian, the magnetic needle and the index of the lower horizontal circle then standing at 0° . On sending the current through the wire, the needle is deflected; the vertical circle is then to be turned in the same direction, till the needle again comes into the plane of the conducting wire, and therefore to the zero of the upper horizontal circle. The amount of its deflection from the magnetic meridian is then read off on the lower circle. Since now the needle is retained in the plane of the wire, it is clear that the current acts upon it at right angles to its axis, and therefore with its full force: hence, in the position of equilibrium, this force must balance that of the earth's magnetism, which tends to bring the needle back to the magnetic meridian; but this terrestrial force varies as the sine of the angle which the needle makes with the magnetic meridian; hence also *the force of the current is proportional to the sine of the angle of deflection*. Hence the name of the instrument.

As the sine-compass does not require the diameter of the circle of conducting wire to be very great in proportion to the length of the needle, it is better adapted than the tangent-compass for the measurement of weak currents; but it is more complicated, and on the whole not so convenient. (For the description of a sine-compass constructed by Siemens and Halske, especially for telegraphic measurements, see Wiedemann's *Lehre vom Galvanismus und Electro-magnetismus*, ii. [1] 207.)

Comparison between the Magnetic Galvanometer and the Voltmeter.—By introducing into the same circuit a voltmeter and a tangent or sine-compass, it is found that the chemical action of the current is proportional to its magnetic action. The magnetic galvanometer affords therefore a measure of the chemical, as well as of the magnetic action of the current.

The indications of different tangent- or sine-compasses are not directly comparable one with the other: for, with a given strength of current, the deflection of the needle varies with the diameter of the ring, and with the intensity of the terrestrial magnetic force, so that the same instrument would give different indications in different localities. By comparison with the chemical voltmeter, however, the indications of all such instruments may be reduced to a common standard.

A series of experiments described by Müller (*Lehrbuch der Physik*, ii. 170), in which a voltmeter and a tangent-compass were included in the circuit of a Bunsen's battery, gave the following results:—

Number of cells in the battery.	Deflection of needle.	Quantity of detonating gas evolved in three minutes.
		Cubic centimetres.
12	28.5°	125
8	24.8	106
6	22.0	92.5
4	18.75	78
3	13.75	66
2	5.9	23.7

The deflection of the needle did not vary more than half a degree during the three minutes. The numbers given in the second column of the table are the mean deviations between those observed at the beginning and end of the time.

The quotient obtained by dividing the quantity of gas evolved in the minute by the tangent of the deflection, is a constant, or nearly constant quantity, which gives the volume of gas evolved in a minute by a current which would produce, with the particular tangent-compass used, a deflection of 45° (since $\tan 45^\circ = 1$). The numbers in the preceding table give, for this quotient, the following values:—

No. of observation.	1	2	3	4	5	6	
Quotient	76.7	76.5	76.2	76.6	76.3	76.6	Mean 76.5

During the experiments, the temperature of the room was 15° C., the barometer stood at 744 mm., and the column of water in the voltmeter was about 10 cent. high, which is equivalent to 7 mm. of mercury. Hence the gas was under a pressure of 737 mm. Reducing by these data the mean volume of gas to 0° C. and 760 mm. pressure, the volume of gas evolved in a minute when the deflection is 45°, is found to be 70 cubic centimetres. A current which deflected the needle of the same instrument through ϕ degrees, would eliminate in a minute a volume of detonating gas = $70 \tan \phi$ cub. cent. Thus a deflection of 54° would correspond to a volume of detonating gas = $70 \times \tan 54^\circ = 70 \times 1.376 = 96.32$ cub. cent. at 0° C. and 760 mm.

Jacobi adopts, as the unit of current strength, the current which eliminates 1 cubic centimetre of detonating gas at 0° C. and 760 mm. in a minute. If then a current which eliminates m cub. cent. of detonating gas per minute, deflects the needle of a particular tangent-compass, 45°, the strength of any other current which, with the same instrument, produces a deflection of ϕ degrees, may be expressed in terms of the above unit, by the formula:

$$S = m \cdot \tan \phi.$$

The indications of the sine-compass may be compared with those of the voltmeter in a similar manner.

Reduction of the Force of the Electric Current to absolute Mechanical Measure.—This important determination has been made the subject of an extensive research by Weber and Kohlrausch (*Abhandlungen der math.-phys. Classe der kónigl.-sächsischen Gesellschaft der Wissenschaften*. Leipzig, 1856). The following are the units of measurement adopted:—

a. The unit of electric fluid is the quantity which, when concentrated in a point and acting on an equal quantity of the same fluid, also concentrated in a point, and at the unit of distance, exerts a repulsion equal to the unit of force.

b. The unit of electro-chemical intensity is the force of the current, which, in a unit of time, decomposes a unit of weight of water, or an equivalent quantity of any other electrolyte.

c. The unit of electro-magnetic force, is the force of a current which—when it traverses a circular conductor whose sectional area is equal to the unit of surface, and acts upon a magnet whose magnetic moment is equal to unity, the magnet being placed at a great distance, and in such a manner that its axis is parallel to the plane of the conductor, and its centre on a line drawn through the centre of the circular conductor, and perpendicular to its plane—exerts upon the magnet a rotatory force equal to unity divided by the cube of the distance between the centre of the needle and the centre of the conductor.

Weber had shown by previous experiments that the unit of electro-chemical force is to that of electro-magnetic force as 106½ to 1. It remained, therefore, to determine the relation between the electro-magnetic unit and the electrostatic unit (1), and thus to establish a numerical relation between static and dynamical electricity. The mode of experimenting was as follows:—

1. A Leyden jar having been strongly charged, its knob was touched with a large metallic ball, which took from it a certain portion of its charge, determined by previous experiments. The charge of the ball was then transferred to the torsion-balance, and the repulsive force measured. At the same time, the remainder of the charge of the jar was made to traverse the wire of a galvanometer, previously, however, having been passed through a long column of water, in order to give it a sensible duration, and prevent it from passing from one coil of the wire to another in the form of a spark. In this manner, a relation was established between the statical and dynamical effects of the charge of the jar.—2. The intensity and duration of a voltaic current were determined, which imparted to the galvanometer needle the same deflection as that produced by the discharge of the Leyden jar.

The results of the experiments were as follows:—

Through each section of a conductor traversed by a current whose force is equal to the electro-magnetic unit, there passes, in a second of time, a quantity of positive electricity equal to $155,370 \times 10^9$ statical units (p. 462), an equal quantity of negative electricity travelling in the opposite direction.

The quantity of electricity required to decompose 1 milligramme of water, amounts to $106\frac{1}{2}$ times this quantity, or $16,573 \times 10^9$ units of electricity, of each kind. To decompose 9 milligrammes of water, or one equivalent, requires of course nine times this amount of electricity. This quantity of positive electricity ($9 \times 16,573 \times 10^9$) accumulated on a cloud situated 1000 metres above the surface of the earth, and acting on an equal quantity of negative electricity on the surface of the earth below the cloud, would exert an attractive force equal to 226,800 kilogrammes, or 208 tons.

From the same data it is calculated that, if all the particles of hydrogen in 1 milligramme of water in the form of a column 1 millimetre long, were attached to a thread, and all the particles of oxygen to another thread, then, to effect the decomposition of the water in a second, the two threads would require to be drawn in opposite directions, each with a force of 147,380 kilogrammes, or 145 tons. If the water were decomposed with less velocity, the tension would be proportionally less.

Electric Resistance of Conductors.

The preceding principles enable us to determine the manner in which the resistance of a metallic wire varies with its length. For this purpose, suppose a one-celled battery (Daniell's) to be used, which maintains a constant action during the time of the experiment. First, let the current be made to pass directly through the tangent-compass, and afterwards let wires of uniform thickness and of the lengths of 5, 10, 40, 70, and 100 metres, be interposed in the circuit, and the resulting deflections observed. Now, as the force of the battery is constant, the resistance is inversely, as the strength of the current. But the total resistance is made up of that of the interposed wires, together with that of the battery itself, and that of the conductor of the galvanometer. These last two resistances we may suppose to be equal to that of a wire of the same thickness as the above, and of a certain unknown length x . Instead, therefore, of the lengths of wire 5, 10, 40, &c., we must substitute $x + 5$, $x + 10$, $x + 40$, &c. An experiment of this kind * gave the following results:—

Length of Wire.	Observed Deflection.	Tangent of Deflection.
x metres	$62^\circ 0'$	1.880
$x + 5$	40 20	0.849
$x + 10$	28 30	0.543
$x + 40$	9 45	0.172
$x + 70$	6 0	0.105
$x + 100$	4 15	0.074

Now, let us assume, as most probable, that the resistance of a wire increases in direct proportion to its length, then, according to Ohm's law, the first two experiments give:—

$$x : x + 5 = 0.849 : 1.880$$

whence, $x = 4.11$. And, by combining in a similar manner the first experiment with all the others, we obtain for x the several values 4.06, 4.03, 4.14, 4.09, the mean of the whole being 4.08. Substituting this value for x in the preceding table, and calculating the corresponding deflections, on the supposition that the strength of the current varies inversely as the resistance, that is as the length of the conductor, we obtain the following results:—

* Müller, Lehrbuch der Physik, 1852, II. 177.

Length of Conductor.	Calculated Deflection.	Observed Deflection.	Difference.
4.08 metre	62 0'	62° 0'	
9.08	40 18	40 20	+ 2'
14.08	28 41	28 30	- 11
44.08	9 56	9 45	- 11
74.08	5 57	6 0	+ 3
104.08	4 14	4 15	+ 1

From the results of this and similar experiments, it is inferred that — *the resistance of a conductor of uniform thickness varies directly as its length.*

The unit of resistance generally adopted is that of a wire of pure silver, 1 metre in length and 1 millimetre in diameter. Jacobi proposed copper; but this metal is not so well adapted to the purpose as silver, on account of the difficulty of obtaining it pure.

Matthiessen has proposed for the same purpose an alloy of gold and silver, containing 2 pts. gold and 1 pt. silver, the conducting power of which he has shown to be very little affected by slight impurities in the metals, and not to be altered by annealing or by moderate variations of temperature. (Phil. Mag. [4] xxi. 107.)

For Weber's absolute standard of electric resistance, see Pogg. Ann. lxxxii. 337; Jahresber. d. Chem. 1851, 272.

The Rheostat or Current-regulator.—This is an instrument for regulating and measuring the relative force of electric currents, by introducing into the circuit a conducting wire, the length of which may be varied at pleasure, without making any alteration in the rest of the circuit. This method applied to different currents, gives, as we shall see, the ratio of their intensities. The great advantage which it presents is, that of bringing the indications of a galvanometer placed in the circuit, always to the same degree, by varying the resistance, and thus dispensing with the use of instruments which depend upon the relations between the deflection of the needle and the strength of the current. In fact, the mode of measurement now under consideration depends merely upon the obvious principle, that two currents of equal strength will deflect the galvanometer in the same degree.

Instruments for introducing a variable resistance into the circuit are of various construction. We shall here describe the rheostats of Professor Wheatstone, of which there are two forms, one for circuits in which the resistance is strong, the other for those in which it is weak.

The rheostat for strong resistances, (fig. 455), consists of two cylinders, *g* *h*,

Fig. 455.

of the same dimensions, the first of dry wood, the second of brass, placed with their axes parallel to each other. The wooden cylinder *g* has a fine screw cut on its surface, and around it, following the thread of the screw, is coiled a thin brass wire. One extremity of this wire is attached to a brass ring at the nearer end of the wooden cylinder, and the other to the farther extremity of the brass cylinder. The ring and the nearer end of the brass cylinder are connected with the wires of the battery, through the medium of the screw joints *j*, *k*. A movable handle *m*, serves to turn the cylinders alternately round their axes. By turning *h* to the right, the wire is uncoiled from *g*, and coiled upon *h*; and the contrary when *h* is turned to the left. The number of coils of wire upon it are indicated by a scale placed between the cylinders, the

fractions of a turn being measured by an index moving round the ring in front of the wooden cylinder, which is graduated accordingly. As the coils of the wire are insulated on the wooden cylinder, but not on the brass, it is evident that the path of the current will be longer, and therefore the resistance greater, in proportion to the number of turns which the wire makes round the wooden cylinder.

The rheostat for circuits of comparatively small resistance, is shown in figure 456; *a* is a cylinder of dry wood, having a screw cut on its surface, and a thick copper wire coiled round it in the thread of the screw. Immediately above this cylinder is a triangular bar of metal *b*, carrying a runner *c*, also of metal, to which is adapted a spring *d*, constantly pressing against the cylinder and yielding to all its inequalities. One end of the coil is attached to a brass ring *e*, against which there presses a spring communicating, by means of a binding screw, with one pole of the battery, while the other

Fig. 456.

pole is connected in a similar manner with the triangular bar. On turning the handle *A*, the cylinder revolves upon its axis, and the runner *d*, guided by the copper wire, moves along the bar in one direction or the other, according to the way in which the handle is turned. The runner is thus brought in contact with different parts of the copper wire, and a variable resistance is introduced into the circuit, according as the current has to traverse a greater or smaller length of wire between the ring *e* and the runner *c*.

The figure shows the manner of using either of these instruments. *B* is a very sensitive galvanometer, having an astatic needle, and provided with a microscope for reading off the divided circle. *C* is the battery. When the object of the experiment is to measure the resistance of a given conductor, that conductor may be introduced in any part of the circuit.

The mode of comparing the electromotive forces of two voltaic batteries is as follows:—Into the circuit of one of the batteries, a sufficient resistance is introduced by the insertion of the rheostat wire—and, if necessary, of one or more reels of wire covered with silk, to reduce the deflection of the galvanometer needle to a convenient amount, say 45° ,—and a further resistance, measured by a certain length of the rheostat wire, is then introduced, sufficient to bring down the deflection, say to 40° . Let this length be l , and let the length of wire required in like manner to reduce the deflection of the needle by the current of the second battery, also from 45° to 40° , be l' . Then the ratio of the electromotive forces of the two batteries is determined by the proportion

$$e : e' = l : l'.$$

For, using the notation explained at page 459, let the quantity of electricity which produces the deflection 45° , be $q = \frac{e}{r}$; then the quantity q' which produces the de-

flexion 40° is $\frac{e}{r + l}$. Now let the ratio of the electromotive forces of the two batteries be denoted by n , that is to say, $e' = ne$. Then to enable the second current to produce the same deflection, 45° , as the first, its resistance must also be nr ; and when the deflection is reduced to 40° , by the introduction of the length of the wire l' , the force of this second battery will be expressed by $\frac{ne}{nr + l'}$; but this must be equal to $\frac{e}{r + l}$,

which can only be the case when $l' = nl$; or $\frac{l'}{l} = n = \frac{e'}{e}$; that is to say, the electromotive forces are as the resistances required to reduce the deflection by the same amount in the two cases.

For example, three simple voltaic couples, differing only in the size of the plates, and each consisting of a liquid amalgam of zinc, placed in a porous cell within a vessel filled with solution of sulphate of copper, in which was also immersed a hollow cylinder of copper, were successively placed in a circuit including a rheostat. All three required the same length of wire, viz. 30 turns of the rheostat, to reduce their electromagnetic force from 45° to 40° . Nevertheless, one was 5 centimetres high and 3.8 cent. in diameter; the second 8.4 cent. high, and 3.8 cent. in diameter; and the third 15 cent. high, and 8.4 cent. in diameter. Hence the electromotive force is independent of the extent of surface in the couple.

In the compound battery, the same mode of experimenting shows that the electro-

motive force increases proportionally to the number of plates. Thus, in a circuit formed successively of 1, 2, 3, 4, 5 couples, similar to the smallest of those above mentioned, it was found that, to bring the deflection from 46° down to 40° , the number of turns of the rheostat wire required, were,

For 1	2	3	4	5 couples
30	61	91	120	150 turns.

Hence, excepting the cases of 2 and 3 couples, which exhibit slight variations, the proportionality between the electromotive force and the number of pairs is completely verified.

The rheostat is likewise easily applied to the measurement of the resistance offered by different conductors to the passage of the current. Suppose that when the wire of the rheostat (*fig. 455*) is completely uncoiled from the wooden cylinder (the index then standing at 0), the galvanometer shows a deflection of 46° . Then let a copper wire four yards long and $\frac{1}{16}$ th of an inch thick, be introduced into any part of the same circuit. The galvanometer-needle will then exhibit a smaller deflection, say 37° . On removing the wire, the galvanometer will again exhibit its former deflection of 46° . Now let the rheostat wire be coiled round the wooden cylinder till the needle returns to 37° , and suppose that to produce this effect twenty turns of the rheostat-wire are necessary. This length of the rheostat wire produces a resistance equal to that of the wire under examination. Next let a similar experiment be made with a wire of the same length but of twice the thickness, and consequently having a transverse section four times as great as that of the former. It will be found that five turns of the rheostat wire, or one-fourth of the former length, are sufficient to produce a resistance equal to that of the second wire. By experiments thus conducted, it is found that: *The resistance of a wire or any other conductor of given length varies inversely as its transverse section.* And comparing this result with that which was established at page 464, we find that: *Conductors of the same material offer equal resistances, when their lengths are to one another in the same proportion as their transverse sections.*

The same law holds good for liquid conductors; hence the resistance offered by a liquid to the passage of the current may be diminished by bringing the solid conductors or electrodes, which convey the current into the liquid, more closely together, or by increasing their surface, and consequently the transverse section of the column of liquid.

The resistance of metals to the electric current increases as they become hotter; that of metalloids, acids, saline solutions, and compound bodies in general, both in the solid and in the liquid state, diminishes with rise of temperature.

The following table exhibits the comparative resistances, at ordinary temperatures, and for the same length and transverse section, of a few of the bodies commonly used in electrical experiments. These resistances are the reciprocals of the conducting powers.

Silver (chemically pure, very soft wire)	1-000
Copper	1-065
Copper, commercial (soft wire)	1-270
Brass (wire)	5-372
Iron (soft, slightly elastic wire)	6-767
Platinum wire	9-590
German silver wire	12-400
Mercury	29-238
Sulphuric acid (specific gravity 1.2 to 1.36)	761,732-000
Solution of sulphate of zinc, containing 38.58 p. c. of the crystallised salt	11,019,000-000
Solution of sulphate of copper, containing 20.83 p. c. of the crystallised salt	14,809,000-000

The resistance of distilled water is at least 700 times as great as that of dilute sulphuric acid.

The resistance of wires increases as they are harder and more brittle. (*Handw. d. Chem. ii. [3] 729.*)

The *conducting powers* of bodies for electricity, are, of course, inversely as their resistances. Matthiessen (*Pogg. Ann. c. 178; Phil. Mag. [4] xiii. 81; Pogg. Ann. ciii. 428*), has determined the conducting powers of metals, alloys, and a few other bodies, by means of an apparatus devised by Kirchhoff, and founded on the following principle, established by Wheatstone: *If four wires are joined together in a quadrangle, the ends of one diagonal being connected with a voltaic battery, and those of the other diagonal with a galvanometer, then the galvanometer will show no deflection, provided the resistances of the four wires are proportional to one another.* If then x be

the resistance of the wire to be determined, r that of a normal silver wire, a and b those of two lengths of one and the same copper wire, the unknown resistance x will, under the circumstances just mentioned, be determined by the equation $x = r \frac{a}{b}$.

The results obtained by this method are given in the following table:—

Conducting Powers of Metals, &c.

Silver	100	at 0° C.	Antimony	4.29	at 18.7° C.
Copper*	77.43	" 18.8	Mercury	1.63	" 22.8
Gold	55.19	" 22.7	Bismuth	1.19	" 13.8
Sodium	37.43	" 21.8	Alloy of bismuth		
Aluminium	33.76	" 19.6	32 pts., anti-	0.884	" 24.0
Zinc	27.39	" 17.6	mony 1 pt.		
Magnesium	25.47	" 17.2	Alloy of 12 bis-	0.519	" 22.0
Calcium	22.14	" 16.8	muth + 1 tin		
Cadmium	22.10	" 18.8	Alloy of 1 zinc	0.413	" 25.0
Potassium	20.85	" 20.4	+ 2 antimony		
Lithium	19.00	" 20.0	Graphite (greatest)	0.0693	" 22.0
Iron	14.44	" 20.4	Graphite (least)	0.00395	" 22.0
Palladium	12.64	" 17.2	Gas-coke	0.0386	" 25.0
Tin	11.45	" 21.0	Bunsen's bat-	0.00246	" 26.2
Platinum	10.53	" 20.7	tery-coke		
Lead	7.77	" 17.3	Tellurium	0.000777	" 19.6

Strontium	6.71	" 20.0			

More extended tables of the conducting powers of metals and alloys are given in Wiedemann's *Lehre vom Galvanismus und Electromagnetismus*, i. 180. See also the article METALS, in this Dictionary.

Matthiessen has also shown (Proc. Roy. Soc. xi. 516) that all pure metals in the solid state vary in conducting power to the same extent between 0° and 100° C.; but that the conducting power of a metal does not vary in the exact inverse ratio of the temperature, as stated by Becquerel and others; the resistance, λ , of a metal at the temperature t degrees being, in fact, expressed by the equation:

$$\lambda = \alpha + \gamma t + \gamma t^2;$$

where α is the resistance at 0° and γ and γ are constants.

HEATING EFFECTS OF THE ELECTRIC CURRENT.

The continuous, as well as the sudden discharge of electricity, raises the temperature of the conductors through which it passes; the plates and liquids of the battery, as well as the connecting wires which close the circuit, and the electrolytes which are decomposed by the current, all become heated in various degrees, according to their specific heats and the resistance which they offer to the passage of the current.

The laws of the development of heat by the electric current have been examined chiefly by Lenz and Joule, who have arrived at nearly the same results. Lenz made use of the apparatus represented in *fig. 457*. A glass stopper b fixed in a board, is fitted by grinding into the mouth of a bottle, and made air and water-tight by means of a little grease. A brass clamp, not shown in the figure, serves to press the horizontal lip of the bottle tight against the board, so that it cannot be disturbed, even by violent agitation of the apparatus. At the top of the bottle, there is an aperture for pouring in liquid and fixing a thermometer by means of a cork. The stopper b is pierced with two holes, through which are inserted thick platinum wires connected by copper wires with the binding screws f, s , and thence with the poles of a voltaic battery. The ends of these wires within the bottle are connected by a thin platinum wire wound into a spiral. The vessel is nearly filled with a measured quantity of alcohol of 85 or 86 per cent.; water would conduct too well, and suffer decomposition to a slight extent, yielding small quantities of gas. A tangent-compass and a rheostat are introduced into the circuit, in order to measure and regulate the strength of the current.

The following table gives the results of sixteen experiments made with three wires of German silver of different thicknesses, and with wires of platinum, iron, and copper.

Fig. 457.

* See the article COPPER, p. 39 of this volume.

The resistance of the spiral wire was determined by removing the apparatus from the circuit, and ascertaining the number of turns of the rheostat-wire required to be brought into the circuit to bring the current to the same strength. These resistances and the strength of the current, in the second column, are expressed in Jacobi's units already mentioned (pp. 462, 464):—

No. of experiment.	Nature of the wire.	Strength of current.	Time required to heat the spirit 1° R.	Resistance of the wire.
1	Nickel-silver, <i>a</i>	6·93	1·349	93·50
2	" "	10·53	0·571	93·63
3	" "	14·30	0·300	58·76
4	Nickel-silver, <i>b</i>	10·53	0·920	58·64
5	" "	14·30	0·481	59·01
6	" "	18·32	0·288	60·16
7	" "	14·30	0·457	44·59
8	Nickel-silver, <i>c</i>	18·32	0·384	50·45
9	Platinum	22·69	0·555	51·41
10	"	18·32	0·325	24·92
11	Iron	22·69	0·435	13·90
12	Copper	18·32	1·301	13·90
13	"	22·69	0·835	13·90
14	"	27·52	0·575	13·92
15	"	32·98	0·381	14·01
16	"	27·52	0·544	14·31

The quantity of spirit in the bottle was 90 grammes.

Comparing now with one another the experiments in which the strength of the current was the same, it appears that the product of the time *t* and the resistance *l* is a constant quantity. Thus:

For the current 10·53.

2. Nickel-silver, *a* $tl = 53·46$
 4. " " *b* $tl = 54·06$

For the current 14·30.

3. Nickel-silver, *a* $tl = 28·18$
 5. " " *b* $tl = 28·11$
 7. " " *c* $tl = 27·49$
 9. Platinum $tl = 28·00$

For the current 18·32.

6. Nickel-silver, *b* $tl = 16·99$
 8. " " *c* $tl = 17·12$
 10. Platinum $tl = 16·71$
 12. Copper $tl = 18·08$

For the current 22·69.

11. Iron $tl = 10·84$
 13. Copper $tl = 11·60$

These numbers show that, with a given strength of current, the time of heating is inversely proportional to the resistance, or the heat evolved in a given time is directly proportional to the resistance, and otherwise independent of the nature of the metal.

Secondly, by comparing together the experiments made with the same wire and currents of different strengths (*s*), it will be found that the product s^2t is nearly constant, thus:

For the nickel-silver wire *a*.

- 1 $s^2t = 64·8$
 2 $s^2t = 63·3$
 3 $s^2t = 61·3$

For the nickel-silver wire *b*.

- 4 $s^2t = 102·0$
 5 $s^2t = 98·4$
 6 $s^2t = 96·7$
 7 $s^2t = 93·5$

For the platinum wire.

- 9 $s^2t = 113·5$
 10 $s^2t = 109·1$

For the copper wire.

- 12 $s^2t = 436·8$
 13 $s^2t = 429·9$
 14 $s^2t = 435·5$
 15 $s^2t = 414·2$
 16 $s^2t = 412·0$

It appears then from these experiments, that *the evolution of heat is proportional:*

1. *To the resistance;* 2. *To the square of the strength of the current.*

These laws are the same as those demonstrated by Riess for the heating of wires by the sudden discharge of electricity (p. 395).

Further, as t is the time in which, with the current s and the resistance l , a given mass of alcohol is heated 1° Réaumur, s^2t will be the time required for heating the same mass of alcohol 1° R. by the unit of current force acting against the unit of resistance. Since, therefore, in all the preceding experiments, the quantity of alcohol was nearly the same, the product s^2t ought to be nearly constant for all the numbers in the preceding table, as in fact it is, the greatest and least values, being 5609 and 6069, and the mean 5856.

Now, the quantity of alcohol heated in the preceding experiments, together with that which would be equivalent (as regards specific heat) to the mass of glass heated at the same time, was 118 grammes. Hence the unit of current force passing through a wire, whose resistance is l , evolves heat sufficient to raise the temperature of 118 grammes of the alcohol used, 1° R. in 5856 minutes.

The specific heat of the alcohol (85 to 86 per cent.) is 0.7, so that 118 grammes of this alcohol require, to heat it through a given range of temperature, as much heat as $118 \times 0.7 = 82.6$ grammes water. Consequently, the time required to heat 1 gramme of water 1° R. by the unit of current force acting with the unit of resistance is:

$$\frac{5856}{82.6} = 70.9 \text{ minutes;}$$

and for 1° Centigrade the time is:

$$70.9 \times 0.8 = 56.72 \text{ minutes;}$$

that is to say: *When a current of the unit of strength passes through a wire whose resistance is equal to that of a copper wire 1 metre long and 1 millimetre in diameter, it develops a quantity of heat sufficient to raise the temperature of 1 gramme of water, 1° C. in 56.72 minutes;* and assuming as the unit of heat the quantity required to raise the temperature of 1 gramme of water 1° C., the result of the preceding experiments may be thus expressed:

A current of the unit of strength, passing through a conductor which exerts the unit of resistance, develops therein 1.057 heat-units in an hour, and 0.0176 heat-units in a minute.

As the temperature of a metallic conductor rises under the influence of the electric current, its resistance to the passage of the current increases (p. 466). Now this increase of resistance acts in two ways: first, by diminishing the strength of the current; secondly, by increasing the heating effect of the electricity which actually passes, so that ultimately these effects balance one another. From the experiments of Robinson (*Trans. of the Royal Irish Academy*, xxii. [1] 8), it appears that the resistance gradually increases up to the melting-point of the wire, the increase being very nearly proportional to the temperature.

The effect of temperature on conducting power is strikingly shown by heating a long platinum wire to low redness by the current, and then plunging the middle part of it into cold water; the extremities immediately become brightly incandescent. On the contrary, if one part of the wire be raised to a very high temperature by means of a spirit-lamp or blowpipe flame, the glow of the other part immediately diminishes in brightness.

The heating of wires by the current is remarkably affected also by the cooling action of the surrounding gaseous medium. A platinum wire is heated to redness much more easily in a vacuum than in air, and more easily in some gases than in others, hydrogen exerting the greatest cooling effect, and nitrogen the least. But further, this abstraction of heat from the wire by a gas, not only lowers its actual temperature, but at the same time diminishes the resistance which it offers to the passage of the current, and therefore also the quantity of heat actually developed in it. This is strikingly shown by the following experiments of Grove.

Two glass tubes (*Fig. 458*) closed at both ends with corks, and having spirals of platinum wire within them attached to thick copper wires passing through the corks,

Fig. 458.

are filled, one with hydrogen, the other with oxygen, and immersed in glass troughs containing equal quantities of water, thermometers *A*, *B*, being immersed in the water to measure the temperature. On sending the current of an eight-pair Grove's battery through the wires, that in the oxygen-tube is heated to whiteness, while the one in the hydrogen-tube scarcely exhibits a visible glow. Moreover, the temperature of the water in the two vessels rises very unequally; that which contains the oxygen-tube rising from 15.6° to 27.2° C. while that which contains the hydrogen-tube rises only from 15.6° to 21° . The following table shows the rise of temperature produced in the water when the platinum-wire is surrounded with different gases, associated in each case with a similar platinum wire surrounded with hydrogen:—

Hydrogen	5.50
Sulphydic acid	6.0
Ethylene	9.2
Carbonic anhydride	11.0
Carbonic oxide	11.0
Oxygen	11.7
Nitrogen	12.0

That the differences are really due to the increased conducting power of the wire resulting from the cooling, is shown by placing a voltameter in the same circuit with a platinum wire immersed successively in each gas. The following table gives the results obtained by Grove:—

<i>Gas surrounding the wire.</i>	<i>Quantity of detonating gas evolved per minute.</i>
Hydrogen	138.6
Ethylene	126.0
Carbonic anhydride	118.8
Carbonic oxide	118.8
Oxygen	117.0
Nitrogen	115.0

The order of the gases in this table is the same as in the preceding.

The development of heat in liquids by the electric current is regulated by the same laws as in metals, the quantity of heat evolved in a given time being proportional to the resistance of the liquid, and to the square of the strength of the current (E. Becquerel, *Ann. Ch. Phys.* [3] ix. 21). Moreover, Joule has shown (*Phil. Mag.* [3] xix. 210) that the evolution of heat in each couple of the voltaic battery is subject to the same law, which therefore holds good in every part of the circuit, and therefore also for the entire circuit, including the battery.

With a current of given strength, the sum of the quantities of heat evolved in the battery, and in the metallic conductor joining its poles, is constant, the heat actually developed in the one part or the other, varying according to the thickness of the metallic conductor. This was first shown by De la Rive, and has been confirmed by Favre (*Ann. Ch. Phys.* [3] xl. 393). De la Rive made use of a couple consisting of platinum and distilled zinc, or cadmium, excited by pure and very strong nitric acid, the two metals being united by a platinum wire, more or less thick, which was plunged into the same quantity of strong nitric acid contained in a capsule similar to that which held the voltaic couple. By observing the temperatures in the two vessels by delicate thermometers, the sum of these temperatures was found to be constant, the one or the other being greater, according to the thickness of the connecting wire.

Favre, by means of a calorimeter, similar to that which he used in his experiments on the development of heat by chemical action (see HEAT), has shown that, in a couple consisting of zinc and platinum, excited by dilute sulphuric acid and connected by platinum wires of various length and thickness, for every 33 grammes of zinc dissolved, a quantity of heat is developed in the entire circuit, equal to 18,137 heat-units (the unit of heat being the quantity required to raise 1 gramme of water from 0° to 1° C.), but variously distributed between the battery-cell and the wire, according to the thickness of the latter. Now this quantity of heat is nearly the same as that which is evolved in the simple solution of 33 grammes of zinc in dilute sulphuric acid, without the formation of a voltaic circuit, viz. 18,444 units. Hence Favre concludes that the heat developed by the resistance of a metallic or other conductor connecting the poles of the battery is simply borrowed from the total quantity of heat evolved by the chemical action taking place in the battery, and is rigorously complementary to that which remains in the cells of the battery, the heat evolved in the entire circuit being the exact equivalent of the chemical action which takes place. If any external work is performed by the current, such as electrolysis or mechanical work, as by an electromagnetic engine,

the heat evolved in the circuit is diminished by the heat-equivalent of the decomposition or mechanical work done. (Favre, *Compt. rend.* xlv. 56.)

LIGHT PRODUCED BY THE ELECTRIC CURRENT.

The closing and interruption of the voltaic circuit are attended with the production of sparks. With a single pair of plates, however, the spark, unless assisted by the formation of induced currents (p. 452), or by the combustion of the metallic surfaces between which it passes, is scarcely perceptible. Thus, when two short wires attached to the plates of a single voltaic couple are brought together, only a very faint spark is produced, either on making or on breaking contact; but if the same plates are connected by a long copper wire formed into spiral, the spark is much brighter, especially on breaking contact, because the induced current then coincides in direction with the primary current. A still higher exaltation of the effect is produced on placing a bar of iron within the coil. When a cup containing mercury is fixed on one of the plates, and a wire attached to the other is brought down to the surface, a bright spark is produced, the light being probably intensified by the combustion of the mercury.

A compound battery of four or more couples gives a spark between the connecting wires without any of the means of assistance just mentioned; but, unless the number of plates is very large indeed, the spark does not strike through a perceptible distance like that of the electrical machine or the induction coil. Jacobi found that the poles of a 12-pair Grove's battery did not give a spark, even at the distance of 0.00005 of an inch. Gassiot's water-battery of 3520 pairs well insulated (p. 422), gave sparks when the distance between its polar wires was reduced to 0.02 inch, the spark discharge going on without interruption for five weeks. In all ordinary cases, the light of the spark produced by the battery appears to arise in great part from ignition, fusion, or combustion of the metallic surfaces.

The most brilliant manifestation of voltaic light is that which is produced when the discharge takes place between two pointed pieces of charcoal. The light is white and dazzling, and when produced by a powerful current, such as that of a Bunsen's battery of 40 or 50 cells, has a brilliancy which the eye cannot endure. With such a battery, the charcoal points, after having been brought in contact, may be separated to some distance from one another without interrupting the current, the discharge then assuming the form of a splendid arch of light. This phenomenon takes place in a vacuum as well as in air, and even with greater regularity in the former case, because the extremities of the charcoal terminals do not then burn away.

The light of the voltaic arc is due, partly to the electric light itself, partly to the incandescence of the charcoal terminals, partly to the transport of small particles of carbon from the positive to the negative pole. By projecting the image of the poles during the passage of the current, on a screen by means of a system of lenses, this transference of particles may be distinctly seen, the positive terminal being gradually eaten away, while the negative terminal seems to grow. With the softer kinds of charcoal this transference takes place more easily than with hard charcoal; soft charcoal gives therefore a longer arc; hard charcoal is, however, usually preferred for producing the light, because the continual alteration in the terminals interferes greatly with the steadiness of the light.

The transference of matter takes place between metal terminals as well as with charcoal, the more fusible or oxidable metals, zinc and iron for example, exhibiting it more easily than the more refractory or less oxidable, such as platinum or silver; hence the arc may also be produced with metals, but it is then much shorter. In almost all cases, the transference of matter is from the positive to the negative pole, and when the discharge takes place between oxidable metals in the air, the transferred matter always consists of the oxidised metal of the positive terminal. The same transference of matter takes in the ordinary electric spark, as observed long ago by Fusinieri.

The intensity of the light of the voltaic arc has been examined by Casselmann (*Pogg. Ann.* lxiii. 576). The charcoal terminals were formed of hard Bunsen's charcoal (i. 760) saturated with various solutions, nitrate of strontium, boric acid, &c., and then re-ignited. The terminals thus prepared gave a very steady arch of light, variously coloured, according to the substance with which the charcoal was impregnated, and continuing (with a battery of 44 Bunsen's cells) till the points were separated by an interval of 7 or 8 mm., whereas the unsteady arc produced with crude charcoal did not pass over a space exceeding 5 mm.

The following table exhibits the intensity of light of the glowing charcoal points, together with that of the luminous arch, compared with that of a stearine candle, and in each instance, when the terminals were very close, and when they were separated as far as possible. The strength of the current, measured by a tangent-compass, is expressed in chemical units (p. 462). The light was measured by a Bunsen's photometer:—

	Distance between charcoal points.	Strength of current.	Intensity of light.
Crude charcoal	0.5 mm.	95	932
	4.5	68	139
Charcoal with nitrate of strontium .	0.5	120	353
	6.75	88	274
Charcoal with caustic potash . .	2.5	101	150
	5.0	82	75
Charcoal with chloride of zinc .	1.0	80	624
	5.0	67	159
Charcoal with borax and sulphuric acid	1.5	72	1171
	5.0	64	165

These numbers show that both the strength of the current and the intensity of the light diminish as the distance between the terminals is increased.

From the experiments of Fizeau and Foucault, it appears that the intensity of the voltaic arc of a 46-pair Bunsen's battery is thirty-four times as great as that of the oxy-hydrogen lime-light.

The great intensity of the voltaic light has led to various attempts to adapt it to the purposes of illumination. There is, however, considerable difficulty in obtaining a steady light, because, as already observed, the charcoal terminals are continually burning away, and their shape is constantly varying, in consequence of the transference of particles from one to the other. Unless, therefore, some means are provided for maintaining a constant distance between them, the light continually varies in intensity, and sometimes goes out altogether. The most effectual arrangement for this purpose is that adopted by Duboscq in his electric lamp, for a description and figure of which, see *De la Rive's Traité*, ii. 26, or *Ure's Dictionary of Arts, Manufactures, and Mines*, ii. 87. This apparatus is admirably adapted for optical purposes, for exhibiting effects of refraction, dispersion, polarisation, &c., for throwing images of various objects on a screen, and for certain theatrical effects where a strong beam of light is required; but for general purposes of illumination, where a number of small lights are required, rather than one very strong light, the electric light does not appear to be very well adapted, because every break in the circuit increases enormously the battery power required to overcome the resistance.

Mr. Way has obtained a very bright light by passing the electric current along a stream of mercury. The light is produced by the incandescence of the mercury vapour; it has a somewhat flickering character, and a decided greenish tinge.

The magneto-electric light has also been applied to the purpose of illumination, a number of soft iron keepers carrying coils of wire being made to revolve, by steam power, in front of a series of magnetic poles. An apparatus of this kind was tried at the South Foreland Lighthouse for a year, with very good results, as regards the intensity and steadiness of the light.

The stratification of the electric light in highly-rarefied gases has been already mentioned (p. 391). This phenomenon, first observed with the discharge of the induction-coil, has been shown by Mr. Gassiot to be likewise produced by the discharge from the conductor of an electrical machine or from a Leyden jar, and by that of a voltaic battery consisting of a large number of cells, such as Gassiot's water battery, or a Grove's battery of 400 cells well insulated, so as to obtain high tension at the poles. It is therefore wholly independent of the peculiar conditions of the induction apparatus. In short, the stratifications are produced, whether the discharge is continuous, like that of the voltaic battery under ordinary circumstances, or intermittent like that of the water battery, or that of the nitric acid battery just mentioned, when a small interruption is made in the circuit, so as to give rise to the passage of sparks; but they are much more brilliant with the (apparently) continuous than with the intermittent discharge, because the action of the battery is much more energetic in the former case. Mr. Gassiot regards the stratified discharge as arising, in all cases, from the impulses of a force acting on highly-attenuated but resisting media, and thence concludes that the discharge of the voltaic battery, under every condition, is not continuous but intermittent, consisting of a series of pulsations or vibrations of greater or less velocity, according to the resistance in the metallic and electrolytic elements of the battery, and the conducting media through which the discharge passes. (*Proc. Roy. Soc.* x. 393; xii. 629.)

The voltaic arc and the streams of electric light produced in rarefied gases, are deflected by the magnet, like a wire conveying a current of electricity. Some very

remarkable phenomena are exhibited when the pole of a magnet is held near the metallic terminals in an exhausted tube through which the discharge is passing, the current being sometimes completely interrupted, as if the luminous stream had been driven away from the terminal, and thus the continuity of the circuit broken. (Proc. Roy. Soc. ix. 146, 604; x. 269.)

PHYSIOLOGICAL ACTION OF THE ELECTRIC CURRENT: ANIMAL ELECTRICITY.

General Law of Nervous Excitation by the Electric Current.—A voltaic battery of a moderate number of pairs, gives a shock at the moment when the circuit is completed by touching the two poles with the hands, and likewise on interrupting the circuit; but the continuous passage of a current of constant strength does not produce any nervous agitation.

For more delicate observations on the physiological action of electricity, the limbs of a recently killed frog are used, prepared as in Galvani's original experiment (p. 415), by cutting through the spinal column, leaving three or four vertebrae, then stripping off the skin, and leaving the lower extremities suspended by the lumbar nerves, as in *fig. 459*. Sometimes only one of the legs is used, with a considerable length of the lumbar nerve attached to it, and without the vertebrae. Such a preparation, which gives exceedingly delicate indications of the presence of an electric current, is called a galvanoscopic or rheoscopic limb.

In the rheoscopic limb, as in the human body, the contractions are produced at the closing and opening of the circuit, or generally on the occurrence of any variation in the strength of the current, but not while it continues of constant strength. In this respect the physiological action of the current resembles its inductive action (p. 451). The nervous agitation produced by a current of given strength is greater in proportion as the variations in its strength take place more quickly; hence the discharge of a Leyden jar, even if of small dimensions, produces a very violent shock, the current, though very small in quantity, passing through all its variations, from the commencement to its maximum strength, and down again to its termination, in a time imperceptibly small.

The preceding observations must, however, be understood as applying only to the action of the current on the motor nerves; for the nerves of sensation are affected by the continuous current, as well as by the sudden discharge; a peculiar sensation is experienced when the current of a voltaic battery of a considerable number of pairs is

Fig. 459.

Fig. 460.

passed through any part of the body, and the current, even of a single pair, produces a severe sensation of smarting when it passes over any part of the surface from which the skin is abraded. The effect on the nerves of sensation, like that on the nerves of

motion, is, however, much greater at the commencement and cessation of the current than during its continuance.

Recently-prepared frog's legs, which are very excitable, exhibit equally strong convulsions, both at the opening and closing of the circuit, in whichever direction the current is sent through them; but as the excitability becomes less, this equality no longer exists, and Du Bois-Reymond has shown, that, with a medium degree of excitability in the prepared frog's limb, the contractions are stronger at the *closing* of the circuit, when the positive current passes from the origin of the nerves to their ramifications, and at the *opening* of the circuit, when the current is in the contrary direction. This may be shown by immersing the two legs of the frog in separate glasses of salt water connected with the poles of a battery, as in *fig. 460*, so that the $+E$ may pass up one leg and down the other; it will then be found that the leg in the cup connected with the negative pole exhibits convulsions at the closing of the circuit and the other at the opening.

The Muscular Current. The rheoscopic limb may be made to exhibit convulsions without the action of any external source of electricity. Galvani, who first observed the contractions produced on touching the nerves of the limb with a copper, and the muscles with an iron rod, the two metals being in contact, attributed the effect to a peculiar fluid which he supposed to pass through the limb from the nerves to the muscles. Volta, however, showed that an essential condition to the production of the powerful contractions observed by Galvani, was the presence of two metals in the circuit, and he attributed the entire effect to electricity developed at the point of contact of the dissimilar metals (p. 415). The invention of the pile, to which this theory led him, and the splendid series of discoveries thence resulting, diverted attention for a considerable time from the original phenomenon. Galvani, however, retained his original view, and succeeded in showing, that the prepared frog's limbs, when very excitable, that is to say, soon after separation from the living body, exhibit the contractions, not only when the nerves and muscles are connected by a homogeneous metallic wire, but even without any metal at all, namely, by simply bringing the extremities of the lumbar nerves in contact with the muscles of the leg or foot.

The contractions may also be produced by dipping the feet into a vessel containing salt water, the vertebral column into another vessel of salt water placed by the side of it, and connecting the two portions of liquid by means of a bundle of moistened cotton threads; the limbs exhibit convulsions every time the circuit is completed or broken.

If the two vessels are connected by dipping into them platinum plates attached to the coil of a very delicate galvanometer, the needle exhibits a deflection, indicating the existence of a current from the feet towards the head. This was first shown by Nobili; and Matteucci afterwards found that an equally strong current is produced, when, instead of the prepared limbs, the entire body of a frog, recently killed and skinned, is placed between the two glasses, with the head in one and the feet in the other, the current always passing in the body of the frog from the feet to the head. With the galvanoscopic limb, a current is obtained still in the same direction, when the leg is immersed in one vessel and the thigh in the other.

As the saline solutions may act chemically on the animal fluids, and thus generate currents which interfere with the true muscular and nervous currents, it is necessary, in the more delicate investigations relating to animal electricity, to make use of apparatus in which the direct contact of the nerves

Fig. 461.

and muscles with these solutions is avoided. Such is the contrivance adopted by Du Bois-Reymond (*Untersuchungen über thierische Electricität*, Berlin, 1848 and 1849; *Ann. Ch. Phys.* [3] xxx. 119, 178; xxxix. 114), which consists in laying the nerve or muscle between two pads, composed of a great number of layers of thin filtering paper, saturated with the saline solution, and laid over the edges of the vessels in which the platinum terminals of the galvanometer are immersed, the animal substance not, however, being in direct contact with the moistened paper, but separated from it by a

small piece of moistened bladder soaked in white of egg: this prevents any chemical action between the saline solution and the animal fluids, but does not stop the current.

During the intervals between the experiments, the two pads are connected by a third, as shown in the figure, the object of this connection being to keep the circuit closed, and allow any polarisation of the platinum plates that may have taken place to neutralise itself.

A better mode of experimenting, however, is that of Matteucci (*Proc. Roy. Soc.*

x 577), who uses, as extremities of the galvanometer, plates of amalgamated zinc, immersed in a neutral saturated solution of sulphate of zinc. This liquid possesses great conducting power, but does not act chemically on the animal tissue; the apparatus is also quite free from secondary polarity.

By the mode of experimenting above described, the following facts have been established:—

1. When a muscle having two membranous terminations is laid between the conducting pads, as in *fig. 462*, no current is produced; but if the muscle is placed as in

Fig. 462.

Fig. 463.

fig. 463, with one of its extremities in contact with one pad, and its red muscular surface with the other, a very strong current is produced, passing through the muscle from the tendinous extremity, *a*, to the point of contact of the muscular flesh with the pad. If the muscle be removed, the circuit completed by the connecting pad, so as to destroy the polarity of the plates, the connecting pad then removed, and the position

Fig. 464.

Fig. 465.

of the muscle reversed as in *fig. 464*, the direction of the current is reversed, that is to say, it is still from the tendinous extremity *b*, to the touched point of the muscular flesh.

2. If the muscle be cut transversely and then placed between the pads, so that the cut surface, *a*, is in contact with one, and a point of the outer surface with the other (*fig. 465*), the current passes from *a* through the muscle towards the latter point.

The artificial transverse section of the muscle plays, therefore, the same part as the tendinous extremity; in fact, this extremity may be regarded as a natural transverse section, covered with a neutral substance, the tendon, which acts merely as a conductor.

3. If the muscle be torn in the direction of the fibres, an artificial longitudinal section is obtained, which acts just like the natural lateral surface of the muscles, or natural longitudinal section.

These results lead to the following general law of the direction of the muscular current, *The longitudinal section, natural or artificial, of a muscle, is positive to its natural or artificial transverse section.*

This law of the muscular current is not confined to any particular class of animals, but extends throughout the animal kingdom. Du Bois-Reymond has observed it in the muscles of man, of the rabbit, guinea-pig, mouse, dove, sparrow, tortoise, lizard, adder, blind-worm, many kinds of frog and toad, the earth- and water-salamander, the liver-eel, and the common earth-worm.

Du Bois-Reymond has further shown that currents exist between different points of the longitudinal section, either natural or artificial, any point in such longitudinal section being negative with respect to any other point farther than itself from the extremity of the section.

The central points of any transverse section are negative to those situated beyond them.

These currents existing between different points of the same section, longitudinal or transverse, are, however, very feeble in comparison with those between a transverse and longitudinal section.

It appears, then, that every fragment of a muscle, however small, exhibits currents following the same general law. Hence it may be inferred that the muscular currents are molecular, like those to which the effects of magnetism are attributed in Ampère's theory, so that the muscular currents really form closed circuits, and the currents actually observed in experiments like those above described, are merely derived currents,

obtained by diverting a portion of the principal current through a neighbouring conductor, and probably very greatly inferior in intensity to the primitive currents.

The strength of the muscular current is greater in proportion as the muscle has to exert a stronger mechanical power, whether voluntary or involuntary (Du Bois-Reymond). According to Matteucci (Proc. Roy. Soc. viii. 209), the electromotive power of a muscle is independent of the surface of its transverse section, but increases with the length of the muscle. It is greater in mammals and birds than in fish or amphibia.

The nerves have no direct influence on the electromotive force of muscles, but any causes which exert an influence on the physical structure and chemical composition of muscles, so as to modify their irritability or contractility, act equally on their electromotive power. (Matteucci, *loc. cit.*)

According to J. Regnault, the maximum electromotive force of the gastro-cnemian muscle of the frog is between 4 and 5 times as great as that of a thermo-electric couple of bismuth and antimony having one of its joints at 0° C. the other at 100° ; that of the thigh-muscles of the frog is 9 or 10 times that of the same couple. Referred to the same unit, the electromotive force of the gastro-cnemius of the rabbit is between 6 and 7, that of the biceps between 5 and 6.

The electromotive power of the muscles diminishes after death at the same rate as the irritability, and when the rigidity of death sets in, the muscular current ceases altogether, and cannot be renewed by any means whatever. It is therefore essentially a vital phenomenon.

A muscle during contraction exhibits an electric current in the same direction as when it is in the uncontracted state, but the current is much weaker. (Du Bois-Reymond, Matteucci.)

The Nervous Current. By operating with the sciatic nerve of a frog in the same manner as in the experiments with muscle above described, placing a transverse section in contact with one of the pads of filtering paper, and a point of the lateral surface with the other, a strong current is obtained, passing from the transverse section through the nerve to the touched point of the lateral surface.

Generally, the nervous current is subject to the same laws as the muscular current; the nerves may therefore be supposed to be the seat of a number of closed molecular currents, of which the currents actually indicated by the multiplier are merely derived portions, greatly inferior in strength to the nervous currents themselves.

When an electric current from a voltaic couple is passed along any portion of a nerve, the nerve begins to act electromotively at all its points, independently of its ordinary electric state, the direction of the currents thus produced coinciding with that of the exciting current. This is called the electro-tonic state of the nerve.

When, on the contrary, the nerve is tetanised, by the passage of momentary currents through it in opposite directions, as from an induction-coil, the ordinary nervous current is weakened, like the muscular current under similar circumstances.

For further details on the muscular and nervous currents, see Müller *Lehrbuch der Physik*, ii. 410-432.—De la Rive, *Traité* iii. 1-61.—Matteucci, *Ann. Ch. Phys.* [2] lvi. 429; lxxviii. 93, [3] vi. 30; viii. 309; xv. 64; xviii. 109; xxiii. 230; Phil. Trans. 1847-1850;—Proc. Roy. Soc. viii. 209; x. 344.—C. B. Radcliffe, *ibid.* ix. 690; x. 347.

Electric Fishes. There are certain fishes provided with peculiar organs, in which electricity is developed with such intensity as to give powerful shocks, and exhibit various other signs of electric action, such as attraction and repulsion, the spark, magnetisation of steel, &c.

The fishes in which this power is known to reside, are the *Torpedo* or *Electric Ray*, found in the Mediterranean and in the Atlantic, rarely in the North Sea; the *Gymnotus electricus* or *Surinam Eel*, found in the lakes and rivers of South America, especially in Guiana; and the *Silurus electricus*, found in the Nile, Niger, and other African rivers. Besides these, the *Rhinobatus electricus*, *Tetraodon electricus*, and *Trichiurus electricus*, are said to possess similar powers, but the statements respecting them are somewhat vague and require confirmation.

The torpedo has long been known to possess the power of giving shocks; but the electric character of this power was first pointed out by Muschenbroek, and further established by Dr. John Davy, who obtained a deflection of a galvanometer needle by bringing the extremities of the coil, furnished with platinum plates, in contact with the back and front of the fish, and magnetised a steel needle by placing it in a helix, the ends of which were made to touch the fish in a similar manner. He likewise succeeded in decomposing water by the same current, and proved, by the manner in which this decomposition took place, as well as by the magnetic phenomena, that the upper or back surface of the torpedo is positive, the lower negative. These results

were confirmed by Becquerel and Breschet, and further by Matteucci and Linari. The latter first obtained a spark from the torpedo by bringing an iron wire touching one surface of the fish in contact with a cup of mercury connected with the opposite surface; he likewise obtained an induction-spark by passing the discharge from the fish through an electro-dynamic helix. Matteucci afterwards obtained a spark and effects of attraction, by placing a torpedo just taken out of the water between two metallic plates (*fig. 466*), the lower supported on glass legs, the upper provided with an insulating handle, and both having attached to them metallic rods, terminating in balls A B, to which gold leaves were attached. On gently moving the upper plate, so as to irritate the animal a little, the gold leaves moved together, and a bright spark passed between them.

Fig. 466.

In the gymnotus, the direction of the electric discharge is from the head through an external conductor to the tail, the head being the positive extremity. When the fish bends its long body into a curve, the water included in the curve is traversed by a number of electric currents, which kill any small fishes that may be in their way. Faraday showed that the electric current from the gymnotus is capable of decomposing iodide of potassium, magnetising steel needles, and producing an induction spark; and Schönbein, by connecting two strips of gold leaf, one with the head, the other with the tail of the fish, obtained vivid sparks, attended with combustion of the gold.

The shock given by the gymnotus is much more powerful than that of the torpedo; indeed, when the fish is in full vigour in its native element, it is capable of killing large animals. The discharge from both these fishes is of high intensity, like that of a Leyden jar, and will give a shock to a chain of several persons joining hands.

The power of all the electrical fishes resides in peculiar organs, bearing a general resemblance to a voltaic pile. In the torpedo, the electrical organ, situated between the pectoral fins, the head, and the gills, is formed of a number of small membranous tubes, A, B (*fig. 467*), passing perpendicularly from front to back of the fish, pressed together like the cells of a honey-comb, and divided by transverse diaphragms into a great number of small cells, which are filled with an albuminous liquid ($\frac{2}{3}$ salt water and $\frac{1}{3}$ albumen). There are about 940 of these tubes, each divided into 2000 cells, and the organ is traversed throughout by numerous ramifications of nerves proceeding from the eighth pair. The direction of the tubes is in accordance with the opposite polarities of the two flat surfaces of the fish.

Fig. 467

Fig. 468.

Fig. 469.

In the gymnotus, the electric organ (*fig. 468*) is of similar construction; but the tubes are rectangular and directed parallel to the axis of the fish. The transverse diaphragms, A, B, which are perpendicular to the length of the animal, consists of two solid membranes superposed but not in contact, one having a cellular structure, the other composed of minute fibres. There are also two liquids—one the *sub-cellular liquid*, contained between the two membranes just mentioned, the other, the *super-cellular liquid*, between two successive diaphragms. Pacini, to whom the anatomical examination of the organ is due, compares it with the voltaic battery of one metal and two liquids; the chemical action taking place between the cellular substance and the sub-cellular liquid, the super-cellular liquid acting merely as a conductor, and the fibrous substance

as the porous cell. The fibrous substance in each cell is situated towards the head of the animal, so that this mode of action is in accordance with the direction of the positive current in the body of the fish from the tail to the head.

The electrical organ of the silurus is composed of small membranes *BB* (fig. 469) crossing one another in various directions, and forming a number of octahedral cells, each having the capacity of about a cubic millimetre, and filled with an albuminous liquid. The whole forms a spongy mass just beneath the skin, and envelopes the whole body like a sac, excepting the muzzle and the fins. It is separated from the body of the fish *FE* by a thick layer of fat *DD*, which, being a non-conductor, appears to be designed to protect the animal from the effects of its own electricity.

In all the electric fishes, the action of the electric organ is to a considerable extent under the control of the will, and its exertion is attended with exhaustion of nervous energy, the animal, after giving repeated shocks, requiring rest and good nourishment to restore its electric power. But the recent experiments of Matteucci (Proc. Roy. Soc. x. 576) on the torpedo, have shown that the electric organ is not entirely under the control of the will, but is always charged, and that, round the body of the torpedo, and of every other electric fish, there is a continual circulation of electricity in the liquid medium in which the animal is immersed. In fact, when the electric organ, or even a fragment of it, is removed from the living fish and placed between the ends of a galvanometer, the needle remains deflected at a constant angle for 20 or 30 hours, or even longer.

The electric organ, or a portion of it detached from the fish and kept at the freezing temperature, preserves its electromotive power for six, or even eight days; and an organ which has been kept for 24 hours in a vessel surrounded with a mixture of ice and salt, is found to possess an electromotive power as great as that of the organ recently detached from the living fish. Thus the electric organ retains its functional activity long after nervous and muscular excitability have been extinguished. Matteucci has also shown that the electric organ may be excited by mechanical irritation, independently of nervous influence; that influence, however, renews and renders persistent the activity of the apparatus. The discharge, which is only a state of temporary activity of the organ, is brought on by an act of the will of the living animal, or by the excitation of the nerves of the organ.

DEVELOPMENT OF ELECTRICITY IN PLANTS.

The electric relations of the different parts of a living plant have been examined by Pouillet, Riess, Becquerel, and Wartmann, without any very definite results. The most complete experiments on the subject are those of Buff (Ann. Ch. Phys. [3] xli. 198), who has shown, that *the roots and all the internal parts of plants, which are filled with vegetable juices, are negative with regard to the more or less humid surface of the leaves, flowers, fruit, and young branches.*

The origin of this phenomenon is easily traced. The interior of the plant contains juices of various nature, which cannot pass through the epidermis, whereas that membrane is always impregnated to a certain extent with the moisture of the air. There are then in contact, a membrane impregnated with water, and vegetable organs containing liquids of various nature; if, then, a closed circuit be formed between the two, a current must necessarily be produced; this current has, however, only a very distant and indirect relation with the phenomena of vegetation.

So far, indeed, as observations have yet gone, it does not appear that living plants exhibit an electric state analogous to that which has been shown to exist in the nerves and muscles of animals, all the signs of electricity observed in them being attributable to ordinary chemical reactions, and in some cases perhaps to the electricity of the atmosphere. (De la Rive, *Traité*, iii. 82—88.)

ELECTRICITY, ATMOSPHERIC. The atmosphere exhibits signs of electricity in its normal state as well as during storms. A gold-leaf electroscope connected with an insulated pointed metal rod projecting into the air, gives almost constant indications of electric charge, the kind and degree of which vary with the state of the atmosphere, and the height above the surface of the earth at which the electricity is collected.

When the sky is quite cloudless and the air dry, the electricity of the atmosphere is always positive, the intensity increasing regularly with the altitude above the surface, where it is nothing. At any given altitude, the intensity of the positive charge exhibits variations, both monthly and diurnal. The monthly variations are such that the maxima of electric charge show themselves in the months when the days are the longest, and the minima in those when they are the shortest. The diurnal variations differ considerably in amount in different places, and are, for the most part, proportional to the variations of humidity in the air.

The precipitation of aqueous vapour in the form of cloud, fog, or rain gives rise to great and sudden changes in the electrical state of the atmosphere, the positive charge no longer following the regular course of variation above mentioned, but sometimes falling to nothing, and sometimes giving place to a negative charge of greater or less intensity. Indeed, the formation of a cloud or fog is always accompanied by a change of distribution in the electricity of the stratum of air in which it takes place. When a number of particles of aqueous vapour combine together into a vesicle or a liquid globule (see CLOUD, i. 1028) the small quantities of $+E$ associated with them unite in the globule, and are accumulated on its surface, and when a number of these globules are aggregated in the form of a cloud, a considerable portion of the charge is transferred to the exterior surface. The cloud consequently acts like a charged conductor on the air below it, rendering the contiguous portion negative, and increasing the positive charge at a certain distance on either side of this negative portion. Suppose now a cloud thus charged to pass over the electroscope. When it is within a certain distance, the positive divergence of the leaves increases, then it diminishes, and at a certain time, viz. when the neutral limit between the positive and negative columns of air is passing over the electroscope, the leaves collapse; then, as the cloud passes on, they diverge with negative electricity, then again collapse, and when the cloud has passed, they again diverge with $+E$, showing that the air has returned to its normal electric condition. Independently, however, of this inductive action, portions of the air frequently acquire a direct negative charge, from a cause to be explained hereafter; the same cause also gives rise to the formation of negative clouds. It is easy to understand how the effects above described may be complicated by the presence of positive clouds in different parts of the sky, or of a positive cloud in one part and a negative cloud in another.

A large cloud strongly charged with $+E$, disturbs the electricity on the earth's surface below it, rendering the part immediately below it strongly negative, and when the opposite electricities on the ground and the lower surface of the cloud have reached a certain tension, discharge takes place between them in the form of lightning. One cloud may also act in this manner on a neighbouring cloud; and in that case, the lightning passes from one to the other without striking the earth. The discharge between two clouds may, however, affect objects on the earth's surface in this way: A positive cloud may render negative the surface of the ground below it, as well as that of a neighbouring cloud, and if discharge takes place between the two clouds, the cause which had separated the electricities of a certain portion of the earth's surface is suddenly removed, so that they recombine with equal suddenness. This is called the *return stroke*. It is not attended with any visible discharge, and is never so violent as the direct stroke of lightning, but men and animals are sometimes killed by it.

An electrified cloud never discharges all its electricity at once. This arises from the imperfect conducting power of its mass; in fact, when a number of globules of water unite to form a cloud, although a certain portion of their free electricity is transferred to the outer surface, this is not the case with the whole—because the globules are not in sufficiently close contact to form a continuous conducting mass. The charge appears rather to be distributed through the cloud in successive strata; accordingly, when an electroscope is placed in the midst of a fog or cloud driven onwards by the wind, the divergence of the leaves continually varies as strata of different intensity pass over it. An electroscope exposed to the influence of the electrified clouds during a thunderstorm, shows that every stroke of lightning, whether taking place between two clouds, or between a cloud and the earth, is preceded by a multitude of small discharges in the interior of the clouds themselves. The leaves diverge suddenly and by fits during an interval when all appears quiet; then a clap of thunder is heard; the leaves immediately collapse, and remain quiet for a time, but soon recommence their divergence, until another discharge takes place between the clouds, and so on.

Lightning assumes three different forms: the *zig-zag* or *forked lightning*, the *flash* or *sheet lightning*, and the *globe*. The first is like an ordinary electric spark, its zig-zag form being due to the cause mentioned at page 388—viz. that it seeks out the path of least resistance, striking from one collection of watery particles in the air to another; sometimes in the midst of its course it divides into two or even into three branches. Wheatstone has shown that the duration of a stroke of forked lightning, like that of the common electric spark, is less than the millionth part of a second.

Sheet-lightning is much more common than forked lightning. It has neither the whiteness nor the intense brilliancy of the latter, but is generally of a blue or violet colour, sometimes deep red; sometimes it seems to illuminate only the edges of a cloud, at other times it embraces the entire surface of the clouds, and seems to issue from the midst of them, lighting up the whole atmosphere. It probably arises from a multitude of minute discharges taking place simultaneously between the particles of a cloud, or between two clouds in the manner already mentioned.

The third kind, or globe-lightning, differs from the other two in duration, as well as

in power, being sometimes visible for one, two, or even ten seconds, passing from the clouds to the earth at a rate which the eye can easily follow. Its form is nearly spherical; in fact, it constitutes a true ball of fire, which sometimes splits up into several pieces as it falls, rebounding several times from the earth, sometimes exploding with a report like the discharge of several pieces of ordnance, and scattering streams of forked lightning in all directions. It is less common than the two former kinds, but appears to be the form which lightning generally assumes when it penetrates into the interior of a building.

It is clear that this form of lightning is of very different nature from forked and sheet lightning; in fact, it cannot be a mere electric spark, but probably consists of a portion of moist air or vapour condensed and strongly electrified: in fact, a small cloud charged so intensely as to become luminous. De la Rive suggests that it may contain a mixture of air and hydrogen gas, resulting from the decomposition of aqueous vapour by previous electric discharges, and that when it comes into the line of a stroke of lightning, or when its own electric charge becomes high enough to produce a spark, it explodes. The explanation is not very probable: for the electric discharges in the air, even if they did resolve the aqueous vapour into oxygen and hydrogen, would cause the gases instantly to recombine.

Thunder is the noise resulting from the violent concussion of the air attending the electric discharge. The reverberation or roll arises from the manner in which the discharge takes place, which, as already observed, is not instantaneous, but consists of a great number of comparatively small discharges, sometimes accompanied by a great one; but even an instantaneous lightning-stroke will not generally produce a mere instantaneous report, because the different parts of the line, even when it is vertical, and still more when it is horizontal, are situated at different distances from the observer. The reflection of the sound-waves from the clouds doubtless also adds to the effect; among mountains, the reverberation is very much increased by the echoes thus produced.

Source of Atmospheric Electricity.—Volta and Saussure attributed the electricity of the atmosphere to the evaporation of water from the surface of the earth. Pouillet took a similar view, excepting that he regarded the electric charge as arising, not from the mere evaporation of the water, but from the decomposition of a saline solution—viz. sea-water, the water escaping in vapour and the salt remaining behind. We have seen, however (p. 429), that it is only when the evaporation is very rapid, that any signs of electricity can be thus obtained, as, when it takes place slowly, the separated electricities have time to recombine before the water escapes.

It seems necessary, therefore, to look to some more general cause for the development of atmospheric electricity. The action of the sun upon the atmosphere, and the consequent unequal distribution of temperature therein, has been suggested as a cause; but we have no proof that gases and vapours exhibit the slightest trace of thermoelectricity.

De la Rive ascribes the electric charge of the atmosphere to chemical action taking place on the inner surface of the solid crust of the earth, where it is in contact with the internal incandescent mass, this action proceeding partly from local causes, but chiefly from the infiltration of sea-water, in consequence of which the water acquires a positive, the solid part of the earth a negative charge (p. 414). The whole mass of sea-water thus becoming positive, the vapours which rise from it are also positive, and communicate a positive charge to the atmosphere. This evaporation takes place over the whole surface of the ocean, but most abundantly in the tropical regions; and the positively-charged vapours rising at first in these regions more or less vertically, are afterwards carried away towards the poles by the tropical current (the return trade-wind) in the higher regions of the atmosphere. This current, travelling at first horizontally, bends down more and more to the earth as it approaches the poles, and becomes cooler; and in the polar regions themselves it comes nearly down to the negatively-charged surface of the earth, whence results a discharge of electricity, constituting the *aurora borealis* or *australis*.

The greater amount of evaporation taking place in the hemisphere in which the sun is situated, accounts for the greater prevalence of storms during summer; in winter, on the other hand, the positively-charged vapours descend nearer to the ground; hence the greater intensity of the permanent charge of the atmosphere during the winter months.

The solid crust of the earth being negative, the vapours rising from it and from ponds and rivers on its surface must also be negative. This is another cause of the diminution of the permanent positive charge of the atmosphere in summer, and likewise accounts for the formation of negative clouds. As these negative clouds play a considerable part in the production of thunderstorms, the occurrence of a greater number of storms during the summer season in temperate climates is easily accounted for; in the

tropical regions, where evaporation from the surface of the ground is more abundant, and goes on at much the same rate all the year through, storms are of constant occurrence. Over large expanses of water, such as the great oceans, at a long distance from land, thunderstorms rarely occur, because no negatively-charged vapours are poured into the atmosphere.

That the water of the ocean and the solid crust of the earth are actually in opposite electrical states has been proved by the observations of Peltier (*Ann. Ch. Phys.* [3] iv. 385), and of Becquerel (*Compt. rend.* xlii. 661); this opposition of electric states likewise accounts for the fact that the air is positive in immediate contact with the surface of the sea, whereas over planes far from the sea, the positive charge shows itself above a certain height only.

The development of electricity by the chemical action of sea-water on the fused matter below the solid crust of the earth appears also to be the origin of the intense signs of electric action which usually accompany volcanic eruptions. In the eruption of Vesuvius in 1794, clouds were emitted which gave out flashes of lightning, accompanied by loud peals of thunder, and many houses were struck by the lightning. The observations of Palmieri (*Arch. des Sc. Phys.* xxxvi. 105) have shown that the vapours emitted from the crater of Vesuvius are charged with positive electricity.

ELECTRODES. The terminals, metallic or otherwise, which convey an electric current into a liquid (p. 432).

ELECTRO-DYNAMICS. The science which treats of the mutual action of electric currents, and of electric currents and magnets (pp. 442, 446).

ELECTROLYSIS. Decomposition by electricity (pp. 397, 432).

ELECTROLYTE. A compound liquid decomposable by electricity (pp. 397, 432).

ELECTRO-MAGNETISM. The branch of electro-dynamics which treats of the mutual action of the magnet and the electric current.

ELECTROMETER. An instrument for measuring the strength or degree of the electric charge of a body (p. 330).

ELECTRO-MOTIVE FORCE. This term, originally employed by Volta to signify the force which, as he supposed, gave rise to the separation of the two electricities at the point of contact of two dissimilar metals, is now applied to any source of electric excitement whatever, but is used for the most part in speaking of arrangements which generate a continuous current of electricity.

ELECTROMOTOR. Any arrangement by which a current of electricity is generated.

ELECTRO-NEGATIVE and **ELECTRO-POSITIVE.** Terms used to denote the relative position of bodies in the electric series (p. 432).

ELECTRO-NITROURETS. *Alloys of Ammonium.* Many metallic salts—as those of gold, silver, cadmium, &c.—when electrolysed in presence of ammoniacal salts, yield at the negative electrode, metallic deposits containing nitrogen, which have not been accurately investigated, but are supposed by Grove (*Phil. Mag.* [4] xix. 19) to be ammonium-compounds.

ELECTROPHORUS. See page 385.

ELECTRO-PLATING. The coating of metals with silver by electrolysis. (See *Ure's Dictionary of Arts, Manufactures, and Mines*, art. **ELECTRO-METALLURGY**, ii. 95.)

ELECTROSCOPE. An instrument for detecting the existence of an electric charge, and indicating its nature, whether positive or negative (pp. 380, 424).

ELECTROTYPE. The deposition of metals in the compact state by electrolysis, so as to form casts or models. (See *Ure's Dictionary of Arts, Manufactures, and Mines*, art. **ELECTRO-METALLURGY**.)

ELECTRUM. A term applied to those native alloys of gold and silver, which contain sufficient silver to make their colour perceptibly lighter and their specific gravity considerably less than that of pure gold. Hausmann (*Handb. d. Miner.* ii. 25) applied it to such as contain from 20 to 50 per cent. silver. According to C. Rammelsberg, alloys containing not more than 20 per cent. silver are completely decomposed by nitro-muriatic acid; whereas those which are richer in silver, do not readily yield up their gold to that reagent. Before the blowpipe, gold containing silver yields an opalescent glass with phosphorus-salt; a larger proportion of silver renders the glass yellow and opaque.

ELEMENTARY ANALYSIS. See ANALYSIS, ORGANIC (i. 225).

ELEMENTS. *Elementary Bodies. Simple Substances. Grundstoffe, Urstoffe.* By these terms we understand substances which cannot be, or rather which have not hitherto been, resolved into more simple forms of matter. To the list of elementary bodies given in the article ATOMIC WEIGHTS (i. 465, first edition), we must now add four, viz. Cæsium and Rubidium, discovered by Bunsen, Thallium, by Crookes, and Indium, by Reich and Richter. The number of elements at present known with certainty is 63; two others, Dianium (p. 318) and Norium, may be mentioned as of uncertain existence. The list will doubtless be increased by future researches, especially by the new method of spectrum analysis, which has already led to the discovery of the four elements above mentioned, cæsium, rubidium, thallium, and indium. But it is scarcely probable that any element existing in considerable quantity in the earth's crust yet remains to be discovered. The elements which constitute the great mass of the earth's crust are, indeed, comparatively few, viz. *aluminium, calcium, carbon, chlorine, hydrogen, magnesium, oxygen, potassium, silicium, sodium, sulphur.* The last of these has been known from the remotest times, and the rest were discovered in the early days of modern chemistry. The more abundant metals, iron, copper, lead, which occur chiefly in veins in the older rocks, have likewise been known from remote antiquity. Most of the other elements, the discovery of which is of comparatively recent date, occur but sparingly, and many of them only in extremely small quantity, *e.g. thorium, tantalum, tellurium, ruthenium, cæsium, and rubidium.*

The elements are usually divided into two classes, Metals and Metalloids, which, however, like most divisions of natural objects, blend into each other by insensible degrees. The metals for the most part form basic oxides; the metalloids, acid or indifferent oxides. The compounds of metals with each other possess the metallic lustre; those of metalloids with one another, or with the metals, do not for the most part exhibit that lustre.

The elements may be divided into groups or families resembling one another more or less in their chemical characters and crystalline forms (see ISOMORPHISM). The members of the same group generally occur together in nature; and minerals containing one of them, as principal constituent, usually contain also small quantities of the other elements of the same group. Examples of these groups are:—

Chlorine	Potassium	Oxygen	Barium	Magnesium	Cerium
Bromine	Sodium	Sulphur	Strontium	Zinc	Lanthanum
Iodine	Lithium	Selenium	Calcium	Cadmium	Didymium
Fluorine	Cæsium	Tellurium			
	Rubidium				
Silicium	Platinum	Iron	Nitrogen	Chromium	
Titanium	Palladium	Cobalt	Phosphorus	Molybdenum	
	Iridium	Nickel	Arsenic	Tungsten	
	Rhodium	Manganese	Antimony		
	Ruthenium		Vanadium		
	Osmium		Bismuth		

Many of the elements which resemble one another closely in their chemical relations, have also nearly equal atomic weights, *e.g.* iron, manganese, cobalt and nickel; cerium and lanthanum; platinum and iridium; rhodium and ruthenium. On the other hand, instances of this equality of atomic weights exist between elements which exhibit no such resemblance of properties, *e.g.* molybdenum and cerium; osmium and mercury.

The members of some of the preceding groups exhibit nearly equal differences in their atomic weights. Thus a difference of 48 is exhibited by the atomic weights of calcium 40, strontium 88, and barium 136; also by those of sulphur 32, selenium 80, and tellurium 128; of 16, by lithium 7, sodium 23, and potassium 39. The atomic weights of other groups exhibit nearly equal differences, *e.g.* chlorine 35.5, bromine 80.4, and iodine 127.0; also phosphorus 31, arsenic 75, and antimony 120.

Other relations between the atomic weights of elements have been pointed out by Kromers (Pogg. Ann. lxxxv. 56); Low (Sill. Am. J. [2] xvii. 387); Lenssen (Ann. Ch. Pharm. ciii. 121); Gladstone (Phil. Mag. [4] v. 313); and Dumas (Ann. Ch. Pharm. cv. 74; cviii. 324).

ELEM. A resin of which several kinds occur in commerce. Ordinary or West Indian elemi, *Elemi occidentale*, is said to be the produce of *Icica icicariba*, Dec. (*Amarys elemifera*, L.); East Indian elemi, *Elemi orientale*, which is more esteemed, but rarely met with, is said to be obtained from *Amarys ceylonica* or *Balsamodendron ceylonicum*, Kunth. According to Landerer, an African elemi, *Elemi aegyptiacum*, *e. ethiopicum*, is sometimes sold at Smyrna and Constantinople: it is said to be imported from Nubia and Egypt, and is perhaps the produce of *Elaeagnus hortensis*.

Common elemi forms more or less translucent masses, having a fatty lustre and yellowish or brownish-yellow colour; it is soft when fresh, but gradually hardens. It shines in the dark when rubbed or warmed. It is chiefly used as an ingredient of varnishes, especially of spirit and turpentine varnishes, which it prevents from cracking as they dry.

Elemi resin is a mixture of an amorphous acid resin easily soluble in cold alcohol, and a crystallisable indifferent resin, soluble in cold, and sparingly soluble in boiling alcohol, together with variable quantities of a volatile oil, and foreign matters, including ash (2 or 3 per cent.)

The resin soluble in cold alcohol contains, according to Johnston (Ann. Ch. Pharm. xlv. 338), 78·7 per cent. carbon and 10·5 hydrogen, agreeing nearly with the formula $C^{10}H^{12}O^4$, or $C^{20}H^{22}O^8$; this substance forms about $\frac{2}{3}$ of the entire resin.

When the remaining portion of the resin is boiled with alcohol, and the solution left to evaporate, a considerable quantity of a crystalline resin is deposited, which may be purified by repeated crystallisation from alcohol. It forms a white confusedly crystallised mass, perfectly soluble in strong boiling alcohol, and forming a solution neutral to litmus paper.

According to analyses by H. Rose (Ann. Ch. Pharm. xxxii. 93; xl. 307), and Johnston (*loc. cit.*), this crystalline resin appears to have the composition $C^{10}H^{12}O$; those of Hess (Ann. Ch. Pharm. xxix. 139) agree rather with the formula $C^{10}H^{12}O^2$ or $C^{20}H^{22}O$, which is more probable.

				Hess.		Rose.		Johnston.
C ²⁰ .	.	240	.	83·3	.	83·8	.	81·7 84·5
H ²² .	.	32	.	11·1	.	11·5	.	11·2 12·8
O	.	16	.	5·6	.	4·7	.	7·1 2·7
		<u>288</u>		<u>100·0</u>		<u>100·0</u>		<u>100·0 100·0</u>
								<u>100·0</u>

The analyses agree nearly with that of the constituent of animé resin, examined by Laurent, and with that of arbol-a-brea resin, analysed by Dumas. (Baup's *amyrgin*, i. 354.)

The alcoholic solution of elemi resin is not clouded by alcoholic potash, but is precipitated by aqueous potash. Ammonia added to the alcoholic solution converts it into a gelatinous mass. The alcoholic solution is not precipitated by alcoholic acetate of lead or nitrate of silver, even the addition of a drop of ammonia causing no precipitate, but only a slight turbidity.

Crystallised elemi resin is decomposed and charred by dry distillation, yielding first a viscid, brown, acid oil, having an agreeable odour, afterwards a black, disagreeably smelling tar.

Oil of Elemi.—Elemi. Elemi resin distilled with water yields a transparent colourless oil, having the composition of a camphene, $C^{10}H^{16}$. It has an agreeable colour like that of the resin, and a faint taste. Specific gravity = 0·852 at 24° C. (Stenhouse), 0·849 at 11° C. (Deville). Boiling point 166° C. (Stenhouse), 174° C. (Deville). Vapour-density = 4·0. Index of refraction = 1·47 at 14° C. (Deville). Optical rotatory power, 90° 30'.

Oil of elemi is insoluble in water, but easily soluble in alcohol and ether. With *hydrochloric acid*, it forms two isomeric compounds, $C^{10}H^{16}.HCl$, one solid, the other liquid; the solid compound is optically inactive. With *iodine*, *nitric acid*, and *sulphuric acid*, oil of elemi behaves like oil of turpentine; it is also similarly affected by *heat*. The proportion of volatile oil in the resin probably varies according to its age. Bonastre found 12·5 per cent., Stenhouse only 3·5 per cent. oil; good elemi resin contains, according to Deville, more than 13 per cent. oil. (Stenhouse, Ann. Ch. Pharm. xxxv. 304; Deville, *ibid.* lxxi. 352.)

ELEMINE. Syn. with OIL OF ELEMINE.

ELEPHANT'S FAT, according to Filhol and Joly (Compt. rend. xxxv. 393), is white, soft, inodorous, melts at 28° C., contains 79 pts. liquid, and 21 pts. solid fat (stearin and palmitin): the liquid fat is easily soluble in alcohol, does not dry up on exposure to the air, and is not solidified by hyponitric acid.

ELEPHANT'S URINE, according to Brandes (Arch. Pharm. xviii. 64), contains hippuric acid and urea, together with alkaline and earthy phosphates and carbonates. Purree or Indian yellow is said to be formed from elephant's urine.

ELUYARITE. A name sometimes applied to the allophane of Frieddorf, near Bonn.

ELIQUATION. An operation by which a more fusible substance is separated from another which is less fusible, namely, by the application of a degree of heat sufficient to melt the former, but not the latter. (See COPPER, p. 32.)

ELIASITE. A mineral consisting of hydrated uranic oxide, mixed with several foreign substances, but forming, according to W. Haidinger, a distinct species. It occurs in the Elias mine, near Joachimsthal, in Bohemia, in flattened pieces of a dark reddish-brown colour, translucent on the edges, and with a waxy lustre. It is brittle, has a specific gravity = 4.129, and hardness = 3.5. According to Ragsky's analysis (Kenngott's *Uebersicht*, 1852, p. 81), it contains 61.38 per cent. U^2O^3 , 10.68 H^2O , 1.17 Al^2O^3 , 6.63 Fe^2O^3 , 1.09 FeO , 3.09 CaO , 2.20 MgO , 4.62 PbO , 5.13 SiO^2 , 2.62 CO^2 , 0.84 P^2O^5 , and a trace of arsenic. The carbonic acid is perhaps combined with the lime and magnesia, making up 5.7 per cent.

ELLAGIC ACID. *Bezoardic acid.*— $C^{14}H^4O^8 = (C^{14}H^4O^8)_{H^2}^2 O^2$. In the crystallised state, $C^{14}H^4O^8.2H^2O$. (Chevreul [1815], *Ann. Ch. Phys.* [2] ix. 629. Braconnot, *ibid.* 187. Pelouze, *ibid.* liv. 367. Taylor, *Phil. Mag.* [3] xxiv. 354. Lipowitz, *Simon's Beiträge zur. physiol. u. pathol. Chemie.* i. 464. Wöhler and Merklein, *Ann. Ch. Pharm.* lv. 129.)

Ellagic acid exists as a constituent of certain animal concretions; it is also a product of the decomposition of gallic acid. According to Chevreul, when a solution of gall-nuts is exposed to the air, a grey powder is deposited. This is exhausted by boiling water, which extracts gallic acid; the residue is treated with potash, and the ellagic acid thereby dissolved, is precipitated by a mineral acid.

The acid is contained in largest quantities in certain animal concretions called oriental bezoars. They are found of different sizes, from that of a bean to that of an egg.

To obtain the acid, the bezoars are dissolved in strong caustic potash, care being taken not to heat the mixture, and to prevent access of air as much as possible. As soon as the whole is dissolved, a current of carbonic acid is passed through the clear liquid. In this way, ellagate of potassium is precipitated as a whitish powder. It is filtered, washed, and pressed, recrystallised from boiling water, and the acid is separated by throwing the solution into concentrated hydrochloric acid.

Pure ellagic acid is a light, pale yellow, tasteless powder, seen under the microscope to consist of transparent prisms. At an elevated temperature, it decomposes without melting, and the carbonised mass is covered with crystals. It is insoluble in *water*, but dissolves in *alcohol* to a pale yellow liquid, having a slight acid reaction. It gives off 2 at. of water, at 100° C.

Sulphuric acid dissolves ellagic acid without alteration; water precipitates it unchanged. *Nitric acid* converts it into oxalic acid. *Iodic acid* converts it into a peculiar acid, with rapid evolution of carbonic acid, and separation of iodine. A neutral aqueous solution of *ferrie chloride* is coloured by ellagic acid, greenish at first, but ultimately becomes bluish-black and opaque, like ink, the solution then containing ferroso-ferrie salts.

The ellagates are little known; many of them appear to be basic salts.

Potassium-salt. $C^{14}H^4K^2O^8$. A light powder, consisting of microscopic prisms. Another salt is obtained as grey powder, consisting of microscopic crystals, by digesting ellagate of potassium in alcoholic potash. It appears to be a basic salt $C^{14}H^4K^2O^8$. KHO.

A solution of ellagic acid in moderately strong potash exposed to the air, gradually changes colour, and deposits dull-black crystals. Wöhler and Merklein call this body *glaucomelanate of potassium*. When it is boiled with water, ellagate of potassium is reproduced. The composition of the salt is represented to be $C^{12}H^4K^2O^7$, which appears improbable, from the fact of the regeneration of ellagic acid by water. Besides glaucomelanate, the solution contains carbonate, oxalate, and another soluble potassium-salt.

Ellagate of Sodium, $C^{14}H^4Na^2O^8$, is a pale yellow crystalline powder, less soluble than the potassium salt.

Barium-salt. $2C^{14}H^4Ba^2O^8.Ba^2H^2O^2$. Insoluble lemon-yellow compound.

Lead-salt. $C^{14}H^4Pb^2O^8 + Pb^2O$. Amorphous yellow precipitate, which by drying becomes olive green. E. A.

ELUTRIATION. The separation of the lighter from the heavier particles of a pulverulent mixture by washing.

EMBOLITE. A chloro-bromide of silver, $Ag^2Br^2Cl^2$, found abundantly in Chile, also at Eulalia in Chihuahua, Mexico, and at Colula, Honduras. It occurs crystallised in cubes and cubo-octahedrons; also massive. Specific gravity 5.31–5.43 (Domeyko), 5.53 (Yorke), 5.81 (Breithaupt). Hardness = 1–1.5. It is perfectly malleable; has a resinous and somewhat adamantine lustre, and varies in colour from asparagus-green to pistachio, olive, and greyish-green. Plattner (*Pogg. Ann.* lxxvii. 134) found in it 66.86 per cent. silver, 20.09 bromine, and 13.05 chlorine, the

formula requiring 67.0 Ag, 19.8 Br, and 13.2 Cl. Domeyko (*Elementos de Mineralogía*, 1845, p. 203) found 51.0 and 52.8 per cent. AgCl; 49.0 and 47.2 AgBr. Yorke (Chem. Soc. Qu. J. iv. 2) found 53.2 AgCl and 46.8 AgBr.

EMBRITHITE. Breithaupt's name for a sulphantimonite of lead from Nertschinsk, of specific gravity 6.3, containing 53.3 per cent. lead, 0.8 copper, 0.04 silver; probably identical with Boulangerite.

EMERALD. The bright green transparent variety of beryl (i. 581), much prized as a gem. The colour is usually attributed to oxide of chromium, of which Vauquelin found 3.50, and Klaproth 6.30 per cent. in emeralds from Santa Fe de Bogota. Lewy, however (Ann. Ch. Phys. [3] liii. 3), found that an emerald from the same locality contained only a trace of chromic oxide, and was rendered quite colourless by ignition. Hence he attributes the green colour to organic matter, which, according to his analysis, exists in the mineral to the amount of 0.12 per cent., going off at a red heat, together with 1.66 per cent. water. According to Hofmeister, on the other hand (J. pr. Chem. lxxvi. 1), emeralds (from the Pinzgau) retain their colour after ignition. The analyses of the (ignited) emerald by Lewy and Hofmeister are as follows:—

SiO ₂	Al ₂ O ₃	GIO	Cr ₂ O ₃	Fe ₂ O ₃	CaO	MgO	Na ₂ O	
67.85	17.95	12.40	trace	.	.	0.90	0.70	= 99.80. Lewy.
66.22	16.26	12.79	.	1.63	0.78	0.83	.	= 98.61. Hofmeister.

EMERALD NICKEL. A native hydrocarbonate of nickel. (See CARBONATES, i. 789.)

EMERALDINE, or *Aniline-green*. See DYEING (p. 358).

EMERY. The opaque crystallo-granular variety of corundum (p. 86), used for grinding, cutting, and polishing glass, metals, enamels, and other hard substances. (See *Uri's Dictionary of Arts, Manufactures, and Mines*, i. 121.)

EMERYLITE. Syn. with MARGARITE.

EMETINE. An alkaloid which forms the active principle of ipecacuanha root. It was discovered in 1807 by Pelletier and Magendie (Ann. Ch. Phys. [2] iv. 172) and further examined by Buchner (Repert. Pharm. vii. 289), and by Dumas and Pelletier (Ann. Ch. Phys. [2] xxiv. 180), who give the following process for obtaining it:—

The powder of ipecacuanha is digested in water with calcined magnesia; the deposit is thrown on a filter, washed carefully with very cold water, and dried; and the emetine is then taken up by alcohol. It may be afterwards combined with an acid, and the salt may be purified with animal charcoal. When the emetine is once more thrown down by magnesia, alcohol redissolves it in a colourless state.

Emetine thus obtained is yellowish-white, pulverulent, and is but slightly coloured by exposure to the air. It is little soluble in cold water, and somewhat more so in hot water. It melts about 50° C. It is very soluble in alcohol, but not in ether or in oils. Its constituents are, carbon 64.57 p. c., nitrogen 4.30, hydrogen 7.77, oxygen 23.36 (Dumas and Pelletier). Emetine is highly alkaline, though acids saturated with it do not afford crystallisable compounds. Gallic acid and nut-galls form with it very abundant white precipitates. Basic acetate of lead has no effect on it.

Strong nitric acid transforms emetine into a yellow resinous substance, and oxalic acid.

Emetine taken internally excites vomiting, 3 milligrammes being sufficient to produce this effect.

The *oxalate* and *tartrate* of emetine are very soluble in water. The *chloromercurate* and *chloroplatinate* are very sparingly soluble. The *gallotannate* is a white flocculent precipitate, soluble in alkalis; it is neither emetic nor poisonous.

EMMONITE. Syn. of STRONTIANITE, or native CARBONATE OF STRONTIUM (i. 797).

EMODIN. C¹⁶H¹⁰O¹³.—A constituent of rhubarb root, discovered by Warren De la Rue and Hugo Müller (Chem. Soc. Qu. J. x. 304). When crude chrysophanic acid, obtained as described at p. 959, vol. i., by treating the root with benzene, is redissolved in hot benzene, emodin remains behind, in the form of a reddish-yellow substance, an additional quantity separating from the solution as it cools. It may be purified by crystallisation from hot glacial acetic acid, and afterwards from boiling alcohol.

Emodin thus prepared crystallises in long, brittle, concentrically-grouped monoclinic prisms of a deep orange-red colour. It melts above 250° C., a small portion volatilising at the same time undecomposed. Chemically it resembles chrysophanic acid, but is much more soluble in alcohol, glacial acetic acid, and amylic alcohol, less soluble in benzene. With caustic alkalis, it behaves like chrysophanic acid.

Emodin gives by combustion 66·63 per cent. carbon and 4·10 hydrogen, agreeing nearly with the empirical formula $C^{66}H^{10}O^{13}$, or $C^{66}H^{10}O^{13}$ (66·66 C. and 4·18 H.).

EMPLECTITE. Cu^2BiS^2 or $CuBiS^2$.—A mineral from Tannenbaum in the Erzgebirg, containing 18·83 per cent. sulphur, 62·6 bismuth, and 18·72 copper; forming needle-shaped rhombic crystals of light grey to tin-white colour and metallic lustre. (Schneider, Pogg. Ann. xc. 166.—Dauber, *ibid.* xcii. 241.—Kenngott, *Uebersicht*, 1853, p. 125.)

EMPYREUMA. The peculiar smell produced by distilling vegetable or animal substances in closed vessels, or by burning such substances with imperfect access of air.

EMULSIC ACID. An acid said to be formed by boiling emulsin with alkalis, ammonia being given off at the same time. (Thomson and Richardson.)

EMULSIN. *Synaptase*. (Robiquet, J. Pharm. xxiv. 326.—Thomson and Richardson, Ann. Ch. Pharm. xxix. 180.—Ortloff, Arch. Pharm. xlviii. 16.—Bull, Ann. Ch. Pharm. lxi. 145.)—A neutral substance contained in sweet and in bitter almonds, and possessing the power of acting as a ferment on the amygdalin of the latter in presence of water, converting it into hydride of benzoyl, hydrocyanic acid, and glucose (i. 292).

To obtain emulsin, sweet almond paste, well freed from fixed oil, is macerated in three times its weight of pure water, the mass is pressed, and the emulsion thus obtained is left to itself at 20° or 25° C. After the lapse of a day, the emulsion is found to have separated into two layers, the upper of which is coagulated, and looks like cream, while the lower is watery and transparent. After two or three days, this watery liquid no longer gives a precipitate of casein with acetic acid, but it forms with alcohol a precipitate perfectly soluble in water. This last precipitate consists of emulsin; after being washed with absolute alcohol and dried in vacuo over sulphuric acid, it forms a white, opaque, friable mass, soluble in water. It is difficult, however, to obtain emulsin quite free from colouring matter, the process succeeding only when performed on small quantities of material.

The property of being precipitated by alcohol does not belong to emulsin itself, but is due to the phosphates which it holds in solution, and from which it cannot be separated. Emulsin possesses a decided acid reaction, and it is this acidity which enables an emulsion of almonds to hold the phosphates in solution.

An aqueous solution of emulsin when boiled deposits a white granular precipitate, which on cooling redissolves completely in the supernatant liquid. This precipitate contains a considerable quantity of inorganic matter, consisting of phosphate of magnesium with a little phosphate of calcium; the filtered liquid contains the products of decomposition of the emulsin, which, strictly speaking, does not coagulate by heat, but is completely decomposed. (Bull.)

Emulsin completely loses the power of transforming amygdalin into hydride of benzoyl, when its aqueous solution is boiled; but it retains this power when heated to 100° C. in the dry state, even for several hours.

The aqueous solution of emulsin is completely precipitated by acetate of lead; the filtrate no longer acts on amygdalin, but the lead-precipitate effects the complete transformation of this substance into hydride of benzoyl.

The solution of emulsin exposed to the air for several days at common temperatures putrefies, giving off gas and becoming turbid; nevertheless it retains for a long time the power of acting on amygdalin.

Lactic acid is found among the products of the decomposition of emulsin.

The analysis of emulsin gives the following results:—

	Thomson and Richardson.		Bull.		
Carbon	48·78	48·40	43·69	43·74	42·75
Hydrogen	7·79	7·68	6·96	7·33	7·37
Nitrogen	18·81	18·64	11·64	11·40	11·52
Sulphur			1·25		
Oxygen	24·62	25·28	36·56	37·53	38·36
	100·00	100·00	100·00	100·00	100·00

Thomson and Richardson do not mention the existence of sulphur or of mineral matter. Bull found quantities of ash varying from 22 to 35·8 per cent.; in the three analyses above given the ashes are deducted.

EMULSION. An imperfect combination of oil and water, by the intervention of some other substance capable of combining with both these liquids. Such substances are either saccharine or mucilaginous. U.

EMYDIN. A substance contained in the yolk of turtle's eggs. It forms white, hard, transparent grains, very soluble in dilute potash; swells up in acetic acid without dissolving; dissolves in boiling hydrochloric acid without violet coloration. Contains 49·4 per cent. carbon, 7·4 hydrogen, and 14·6 nitrogen, together with phosphorus and oxygen. It approaches in composition to the ichthin of the eggs of certain fishes. It yields about 1 per cent. of ash. (Valenciennes and Frémy.)

ENALLOCHROME. Syn. with *Æsculin*.

ENAMEL. There are two kinds of enamel, the opaque, and the transparent. Transparent enamels are usually rendered opaque by adding putty, or the white oxide of tin to them. The basis of all enamels is a perfectly transparent and fusible glass. The oxide of tin renders this of a beautiful white, the perfection of which is greater when a small quantity of manganese is likewise added. If the oxide of tin be not sufficient to destroy the transparency of the mixture, it produces a semi-opaque glass, resembling opal.

Yellow enamel is formed by the addition of oxide of lead, or of antimony. Kunckel likewise affirms, that a beautiful yellow may be obtained from silver.

Red enamel is afforded by the oxide of gold, and also by that of iron. The former is the most beautiful, and stands the fire very well, which the latter does not.

Red oxide of copper likewise yields a very fine red colour, but it is somewhat difficult to manage, on account of its tendency to pass into the higher oxide.

Black oxide of copper affords a green; manganese, a violet; cobalt, a blue; and iron, a very fine black. A mixture of these different enamels produces great variety of intermediate colours, according to their nature and proportion. In this branch of the art, the coloured enamels are sometimes mixed with each other, and sometimes the oxides are mixed before they are added to the vitreous bases.

In the Transactions of the Society of Arts for 1817, a valuable list of receipts for enamel colours is given by Mr. R. Wynn, for the communication of which a premium was awarded. The following are Mr. Wynn's fluxes:—

Parts.		Parts.	
No. 1. Red lead	8	No. 3. Red lead	1
Calcined borax	1½	Flint glass	3
Flint powder	2	No. 4. Red lead	9½
Flint glass	6	Borax not calcined	5½
No. 2. Flint glass	10	Flint glass	8
White arsenic	1	No. 5. Flint glass	6
Nitro	1	Flux, No. 2	4
		Red lead	8

After the fluxes have been melted, they should be poured on a flag-stone wetted with a sponge, or into a large pan of clean water, then dried, and finely pounded in a biscuit-ware mortar for use.

Yellow enamel:—Red lead 8 pts.; oxide of antimony 4 pts.; white oxide of tin 1 pt.

Mix the ingredients well in a biscuit-ware mortar, and, having put them on a piece of Dutch tile in the muffle, make it gradually red-hot, and suffer it to cool. Take of this mixture 1, of flux No. 4, 1½; grind them in water for use. By varying the proportions of red lead and antimony, different shades of colour may be obtained.

Orange enamel:—Red lead 12 pts.; red sulphate of iron 1 pt.; oxide of antimony 4 pts.; flint powder 3 pts.

After calcining these without melting, fuse 1 part of the compound with 2½ of flux.

Dark red enamel:—

	Parts.
Sulphate of iron calcined dark	1
Flux No. 4, 6 pts. } of this	3
Coleothar 1 pt. }	

Light red enamel:—

	Parts.
Red sulphate of iron	1
Flux No. 1.	3
White lead	1½

Brown enamel:—Manganese 2½ pts.; red lead 8½ pts.; flint powder 4 pts.

See Transactions of the Society, or Phil. Mag. vol. li. Mr. Tilloch observes, that borax should be used sparingly, as it causes efflorescence and decay of the enamel colours. For further details, see *Ure's Dictionary of Arts, Manufactures, and Mines*, ii. 125.

U.

ENARGITE. A sulpharsenate of copper originally found at Morococha, in the Cordilleras of Peru, where it is largely worked as a copper ore, and occurs in large masses, occasionally also in small drusy crystals imbedded in crystalline limestone, together with Tennantite (Breithaupt, Pogg. Ann. lxxx. 383). It is also found in Brewer's mine, Chesterfield county, South Carolina (Genth, Sill. Am. J. [2] xxiii. 420), in the

mines near Santa Anna in New Granada (W. J. Taylor, *ibid.* xxvi. 340), and in the Cordilleras of Chile (Field, Chem. Soc. Qu. J. xii. 9; Sill. Am. J. [2] xxvii. 52. 387.) The mineral from this last locality was originally regarded by Field as a distinct species, and named by him *Guayacanite*.

The mineral from Morococha exhibits the following properties:—The crystals are trimetric, with the faces ∞P . ∞P . $\infty P\infty$. $\infty P\infty$. Angle ∞P : ∞P = $96^\circ 11'$. Cleavage perfect parallel to ∞P , distinct parallel to $\infty P\infty$ and $\infty P\infty$, indistinct parallel to ∞P . Specific gravity = 4.43 to 4.45 (Breithaupt); 4.362 (Kerngott). Hardness = 3. Lustre metallic. Colour iron-black. Streak black. Brittle. Fracture uneven. (Breithaupt.)

Decrepitates when heated, and in a tube yields a sublimate of sulphur and sulphide of arsenic; melts easily before the blowpipe, giving off arsenic-vapours and forming a white deposit on the charcoal; the roasted assay exhibits the reactions of copper. Soluble in nitro-muriatic acid. In the state of powder it is partly decomposed by potash-ley, and acids added to the solution throw down sulphide of arsenic containing antimony. (Plattner, Pogg. Ann. lxxx. 383.)

Analyses. a. From Morococha (Plattner) *loc. cit.*—b. From South Carolina (Genth).—c. From New Granada: colour and streak greyish black (Taylor).—d. From Chile: specific gravity = 4.39; hardness = 3.5 to 4 (Field).

	S.	As.	Sb.	Cu.	Fe.	Zn.	Ag.
a.	32.22	17.69	1.61	47.20	0.67	0.23	0.72 = 99.45
b.	33.78	15.63	.	50.59	.	.	. = 100.00
c.	34.50	16.31	1.29	46.62	0.27	.	. = 98.99
d.	31.82	19.14	.	48.50	trace	.	trace = 99.46

These analyses agree nearly with the formula of a tricuprous sulpharsenate, Cu^3AsS^4 (calc. 32.53 sulphur, 18.82 arsenic, and 48.60 copper).

ENCELADITE. *Warwickite*.—An ore of titanium found in the dolomite of Amity (New York), together with spinelle, titaniferous iron, and chondrodite. Externally it resembles warwickite. Oblique rhombic prisms (? monoclinic) having a blue-black or brown-black colour, with bluish streak. Lustre varying from resinous to metallic. Hardness = 3 to 4. Specific gravity 3.188. Heated in a tube, it gives off water and becomes lighter. When heated in the air, it assumes a brick-red colour. It is infusible; is but little attacked by hydrochloric acid; dissolves easily in warm sulphuric acid. According to T. S. Hunt (Sill. Am. J. [2] ii. 30; also xi. 352), it contains—

TiO^2	SiO^2	Al^2O^3	FeO	MgO	CaO	H^2O
28.20	18.50	13.84	10.59	22.20	1.30	7.35 = 101.98,

whence Rammelsberg (*Mineralchemie*, p. 889) deduces the formula,

which by substituting al for $\frac{1}{3}$ Al, may be reduced to $2\text{M}'(\text{Si}; \text{Ti})\text{O}^4 + al''(\text{Si}; \text{Ti})\text{O}^4 + 2\text{aq.}$

Hunt and Dana regard the mineral as warwickite in a state of transformation. According to J. L. Smith (Sill. Am. J. [2] xvi. 293), it is a borotitanate of magnesium and iron, containing about 20 per cent. of boric anhydride.

ENDELLIONITE. Syn. with BOURNONITE.

ENDIVE. *Cichorium Endivia*.—This plant contains, according to Richardson (Ann. Ch. Pharm. lxxvii. 377), 92.5 per cent. water, 6.1 organic substance, and 1.4 ash. The ash contains in 100 pts. 37.9 K^2O , 12.1 Na^2O , 12.0 CaO , 1.8 MgO , 5.2 SO^2 , 24.6 SiO^2 , and 6.4 phosphate of iron.

ENDOMADERM. Syn. with CHITIN.

ENDOPHACIN. The name given by Valenciennes and Frémy to the inner albuminous constituent of the crystalline lens of the eyes of mammalia.

ENDOSMOSE. See OSMOSE.

ENGELHARDITE. See ZIRCON.

ENSTATITE. A variety of augite, Mg^2SiO^6 , found, together with pseudophite, on the Zdjär mountain near the Alosthal, in Moravia. Forms firmly imbedded linear crystals, often transversely broken; they belong to the monoclinic system, exhibiting the faces [$\infty P\infty$] and $\infty P\infty$ (the end-faces not developed), with distinct cleavage parallel to these faces and to those of a prism of nearly 87° . It is greyish-white, sometimes yellowish or greenish; dull on the faces of the crystal, but with a rather strong glassy and nacreous lustre on the cleavage-faces; semi-transparent or

translucent on the edges. Streak white. Brittle. Hardness = 5.5. Specific gravity = 3.10 to 3.13. Nearly infusible before the blowpipe, but becomes white and enamel-like on the edges: does not give any blue colouring with cobalt; insoluble in hydrochloric acid. Contains:—

SiO ²	Al ² O ³	FeO	MgO	H ² O
56.91	2.50	2.76	55.44	1.92 = 99.53
57.28	.	5.00	36.25	. = 98.53

Of the water, 0.41 per cent. goes off at 100° C.; the rest at a red heat. (Kengott, Wien. Akad. Ber. xvi. 162.)

EOIDIN. C²H⁴O³ (?). A red colouring matter obtained from asparagus berries. (Kerndt, *Jahresber. f. Chem.* 849, 457.)

EPHESITE. A micaceous mineral, found, together with corundum, on the magnetic iron ore near Ephesus. It is laminar, easily separable in the direction of the laminae, white, nacreous, resembling white disthene. Specific gravity 3.15 to 3.20. Scratches glass easily. Before the blowpipe it becomes dull, but does not melt. Contains:—

SiO ²	Al ² O ³	CaO	FeO	Na ² O	H ² O	Total.
31.54	57.89	1.89	1.34	.	3.12	.
0.04	56.45	2.11	1.00	4.41	3.06	97.07

whence may be deduced the formula 2M²O.3SiO² + 2(2Al²O³.SiO²). (L. Smith *Ann Min.* [4] xviii. 294.)

EPIBROMHYDRIN. See BROMHYDRINS (i. 667).

EPICHLORHYDRIN. See CHLORHYDRINS (i. 894).

EPICHLORITE. A mineral discovered by Zincken (Pogg. *Ann.* lxxvii. 237) near Neustadt in the Harz, where it occurs in a rock resembling serpentine, in fragments of radiating structure. It easily separates into prismatic forms, has a strong fatty lustre, dark leek-green colour, white streak inclining to greenish, and in thin slips is translucent, with bottle-green colour. Hardness = 2 to 2.5. Specific gravity = 2.76. Gives off water when heated in a tube, and melts with difficulty before the blowpipe. It is but imperfectly decomposed by hydrochloric acid. Contains:—

SiO ²	Al ² O ³	Fe ² O ³	FeO	MgO	CaO	H ² O
40.88	10.96	8.72	8.96	20.00	0.68	10.18

whence the formula 2(4M²O.3SiO²) + 2M²O³.3SiO² + 8 aq. (Rammelsberg, *Mineralchemie*, p. 539.)

EPIDERMIS OF ANIMALS. See HORNY TISSUE.

EPIDERMIS OF PLANTS. The skin of plants consists of one or more layers of compressed cellular tissue, constituting the true skin or epidermis, and of an external very thin layer of organic mucus, called the cuticle. The epidermis covers all parts of the plant which are exposed to the air, except the stigma, but is not found on plants habitually living under water. The cuticle covers every part except the openings through the stomates. According to Fremy, the cellular substance of the epidermis consists of a peculiar substance, which he calls cutin, differing from ordinary cellulose in not being soluble in an ammoniacal solution of copper. Payen, on the other hand, regards the epidermis as consisting of ordinary cellulose impregnated with fats, nitrogenous bodies, and inorganic salts. (See CUTIN, p. 186.)

Mulder analysed the cuticle of *Agave Americana*, separated from the plant by maceration in sulphuric acid. After exhaustion with alcohol, ether, and water, and drying at 130° C. it left 4 per cent. of ash: the organic part contained 52.90 per cent. carbon, 6.79 hydrogen, and 40.31 oxygen and nitrogen. The substance was not, however, quite freed from epidermis cells, so that the result must be regarded as only approximate.

EPIDERMOS. See HORNY TISSUE.

EPIDESMINE. Syn. with EPISTILBITE.

EPIDICHLORHYDRIN. See CHLORHYDRINS (i. 894).

EPIDOTE. Zoisite (in part). Pistacite. Thallite. Withamite. Akanticon. Sorza. Delphinite. Arendalite. Bucklandite. Thulite. Puschkinite. Achmantite. This mineral species, under the general formula 3(2M²O.3SiO²) + 2(2R²O³.3SiO²) = 3(M²O³.SiO²) + 2R².Si²O¹², or 3MO².SiO² + 2(R²O³.SiO²), includes three sub-species, viz. 1. *Lime epidote* or *Zoisite* (in part) in which the bivalent metal M is almost wholly calcium, and the trivalent metal R is chiefly aluminium; this sub-species includes

EPIDOTE.

Thulite—2. *Lime and iron Epidote, Pistacite*, or *Epidote* proper, in which the calcium is sometimes partly replaced by iron (ferrosium), and the aluminium in great part by ferrium: this includes *Bucklandite* and *Puschkinite*.—3. *Manganesian epidote*, in which the sesquiatomic metal is partly manganese (manganicum). Besides these, must be mentioned *Allanite*, which is a true cerium epidote, and *Withamite*.

The crystals of epidote are monoclinic, $a : b : c = 0.5509 : 1 : 0.9924$. Inclination of principal axis to clinodiagonal = $61^{\circ} 41'$. Ordinary combination $\infty P_{\infty} + P_{\infty} - P_{\infty} [P_{\infty}]$. Cleavage most distinct parallel to $+P_{\infty}$, less distinct parallel to ∞P_{∞} . Twin crystals occur, having their face of combination parallel to ∞P_{∞} . The crystals are always prismatic elongated in the direction of the orthodiagonal, (Kopp, *Krystallographie*, p. 309.) Epidote likewise occurs columnar and granular, in particles of various sizes, sometimes impalpable.

Hardness = 6–7. Specific gravity = 3.25–3.5 (of zoisite, 3.2 to 3.45; of pistacite 3.35 to 3.5, of manganesian epidote 3.404; of withamite 3.1 to 3.34). Colour of zoisite grey or brown to white of pistacite, yellowish-green or pistachio-green, passing to olive and leek-green; of puschkinite, green, yellow, and red; of bucklandite, black; of manganesian epidote, reddish-brown, reddish, black or dark violet-blue; of withamite, bright red; of thulite, rose or peach-blossom red. Streak uncoloured, greyish or reddish. Subtransparent to opaque. Fracture uneven. Brittle.

Before the blowpipe, epidote melts on the edges and swells, but does not easily liquefy, the varieties containing most iron being the most fusible; borax-glass coloured by iron. The manganese variety fuses readily with intumescence, and gives with borax, an amethystine glass in the outer flame. Most specimens of epidote afford minute globule of tin before the blowpipe. The specific gravity changes with heating. Epidote is but partially decomposed by acids, except after strong heating.

Analyses.—1. Brush (Sill. Am. J. [2] xxvi. 69).—2. Rammelsberg (*Mineralchemie* p. 750).—3. Hermann (J. pr. Chem. xliii. 35).—4. Gmelin (Pogg. Ann. xix. 539).—5. Rammelsberg (*loc. cit.* 753).—6. For other analyses see Rammelsberg, pp. 750–760; Dana, ii. 207.

The general formula $3(M'')^2SiO_4 + 2(R')^{10}Si_2O_{12}$, deduced from these analyses, is composed of two terms, each of which represents an orthosilicate, and may be exhibited more plainly in that form by reducing the sesquioxides to protoxides, that is, by substituting in the second term of the formula, $m = \frac{1}{2}R$, which reduces that term to $3m'SiO_4$, and brings the entire formula to the general type $M'SiO_4$.

Epidotes occur in numerous localities. Fine crystals are found at Arendal in Norway; hence the name *Arendalite*. Other localities are the Ural, Piedmont, the Fichtelgebirg, Rothlaue in the Canton Berne, Faltigl in the Tyrol, Grossar in Austria, Bourg d'Oisans in Dauphny, Glencoe, the mainland of Shetland, the Island of Icolmkill, &c. Epidote is of very frequent occurrence in primitive rocks, especially in granite, gneiss, and syenite. Iron epidote is, like garnet, a very frequent concomitant.

tant of iron ores, especially of magnetic oxide; the numerous and extensive veins of this ore in Norway and Sweden are almost universally accompanied by these two minerals, especially in the neighbourhood of Arendal, where they almost displace the gneiss, which usually forms the matrix of the ore. The frequent occurrence of epidote and garnet in the same locality is easily explained by comparing the composition of the two minerals, garnet being $3M'SiO^4 + R^2Si^2O^{12}$, and epidote $3M'SiO^4 + 2R^2Si^2O^{12}$; we may therefore suppose that in the formation of the older rocks, when ferroso-ferric oxide came in contact with silica, alumina and lime, epidote (especially pistacite) and garnet were produced, the former when the sesquioxides were present in greatest abundance, the latter when the protoxides predominated. (Scheerer, *Handw. d. Chem.* 1^{te} Aufl. ii. 954.)

EPIGLAUBITE. A crystalline substance found in hardened guano, containing lime, phosphoric acid, and water. (Shepard, *J. pr. Chem.* lxx. 212.)

EPSOMITE. EPSOM-SALT. Sulphate of magnesium. (See SULPHATES.)

EPISTILBITE. A mineral belonging to the zeolite family, and closely allied to stilbite. Forms rhombic prisms with the acute lateral edges truncated. Fracture uneven. Hardness = 3·5 to 4. Specific gravity 2·249 to 2·263. White with glassy lustre, nacreous on the cleavage-faces. Dissolves in hydrochloric acid without gelatinising. Occurs in the almond-stone of Iceland and the Faroe Islands, and in the dolerite of Ireland. Gives by analysis 68·6 per cent. silica, 17·52 alumina, 7·66 lime, 1·78 soda, and 14·48 water: whence the formula, $2CaO \cdot 2Al^2O^3 \cdot 6SiO^2 + 10H^2O = 2CaO \cdot 3SiO^2 + 2Al^2O^3 \cdot 3SiO^2 + 10H^2O$. (G. Rose, *Gm. Handb.*, iii. 413; also Waltershausen, *Jahrsber. f. Chem.*, 1853, 818; 1856, 863.)

EQUATIONS, CHEMICAL. See FORMULÆ.

EQUISETIC ACID. Syn. with ACONITIC ACID.

EQUISETUM. *Horse-tail.*—A genus of cryptogamous plants distinguished chemically by the large amount of inorganic constituents, especially silica, contained in them. The silica partly separates out on the external surface of the stem, where it hardens, forming numerous small concretions on the elevated striæ with which the stem is marked, and rendering it available for polishing substances of no great hardness, such as wood, ivory, horn, &c.

Braconnot found in 100 pts. of dried *Equisetum fluviatile*, 23·61 pts.; of *E. hiemale*, 11·81 pts.; of *E. arvense*, 13·84 pts.; and of *E. limosum*, 15·0 pts. ash consisting of:

	<i>E. fluviat.</i>	<i>E. hiem.</i>	<i>E. arvens.</i>	<i>E. limosum.</i>
Potash, partly as silicate	0·72	0·30	traces	
Sulphate of potassium	2·83	0·37	2·20	
Chloride of potassium	2·72	0·22	1·20	
Carbonate of calcium	1·46	0·93	5·51	1·50
Phosphate of calcium (containing iron) 0·65	0·80	undeterm.	undeterm.	
Sulphate of calcium	3·39			3·30
Magnesia	0·66		0·46	0·30
Silica	12·00	8·75	6·38	6·50
	23·61	11·81	13·24	15·00

Witting (*J. pr. Chem.* lxxix. 149) found in 100 pts. of *E. Telmateja* (a), dried at 100° C., 71·43 pts. organic substance, and 28·57 ash; in 100 pts. of the fresh plant of *E. arvense* (b), 78·45 water, 17·48 organic substance, and 4·07 ash. The ash contained in 100 pts.:

SiO ²	CO ²	SO ³	P ² O ⁵	F ² O ³	MnO	MgO	MgCO ³	CaO	CaCO ³	Na ² O	K ² O	NaCl	KCl
66·15	0·49	2·65	1·24	1·33	0·12	0·62	2·24	2·11	10·67	0·003	1·23	1·12	9·92
11·40	0·98	9·98	2·75	0·70	0·02	2·81		17·01		0·03	11·32	0·44	12·09

E. arvense, *E. hiemale*, and especially *E. palustre*, are said to be very injurious to cattle, whereas *E. fluviatile* forms a harmless and nutritious fodder. The various species of equisetum contain small quantities of equisetie (aconitic) acid in the form of alum- or potassium-salt. Braconnot (*Ann. Ch. Phys.* [2] xxxix. 5) found in *E. limosum* a yellow colouring matter, which he designated as *flavequisetin* (q. v.)

EQUIVALENTS. No two substances in nature are absolutely equivalent in all respects, scarcely perhaps in any respect; but those are most nearly equivalent which manifest the greatest affinity to one another, either in regard to their general functions, or to some particular function taken as the criterion of resemblance. Now the prime indication of this special equivalency between two or more bodies is well known

to consist in their capability of being freely exchanged for one another without loss or detriment; and this holds good no less in the science of chemistry than in the transactions of ordinary life, the idea of exchange, that is, of direct or indirect substitution, forming the basis of the modern doctrine of chemical equivalents.

We find in a great number of compounds that 1 pt. of hydrogen may be replaced directly by 23 pts. of sodium, or by 39 pts. of potassium, or by 108 pts. of silver, &c.; and as the resulting compounds manifest a marked mutual resemblance of constitution and properties, and a general resemblance to the hydrogenised body from which they were obtained, we say that the atoms of sodium, potassium, and silver are equivalent to one another, and also equivalent to an atom of hydrogen. Similarly, we find in a great number of compounds, both organic and inorganic, that one or more atoms of hydrogen may be replaced by an equal number of atoms of chlorine, or bromine, or iodine; and as the resulting compounds correspond closely with one another, and present a marked similitude to the original hydrogenised body, we say that the atoms of chlorine, bromine, and iodine are equivalent to one another, and also equivalent to an atom of hydrogen; whence it follows that the atoms of chlorine, bromine, iodine, hydrogen, potassium, sodium, and silver are mutually equivalent. We are acquainted with numerous bodies of comparable constitution, containing respectively an atom of chlorine or an atom of metal; thus:

HHO .	Water	Cl ² S .	Chlorine-sulphide
ClClO .	Hypochlorous anhydride	H ² S .	Sulphydic acid
HClO .	Hypochlorous acid	Na ² S .	Sodium-sulphide
KClO .	Hypochlorite of potassium	Cl ² S ² .	Chlorine-disulphide
KHO .	Hydrate of potassium	H ² S ² .	Hydrogen-disulphide
KKO .	Oxide of potassium	Na ² S ² .	Sodium-disulphide
C ² H ² Cl .	Ethyl-chloride	Cl ² Sb .	Chlorostibine
C ² H ² H .	Ethyl-hydride	H ² Sb .	Stibamine
C ² H ² Na .	Sodium-ethide	Ag ² Sb .	Stibio-silver

That we are not acquainted with a very great number of such instances of replacement, appears to arise from the circumstance that, in few hydrogenised bodies can the hydrogen be replaced with equal facility by chlorine and by potassium. As a general rule, we find that the facility of replacement by potassium is directly, by chlorine inversely, as the degree of oxidation of the compound under examination, and consequently that the same body does not always afford both chlorine and metal derivatives. Chlorine and potassium are two elements possessing in the highest degree those opposite properties which we denominate chlorous and basylous respectively. They are, however, connected by a great number of intermediate links, and constitute, as it were, the extremities of a very long chain. From the antagonism in properties possessed by chlorous and basylous elements, we find that the correspondence in properties between chlorous and basylous derivatives of the same hydrogenised body is confined within narrow limits; it is, however, well manifested in the phenomena of double decomposition.

We may make a similar comparison between other elements than those which we have as yet considered. Thus in a whole host of most varied bodies, we find that 16 pts., or 1 atomic proportion of oxygen, are replaceable by 32 pts., or 1 atomic proportion of sulphur; and that the comparable oxygen and sulphur compounds are either procurable from one another by an atomic exchange of oxygen for sulphur, or may be obtained by precisely similar reactions from oxygen and sulphur respectively. Just, for instance, as chlorine expels hydrogen from benzene, so does oxygen expel sulphur from stibnite:

Carbon burns in oxygen gas to form the dinoxide CO², and in sulphur-vapour to form the disulphide CS². Again, the analogous bodies, alcohol and mercaptan, are procurable from hydrochloric ether by means of hydrate and sulphydrate of potassium respectively, thus:

In a similar manner we may compare together the elements phosphorus, arsenic, antimony, and bismuth, when we shall find that their respective atoms are mutually interchangeable, and consequently equivalent one to another.

In the different instances of equivalent substitution above referred to, the replacement has been effected by an interchange of atom for atom; but we constantly find in addition, that two, three, or more atoms of one element may be exchanged for one

atom of another. Thus, if we act upon pentachloride and pentabromide of phosphorus with water and sulphydric acid respectively, we have the following reactions:—

In these reactions, as in very many others, we find that two atoms of chlorine and bromine are respectively exchangeable for one atom of oxygen or sulphur. Hence, taking the atom of hydrogen as the unit of equivalency, we say that the atoms of chlorine and bromine have a single, and the atoms of oxygen and sulphur a twofold equivalency. Again, if we take three atoms of hydrochloric acid, H^3Cl^3 , we can either displace the three atoms of hydrogen by three atoms of sodium, to form three atoms of chloride of sodium, Na^3Cl^3 , or we can displace them by one atom of bismuth to form one atom of tri-chloride of bismuth, BiCl^3 ; so that while the atom of sodium has a single, the atom of bismuth has a threefold equivalency, the one atom of bismuth being a representative of three atoms of hydrogen or of sodium. To facilitate comparison, the author of this article proposed, some few years back, that mode of indicating differences in equivalent value which has now come into very general use—namely, by means of one or more dashes placed to the right of the symbols, so as to establish a difference to the eye between the equivalent or substitution values of different atoms, as shown in the following formulae:—

$\text{Ag}^{\text{I}}\text{Cl}^{\text{I}}$. Silver chloride	$\text{Ag}^{\text{I}}\text{PO}^{\text{I}}$. Silver phosphate
$\text{Sn}^{\text{II}}\text{Cl}^{\text{II}}$. Stannous chloride	$\text{H}^{\text{I}}\text{Sn}^{\text{II}}\text{PO}^{\text{I}}$. Stannous phosphate
$\text{Bi}^{\text{III}}\text{Cl}^{\text{III}}$. Bismuth chloride	$\text{Bi}^{\text{III}}\text{PO}^{\text{I}}$. Bismuth phosphate

It is observable that the equivalency of an elementary atom referred to that of hydrogen as unity, may be determined almost equally well by noticing the number of chlorine-, or hydrogen-, or sodium-atoms, with which it can unite, as by noticing the number of chlorine-, or hydrogen-, or sodium-atoms which it can replace. For every combination of an element with chlorine may be looked upon as a substitution-product of chloride of sodium, in which a certain number of sodium-atoms are replaced; and every combination of an element with sodium as a substitution-product of chloride of sodium, in which a certain number of chlorine-atoms are replaced. Trichloride of bismuth, $\text{Bi}^{\text{III}}\text{Cl}^{\text{III}}$ for instance, is derivable from three atoms of chloride of sodium, Na^3Cl^3 , by a displacement of three unequivalent atoms of sodium by one triequivalent atom of bismuth; while sulphide of sodium, $\text{Na}_2\text{S}^{\text{I}}$, is derivable from two atoms of chloride of sodium, Na^2Cl^2 , by an exchange of two unequivalent atoms of chlorine for one diequivalent atom of sulphur, &c. &c.

In modern chemistry, the notion of equivalency is usually extended to that of interchangeable value for hydrogen or for the representatives of hydrogen, as above explained, irrespective of any similarity or dissimilarity in properties between the equivalent bodies. In this broad sense, an atom of oxygen O^{I} is equivalent, not only to an atom of its analogue, sulphur S^{I} , but also to an atom of its heterologue, tin Sn^{I} ; while the atom of antimony, Sb^{III} , is equivalent, not only to the respective atoms of its analogues, arsenic As^{III} and bismuth Bi^{III} , but also to the respective atoms of its heterologues, boron B^{III} , and gold Au^{III} . Again, six atoms of hydrogen 6H^{I} , three atoms of sulphur 3S^{I} , and two atoms of gold 2Au^{III} , constitute equivalent quantities of the three highly dissimilar elements.

This idea of equivalency is widely removed from that of atomicity, and is indeed quite compatible with the notion of fractional proportions. There is no impropriety, for instance, in saying that an atom of hydrogen is equivalent to one-half an atom of tin or sulphur, and to one-third of an atom of bismuth or phosphorus. This mode of expression is associated, moreover, with the use of a special equivalent notation, as distinguished from the atomic notation commonly employed. In this equivalent notation, introduced by Laurent and Gerhardt, the proportions of the different elements which are exchangeable for one atom of hydrogen are represented by the same letters which symbolise their respective atoms, but written in small letters only instead of with capitals, thus:—

HCl	Hydrochloric acid	HCl
NaCl	Sodium-chloride	NaCl
$\text{S}^{\text{I}}\text{Cl}^{\text{I}}$	Sulphur-chloride	$\text{s}^{\text{I}}\text{Cl}^{\text{I}}$
$\text{Sn}^{\text{II}}\text{Cl}^{\text{II}}$	Stannous-chloride	$\text{sta}^{\text{II}}\text{Cl}^{\text{II}}$
$\text{P}^{\text{III}}\text{Cl}^{\text{III}}$	Phosphorous-chloride	$\text{p}^{\text{III}}\text{Cl}^{\text{III}}$
$\text{Bi}^{\text{III}}\text{Cl}^{\text{III}}$	Bismuth-chloride	$\text{bi}^{\text{III}}\text{Cl}^{\text{III}}$
$\text{C}^{\text{IV}}\text{Cl}^{\text{IV}}$	Carbon-chloride	$\text{c}^{\text{IV}}\text{Cl}^{\text{IV}}$
$\text{Si}^{\text{IV}}\text{Cl}^{\text{IV}}$	Silicon-chloride	$\text{si}^{\text{IV}}\text{Cl}^{\text{IV}}$

very commendable, if used merely to represent equivalent quantities, but they cannot be correctly used to represent the atoms of the elements or their smallest indivisible combining proportions; indeed, Gerhardt himself, after he had begun to employ the multiequivalent compound radicles presently to be described, was more and more disposed to regard his symbols as mere expressions of equivalent quantities and not of atomic weights.

The doctrine of equivalency is not by any means confined to elementary bodies, but is applicable to all the varieties of compounds, real or hypothetical, with which chemists are acquainted, and more particularly to those groupings which are denominated compound radicles. Whether or not we admit the independent existence of pre-formed compound radicles, it is indisputable that certain groupings of atoms are capable of being transferred from one combination to another in exchange for an atom of hydrogen, or chlorine, or metal; or in other words, are capable of replacing hydrogen, chlorine, or metal by equivalent substitution. Thus we can transfer the molecular groupings which we denominate cyanogen, CN ; amidogen, NH^2 ; peroxide of hydrogen, HO ; benzoyl, C^7H^3O ; acetyl, C^2H^3O ; ethyl, C^2H^5 ; amyl, C^5H^{11} , &c., from one compound to another, in exchange for one another, or for hydrogen, or its representatives, with a facility by no means inferior to that with which we effect actual elementary substitutions; and for a long time past these groupings have been looked upon as the representatives or equivalents of one atom of hydrogen. But the notion of multiequivalency, in relation to compound radicles, is much more recent, it having been first announced by Williamson in 1851, and then not as a consequence, but as an anticipation, of its already described application to several of the basylous metals, which was first advocated by the author of this article in 1854-55. Just as we can exchange an atom of ethyl (C^2H^5) or cyanogen (CN) for one atom of hydrogen, so can we exchange an atom of sulphuryl (SO^2) or carbonyl (CO) or oxalyl (C^2O^2) or ethylene (C^2H^4) for two atoms of hydrogen, and an atom of phosphoryl (PO) or aldehydyl (CH^3) for three atoms of hydrogen, &c. &c.

A multiequivalent radicle, whether elementary or compound, is characterised by the property of combining several atoms or residues into one more complex atom, and is hence spoken of as polyatomic, the multiequivalency or polyatomicity of radicles being indeed one and the same function, looked at from a somewhat different point of view. Comparing chloride of bismuth, $BiCl^3$, with chloride of hydrogen, $3HCl$, for instance, the atom of bismuth is triequivalent, inasmuch as it displaces three atoms of hydrogen, and it is triatomic, inasmuch as it unites the three chlorine residues into one complex atom or molecule. Again, the diequivalent radicles, ethylene, C^2H^4 , and sulphuryl, SO^2 , by their substitution for hydrogen, bind together the residues of two atoms of hydrochloric acid, of two atoms of water, of two atoms of ammonia, &c. &c., and are consequently diatomic. Thus we have (C^2H^4) Cl^2 and (SO^2) Cl^2 comparable with $2HCl$, (C^2H^4) H^2O^2 and (SO^2) H^2O^2 comparable with $2H^2O$, and (C^2H^4) H^4N^2 and (SO^2) H^4N^2 comparable with $2H^4N$.

By referring to the article CLASSIFICATION, it will be seen that in every definite molecule the sum of the equivalencies or atomicities of the constituent radicles, whether elementary or compound, is always an even number, and that the equivalency or atomicity of a radicle increases by one unit for every atom of hydrogen or hydrogen-substitute abstracted from the molecule. In the case of marsh-gas, CH^4 , for instance, by abstracting H^1 we have the unequivalent radicle *methyl* (CH^3), which combines with one atom of chlorine to form chloride of methyl, (CH^3) Cl ; by abstracting H^2 we have the diequivalent radicle *methylene* (CH^2), which combines with two atoms of chlorine to form dichloride of methylene, (CH^2) Cl^2 ; by abstracting H^3 we have the triequivalent radicle *formyl* (CH), which unites with three atoms of chlorine to form trichloride of formyl, (CH) Cl^3 ; and, lastly, by abstracting H^4 we have the tetrequivalent radicle *carbon* C , which combines with four atoms of chlorine to form tetra-

Similarly, the smallest proportion of platinum that can enter into a combination has the same weight, and not one-half the weight, of an atom of platinum. By reducing all chlorides and oxides to protochlorides and protoxides, we ignore the following facts:—

1. That there is a great distinction in properties between protosalts and di- or sesqui-salts. Aluminium, for instance, forms but one set of salts: these might very well be considered as protoxides, but they are not so considered, simply because their properties are altogether different from those of protoxides.

2. That in well-defined molecules, we rarely find so small a quantity of platinum, or of ferricium, as corresponds with Gerhardt's atomic weights, but twice the former, and three times the latter quantity, thus:—

Hydrochlorate of platinumine	$HCl.NHpt^2$	Iron-alum	$fe^3K(SO^4)^3$
Hydrochlorate of diplatinumine	$HCl.N^2H^4pt^2$	Magnetic oxide of iron	fe^3FeO^2
Ammonio-chloride of platinum	$NH^4Cl.pt^2Cl^2$		

3. That twice pt and three times fe, or, al, &c., are usually the smallest quantities of pt and fe, &c., that can result from, or effect, those reactions in which the reacting quantities are determined by the amount of some other element concerned, thus:—

chloride of carbon, $C^{III}Cl^I$. Again, it will be often found that the same radicle has, and must have, two or more distinct equivalencies or atomicities. Thus the radicle C^II , when resulting from the dehydrogenation of tritylene, C^IIIH^I , is univalent or monatomic, and unites with one atom of chlorine to form chloride of allyl, $(C^IIIH^I)Cl$; but when resulting from the dehydrogenation of hydride of trityl, C^IIIH^I , it is triequivalent or triatomic, and unites with three atoms of chlorine to form trichloride of glyceryl, $(C^IIIH^I)Cl^III$. But how it is that these relations subsist, and why it is that they must subsist, have been already fully considered in the article on CLASSIFICATION, above referred to.

The notion of equivalency, hitherto exemplified in its application to elementary and compound radicles, may likewise be extended to molecules, though with a less degree of precision. Thus every molecule containing a displaceable atom of hydrogen, or the representative of a displaced atom of hydrogen, is in one sense equivalent to a molecule of hydrochloric acid, HCl , or to the double atom of hydrogen, H^2 ; but in another sense it may be equivalent to very many such molecules or double atoms. For instance, a molecule of water, H^2O , is in one sense equivalent to a molecule of hydrochloric acid, HCl . Both molecules, when treated with metallic sodium, lose an atom of hydrogen in exchange for an atom of sodium, which remains combined with the residues, Cl and HO respectively, which residues are capable of being freely exchanged for and are consequently equivalent to one another; as in the following example:— $NO.Cl + Na.HO = NO.HO + Na.Cl$,—so that we have H^2 equivalent to HCl , equivalent to H^2O . Again, the molecule of sulphuric acid, H^2SO^4 , is equivalent to a molecule of hydrochloric acid or of water; for we are acquainted with scores of instances in which the molecules HCl and H^2SO^4 effect precisely similar reactions, or in which the residues Cl and HSO^4 are mutually interchangeable, thus:

But in other cases we find the molecules of water and sulphuric acid equivalent to two molecules of hydrochloric acid, thus:

Moreover, though in the above instances the molecules of sulphuric acid and water are equivalent to one another, yet in other instances one molecule of sulphuric acid is equivalent to two molecules of water, thus:—

Or the molecule of hydrochloric acid being equivalent to two atoms of hydrogen, the molecule of water is equivalent sometimes to two, sometimes to four, atoms of hydrogen, and the molecule of sulphuric acid to two, four, six, or eight atoms, &c. We have already seen that marsh gas, regarded as hydride of methyl, CH^3H^I , is equivalent to two atoms of hydrogen; but regarded as dihydride of methylene, CH^2H^2 , it is equivalent to four atoms of hydrogen; regarded as trihydride of formyl, $CH.H^3$, it is equivalent to six atoms of hydrogen; while regarded as tetrahydride of carbon, $C^{III}H^I$, it is equivalent to eight atoms of hydrogen. We thus arrive at the conclusion, that the maximum equivalency of any molecule is the sum of the equivalencies of its constituent atoms, whilst its minimum equivalency is that of the most simple type to which it can be referred. Generally speaking, however, when comparing the equivalencies of more or less similarly functioned bodies, we consider them to be formulated upon those types with which their most characteristic reactions correspond. Thus, although every dibasic acid is of necessity monobasic also, and capable of undergoing a whole series of reactions, and producing a whole series of compounds, which are strictly comparable to those of an undoubted monobasic acid, yet we seldom refer it to a monatomic type, but remember only its more characteristic dibasic habitudes, and represent its equivalency as double that of a monobasic acid. For example, we do not usually accord to sulphuric acid the formula $H(HSO^4)^2$ comparable with HCl , and equivalent to two hydrogen-atoms, but rather the formula $H^2(SO^4)^2$ comparable with $2HCl$, and equivalent to four hydrogen-atoms, and so in other instances. W. O.

ERBIUM. The metallic radicle of erbia, one of the earths associated with yttria. Its atomic weight has not been determined.

Erbia was discovered in 1843, by Mosander (*Ann. Ch. Pharm.* xlviii. 219); its name is derived from Ytterby, the locality of gadolinite, in which mineral erbia occurs.

together with yttria and terbia. These three earths, which were formerly confounded together under the general name yttria, differ from one another in basic power, erbia being the weakest; but no complete method of separating them has yet been discovered. A partial separation is effected by fractional precipitation with caustic ammonia from the solution of the nitrates, or with acid oxalate of potassium from that of the sulphates, erbia going down first, then terbia, and lastly yttria. (See YTTRIUM).

Erbia, obtained by igniting the precipitated hydrate, has a deep yellow colour; when prepared by igniting the oxalate or the nitrate, it is lighter in colour, probably on account of finer mechanical division. When ignited in hydrogen gas, it yields a small quantity of water, and becomes colourless. It dissolves in hydrochloric acid without perceptible evolution of chlorine. The solutions of its salts are colourless. The sulphate has a sweetish taste, and crystallises like sulphate of terbia (*q. v.*), but is distinguished therefrom by not efflorescing at 80° C., even when kept at that temperature for a week. The solution of the nitrate does not become coloured when concentrated; and the salt, which forms radiating crystals, often colourless, but sometimes with a reddish tinge, does not deliquesce; in both these respects, it differs from sulphate of terbia.

EREMACAUISIS or *Decay*. A slow combustion taking place in presence of air and water, and accompanied by a kind of fermentation. The water doubtless acts in this process in the same manner as in the rusting of iron, viz. by absorbing the oxygen of the air, and transferring it in the liquid form to the constituents of the organic compound. Simple oxidation of organic substances in the air, such as the conversion of aldehyde into acetic acid, or the resinifying of volatile oils by exposure to the air, are not generally regarded as instances of eremacausis.

In eremacausis or decay, the carbon and hydrogen of the compound are converted by combustion into carbonic acid and water, while the nitrogen either escapes in the form of gas, or is converted into nitrous and nitric acid. As in this process the compound continually loses more and more carbon and hydrogen, it might be supposed that the residue would become continually richer in oxygen. This, however, is not always the case. For while the carbon of the compound is combining with the oxygen of the air and forming carbonic acid, it is possible that a large portion of the oxygen contained in the compound may go off with the hydrogen in the form of water, so that the residue may become richer in carbon than the original compound. Such, according to Saussure, is the process which takes place in the decay of wood, and its conversion into humus or mould, a substance which is richer in carbon, but is afterwards, by a further process of decay, completely converted into carbonic acid and water.

A decaying substance may bring other bodies into the state of slow combustion. Decaying organic substances surrounded with a mixture of hydrogen gas and air or oxygen, cause it to condense in the form of water (Saussure). Decaying substances in contact with water and alcohol cause the latter substance to oxidise and form acetic acid. (Liebig.)

Eremacausis is accompanied by evolution of *heat*; which in most cases, in consequence of the slowness with which it takes place, and the cooling produced by surrounding objects, amounts to only a few degrees, but when large masses are concerned, may, under favourable circumstances, rise to such a height as to induce rapid combustion (see COMBUSTION, i. 1093). In some few cases, eremacausis is attended with development of *light*, as in decaying wood, &c.

With regard to the behaviour of nitrogen in eremacausis, a great number of particulars have to be observed.

1. The nitrogen of an organic compound escapes in the form of gas, especially if the air has free access, or the compound is exposed to the sun, and no salifiable bases are present.

2. It is converted into nitric acid, especially with free access of air, in the shade, and in presence of a salifiable base, which favours the formation of the nitric acid. This base may be potash, soda, lime, or magnesia, in combination with carbonic acid or a vegetable acid: for the carbonic acid escapes as fast as the nitric acid comes in contact with the potash, and the organic acid is destroyed by the slow combustion. The ammonia produced by fermentation in the interior of the mass may also, when it reaches the surface, induce the oxidation of the nitrogen which is there being set free, and form nitrate of ammonia by combining with it, as was formerly observed by Thaeer and Einhof, in the putrefaction of cow-dung. If fixed salifiable bases are present, the nitrogen of the ammonia itself may also be oxidised and converted into nitric acid. (Kühlmann.) According to Vaudin's experiments, the formation of nitric acid appears to be preceded by that of nitrous acid.

3. The nitrogen of the compound unites with its hydrogen, and forms ammonia, which generally escapes as carbonate. This ammonia is not so much a product of eremacausis as of fermentation.

4. Non-azotised organic compounds appear, under certain circumstances, to absorb nitrogen from the air during eremacausis, either in the form of ammonia or of nitrous acid.

Extract of *Hyoscyamus*, when kept for a long time, forms carbonates of ammonia in the interior of its mass, but becomes covered on the surface with needles of nitrate of ammonia. (Flaschoff.)

The leaves of mangoldwurzel, grown on a poor, sandy soil, do not contain any perceptible quantity of nitre (those which grow on a rich soil contain a considerable quantity), but chiefly malate and oxalate of potassium. But when suspended on threads for some months, they become thoroughly penetrated with nitre and covered with fine crystals, nitric acid having, in fact, been formed by decomposition of the azotised matter in the leaves; the oxalate and malate are found to have disappeared entirely. (Braconnot, Ann. Ch. Phys. xxxv. 261; also Pogg. Ann. x. 506.)

Extract of quassin, after a year's exposure to the air, contains more nitre than it would contain if kept for the same time in close vessels. (Planché, J. Pharm. xxiii. 548.)

Extract of *Borago officinalis*, when not sufficiently evaporated, gives off nitric oxide gas on being stirred. (Guibourt, J. Pharm. xii. 134.)

The aqueous infusion of orange leaves evaporated in the air on flat dishes, yields, according to Vaudin, an extract, which, if exposed for a few hours to damp air, and then collected in a pot, swells up considerably, from evolution of nitrous acid, and continues for some months to give off this gas, whenever it is stirred.

It appears to be the woody fibre of plants which more especially attracts the nitrogen of the air; and the nitrogen thus absorbed takes up oxygen and remains combined with the woody fibre in the form of nitrous acid, till that acid is transformed into nitric acid, which then unites with the potash and lime contained in the salts of the vegetable acids present. When liquorice-wood is exhausted 22 times, first with cold, and then with hot water, the last extract still gives off nitrous fumes when treated with tartaric acid. The juice expressed from the fresh herb of *Lycopsis arvensis* contains neither nitrous acid nor nitre: but the exhausted residue, after four weeks' exposure to the air, yields with hot water an extract which gives off nitrous acid when treated with tartaric acid, and deflagrates on red-hot coals. When Iceland moss (*Isichen islandicus*) is several times exhausted, first with cold and then with hot water, and exposed to the air for some time after each immersion, all the extracts yield nitrous acid and nitre. (Vaudin, J. Chim. méd. i. 674; ix. 321.)

When the air has but partial access, part of the hydrogen of the organic compound appears to combine with the nitrogen of the air and form ammonia, which can then supply the requisite quantity of nitrogen to the fungi which grow upon these putrefying substances.

When an aqueous solution of milk-sugar or common sugar is left for three months in a stoppered bottle, together with a sevenfold volume of air, and the mould, which is produced in particular abundance from the milk-sugar, is subjected to dry distillation, a large quantity of ammonia is obtained; hence there has been produced in the fungus, together with cellulose, a nitrogenous substance, doubtless of albuminous nature; for when the fungus produced from milk-sugar is digested in acetic acid, a liquid is obtained which gives a precipitate with ferrocyanide of potassium. Starch from arrow-root, when kept under water in a bottle also containing air, soon becomes very turbid, and in ten weeks forms a white deposit, together with a large quantity of mould in the mass, and finally also a little on the surface. A fungus of this kind obtained from potato-starch yielded strong traces of ammonia when subjected to dry distillation. A mixture of humic acid and sugar, moistened with a small quantity of water, and kept for six months in a closed vessel containing air, gives off a large quantity of ammonia when treated with potash. In a similar manner, woody fibre, which putrefies with scanty access of air in the lower strata of a vegetable soil, appears to form ammonia, part of the hydrogen of the wood combining with the oxygen of the air, and another portion with the nitrogen. This ammonia, according to Kühlmann's supposition, may be afterwards transformed into nitric acid. In this manner we might explain the formation of nitre in the caves of Zeilan described by J. Davy, where no animal substances can be discovered [there are, however, nitrogenous vegetable matters present]; also the formation of nitre in India, Spain, Egypt, in the grottoes on the banks of the Seine, and in many cellars. (Mulder, J. pr. Chem. xxii. 326, 344.)

Damp wood, putrefying in confined air, converts the oxygen of the air into an equal volume of carbonic anhydride, producing, at the same time, much more water than carbonic anhydride (Sausure). At the same time, however, a small quantity of nitrogen is absorbed from the air, and some of it is converted into ammonia, while

the remainder enters as nitrogen into the composition of certain fungoid substances, which are formed at the same time. (Hermann, J. pr. Chem. xxvii. 165.)

Many organic compounds do not undergo slow combustion at ordinary temperatures or in the dark, but exhibit that phenomenon when moderately heated or exposed to light, especially to direct sunshine.

Air is necessary as well as heat; substances which, between 100° and 120° C., suffer no alteration out of contact of air, decompose in the air, even when but slightly heated. (Chevreul, *Analyse Organique*, p. 69.)

Compounds which remain unaltered when exposed to the air at medium temperatures in the dark, become changed when likewise exposed to light. These changes, due to the action of light, are especially conspicuous in many organic colouring matters, such as indigo, prussian blue, safflower, turmeric, and the colours of many flowers which are bleached thereby. (Chevreul.)

Coloured fabrics, e.g. silk and wool dyed with safflower, weld, or turmeric, which gradually fade on exposure to sunlight, suffer the same change in an hour or two, when subjected in the dark to a heat between 160° and 200° C., the air having access to them at the same time. (Gay-Lussac and Thénard, *Recherches physico-chimiques*, ii. 166; Gm. vii. 96.)

ERDMANNITE. A silicate containing cerium (perhaps an impure orthite), from the island of Stokö, near Brevig, Norway, where it occurs in dark brown, translucent, imbedded grains and folia, with no traces of crystallisation. Lustre vitreous. Specific gravity 3.1. According to a preliminary analysis by Blömstrand (Pogg. Ann. lxxxvii. 168), it contains 31.36 per cent. silica, 34.89 oxides of cerium and lanthanum, 11.71 alumina, 6.46 lime, 8.52 ferrous oxide, 0.86 manganous oxide, 1.48 yttria, 4.28 water and loss.

EREMITE. The name given by Shepard (Sill. Am. J. xxxii. 341; xxxiii, 70) to a ceriferous mineral, which, according to Berzelius, is perhaps fluorcerite, but is regarded by Dana as monazite (q. v.), although, according to Shepard, it contains fluorine.

ERGOTINE. The active principle of ergot of rye. It is obtained by treating the ergot with ether to remove fatty and waxy matters, digesting the residue in boiling alcohol, concentrating the solution by evaporation, and precipitating by cold water. It is a red-brown powder, having a sharp bitter taste, infusible, insoluble in water, ether, and dilute acids, soluble in alcohol, strong acetic acid, and caustic potash; sulphuric acid dissolves it with red-brown colour. Its action on the animal economy is said to be slowly but mortally narcotic. (Wiggers, Ann. Ch. Pharm. i. 171.)

ERICA CARNEA. This plant, grown on a magnesian limestone soil, and gathered in June, gave off 48.75 per cent. water, at 100° C., and the dry residue yielded 2.66 ash, containing 21.95 per cent. K_2O , 1.46 Na_2O , 32.07 CaO , 14.28 MgO , 3.44 FeO , trace of manganic oxide, 5.43 P_2O_5 , 5.44 SO_3 , 3.57 $NaCl$, and 12.38 silica. (Rüthe, Ann. Ch. Pharm. lxxvii. 118.)

ERICA VULGARIS. Syn. with *CALLUNA VULGARIS* (i. 722).

ERICACEÆ. According to Rochleder (Ann. Ch. Pharm. lxxxiv. 368) all plants of this order contain tannic acids, the anhydrides of which may be represented by the general formula $C^{14}H^{12}O^8$, e. g.

Gallic acid	$C^{14}H^{12}O^{10}$	in <i>Arcostaphylos uva ursi</i>
Callutannic acid	$C^{14}H^{12}O^8$	„ <i>Calluna vulgaris</i>
Rhodotannic acid	$C^{14}H^{12}O^7$	„ <i>Rhododendron ferrugineum</i>
Leditannic acid	$C^{14}H^{12}O^6$	„ <i>Ledum palustre</i>

and according to Kuberth's investigations (*loc. cit.*) *Erica herbacea* contains a similar acid, the anhydride of which is $C^{14}H^{12}O^7$. All these acids (excepting gallic acid) turn ferric salts green, form a yellow precipitate with stannic chloride, and, when heated with sulphuric or hydrochloric acid, give up the elements of water, and form a yellow or red colouring matter. They all contain ericolin, a volatile oil, and probably also small quantities of citric acid (Rochleder). According to Uloth (Ann. Ch. Pharm. cxi. 215) all ericaceous plants yield, by dry distillation, a crystallisable substance called ericinone.

ERICINOL. $C^{14}H^{14}O$. A product of the decomposition of ericolin (p. 500) and of pinipicin, obtained together with glucose, by distilling either of those substances with dilute sulphuric or hydrochloric acid. It then passes over as a volatile oil, colourless at first, but sooner turning brown, from oxidation (Rochleder, Schwarz, and Kawalier). Its formation from ericolin is represented by the

equation, $C^{24}H^{34}O^{21} + 4H^2O = 4C^6H^{12}O^6 + C^{10}H^{10}O$; and from pinipierin, by $C^6H^{10}O + 2H^2O = 2C^6H^{12}O^6 + C^{10}H^{10}O$.

The same volatile oil, but already somewhat altered, is obtained by distilling with water the leaves of *Calluna vulgaris*, *Rhododendron ferrugineum* (Rochleder), *Arctostaphylos uva ursi* (Kawalier), *Ledum palustre* (Willk.), and *Erica herbacea* (Kunberth).

The volatile oil of *Ledum palustre* is a mixture of ericinol with valeric acid, another oily acid, and an oil isomeric with oil of turpentine, boiling at 160° C. When freed from the acids by repeated agitation with potash-ley, then washed and dehydrated, it yields by distillation between 115° and 160° C. a mixture of ericinol and non-oxygenated oil, but between 236° and 250° , chiefly ericinol, while a resin remains behind.

Ericinol thus obtained is a bluish green oil, having a disagreeable smell, and burning, nauseously bitter taste, and boiling between 240° and 242° C. When once distilled with sticks of potash, it is partially discoloured, has a specific gravity of 0.874 at 20° , and contains on the average 79.96 per cent. carbon and 11.03 hydrogen, agreeing approximately with a formula $C^{10}H^{10}O$ (calc. 78.96 C and 10.52 H). By cohabitation with excess of solid potash, it is converted into a non-oxygenated oil, $C^{10}H^{10}$ (Fröhde, J. pr. Chem. lxxxii. 181).

ERICINONE. $C^{24}H^{20}O$ (?) (Uloth, Ann. Ch. Pharm. cxi. 215.) An indifferent crystalline substance, obtained by the dry distillation of ericeaceous plants. On submitting the extract of a plant of this order to dry distillation, and precipitating the liquid distillate with acetate of lead, ericinone remains dissolved, and may be obtained in the crystalline form by precipitating the lead with sulphydric acid, evaporating the filtrate to dryness, and subliming the residue between two watch-glasses in small quantities at a time.

Pure ericinone sublimes in feathery groups of white crystals having a silky lustre. It dissolves easily in alcohol and ether, and crystallises from the alcoholic solution in quadratic needles, acuminate with triangular or rhombic faces. Its solution, when fresh, is neutral to vegetable colours, but decomposes gradually, turning brown and acquiring an acid reaction: the crystals likewise undergo slow alteration, especially under the influence of light. Ericinone is inodorous, but has a sweetish taste, with somewhat astringent after-taste. It melts at about 167° C., and solidifies in the crystalline state. Sublimation begins far below the melting point; at higher temperatures it is attended with partial carbonisation.

The solution of ericinone is not precipitated by acetate of lead, either neutral or basic, but on addition of ammonia a white precipitate is formed, which afterwards becomes dark-coloured. It is not altered by ferrous or ferric salts: it quickly reduces silver and gold from their salts; platinum from the chloride on addition of ammonia, and boiling; cuprous oxide from an alkaline cupric solution, even in the cold. In contact with alkalis, it quickly turns brown and absorbs oxygen, the colour disappearing, however, as soon as all the ericinone is decomposed.

Nitric acid converts ericinone into oxalic acid. Hydrochloric acid dissolves it without decomposition; but on adding chlorate of potassium to the warm solution, chloranil, $C^6Cl^4O^2$, separates out.

According to Uloth's analyses, ericinone contains 62.85—63.40 per cent. carbon and 5.48—5.26 hydrogen, whence he deduces the formula $C^{24}H^{12}O^6$ or $C^{24}H^{20}O^6$ (calc. 63.16 carbon and 5.26 hydrogen). He thinks it probable that ericinone is a product of the decomposition of ericolin. Hesse (Ann. Ch. Pharm. cxiv. 301) regards ericinone as identical with hydroquinone; but Zwenger (*ibid.* cxv. 108), under whose direction Uloth's experiments were made, is of opinion that the two bodies are distinct.

ERICOLIN. A resinous substance found in several plants of the ericeaceous order, especially in the herb of the marsh wild rosemary, *Ledum palustre* (Rochleder and Schwarz, Ann. Ch. Pharm. lxxxiv. 368), less abundantly in the common heath or ling, *Calluna vulgaris* (Rochleder, *ibid.* 354), in *Rhododendron ferrugineum* (Schwarz, *ibid.* 361), and in the red bearberry, *Arctostaphylos uva ursi* (Kawalier, Wien. Acad. Ber. ix. 29).

It is prepared from *Ledum palustre* by throwing the chopped leaves into boiling water and boiling for several hours; then straining the liquid; precipitating with basic acetate of lead; evaporating the filtrate in a retort to one-third of its bulk; filtering from the separated lead-salt; freeing the liquid from lead by sulphydric acid; evaporating the filtrate to an extract; and dissolving out the ericolin by anhydrous ether-alcohol. The substance left on evaporating this solvent is then repeatedly dissolved in ether-alcohol, till it no longer leaves any residue. (Rochleder and Schwarz.)

Ericolin may also be separated from the mother-liquor obtained in the preparation of arbutin from the leaves of red bearberry (i. 354), by heating that liquid with

hydrochloric or sulphuric acid; it is then deposited as a resinous precipitate, which may be purified by solution in alcohol and precipitation by water. (Kawalier.)

Ericin obtained by the first process is a brownish-yellow powder, which cakes together at 100° C. and has a very bitter taste. Rochleder and Schwarz found it to contain (after deduction of 10.6 per cent. ash) 51.71 per cent. carbon and 7.19 hydrogen; whence they deduce the formula $C^{21}H^{20}O^{21}$ (61.00 C and 7.00 H).

Heated with dilute sulphuric acid, it is resolved into ericinol and glucose:

ERINITE. A cupric arsenate, occurring in mammellated crystalline groups, of a fine emerald-green colour, in the county of Limerick, Ireland. Specific gravity = 4.043. Hardness = 4.5—5. Lustre almost dull, slightly resinous. Streak green, paler than the colour. Subtranslucent or nearly opaque. Brittle. Contains, according to an approximate analysis by Turner (Ann. Phil. [2] iv. 154), 33.78 per cent. As^2O^3 , 59.44 CuO, 6.01 water, and 1.77 alumina; whence the formula $5CuO.As^2O^3 + 2H^2O$, or $(Cu^2As^2O^3).2CuH^2O^2$.

The name *erinite* has likewise been applied to a variety of bole found at the Giant's Causeway. (See analysis f, i. 618.)

ERIOPHORUM VAGINATUM. *Hare's-tail Cotton Grass.*—The plant grown on a marshy peat soil in the neighbourhood of Berlin, yielded in the fresh state 57.13 per cent. water, 41.65 organic substance, and 1.22 ash. Of the ash, 47.43 per cent. was soluble in water, 32.03 soluble in weak nitric acid, 20.54 insoluble in nitric acid.

The ash contained in 100 pts. 32.26 SiO^2 , 4.59 CO^2 , 2.18 SO^3 , 6.10 P^2O^5 , 3.74 MnO , 3.86 Fe^2O^3 , 4.38 MgO , 10.48 CaO , 1.15 Na^2O , 28.52 K^2O , 2.40 $NaCl$, 0.34 KCl . (E. Witting, J. pr. Chem. lxxix. 149.)

ERITANNIC ACID. $C^{14}H^{10}O^7$.—A constituent of *Erica herbacea*. It colours nut-salts green, and is decomposed by sulphuric acid, yielding a yellow colouring matter called erixanthin.

ERLANITE. An imperfectly crystallised silicate from the Erzgebirg, of greenish grey colour, with traces of finely laminated structure. Specific gravity = 3.0—3.1. Hardness between apatite and felspar. Melts before the blowpipe to a clear bead, and dissolves with greenish colour in borax (Handw. d. Chem. 1^{re} Aufl. ii. 966). According to Lampadius, it is a silicate of calcium. C. Gmelin, on the other hand, found it to contain 53.16 per cent. SiO^2 , 14.03 Al^2O^3 , 7.14 Fe^2O^3 , 0.64 Mn^2O^3 , 14.4 CaO , 5.42 MgO , 2.61 Na^2O , and 0.6 loss by ignition. (Rammelsberg's Mineralchemie, p. 771.)

ERSBYITE. Pure lime labradorite from Ersby in Finland, formerly regarded as anhydrous scolezite. (See LABRADORITE.)

ERUBESCITE. Purple copper (p. 78).

ERUCIC ACID. $C^{22}H^{42}O^2$.—An acid obtained, together with oleic acid, by the saponification of the fixed oil of white mustard (*Sinapis alba*). The oil is saponified with soda; the soap is decomposed by hydrochloric acid; the mixture of erucic and oleic acid thus produced is treated with oxide of lead at the heat of the water-bath; the product digested with ether, which dissolves the oleate of lead; the residue treated with hydrochloric acid and alcohol; and the chloride of lead separated by filtration; the liquid is distilled to separate the alcohol; and the remaining fatty acid is boiled with water to remove hydrochloric acid, then crystallised several times from alcohol, till it exhibits a constant melting point. The fixed oil of black mustard likewise contains erucic acid.

Erucic acid crystallises in shining needles, which melt at 34° C. Its sodium-salt is soluble in alcohol. The barium-salt, $C^{22}H^{40}BaO^2$, is precipitated in flocks on mixing the alcoholic solutions of acetate of barium and erucate of sodium. The lead-salt, $(C^{22}H^{38}Pb^2O^4)$, is a white precipitate obtained in like manner. The silver-salt, $C^{22}H^{36}AgO^2$, is a curdy precipitate, which becomes coloured on exposure to light.

ERUCIN. A crystalline substance, said to exist in white mustard seed. Insoluble in water, sparingly soluble in alcohol, easily in ether and in oils. Does not contain sulphur. (Simon, Pogg. Ann. xlv. 593.)

ERVUM LENS. See LENTIL.

ERYGLUCIN. Syn. with ERYTHROMANNITE.

ERYPICRIN. Syn. with PICOERYTHRIN.

ERYSIMUM ALLIARIA. *Alliaria Officinalis.*—A common weed of the cruciferous order, the herb of which contains sulphocyanate of allyl (Wertheim, Ann. Ch. Pharm. lii. 52). From the seed Piesse (*ibid.* lxxviii. 75) obtained 0.6 per cent. volatile oil containing sulphocyanate of allyl, sometimes alone, sometimes mixed with oxide of allyl.

ERYTHRARSIN. $C^4H^{10}O^3As$.—A red amorphous substance produced from cacodyl by combustion with insufficient access of air, by the action of hydrochloric acid and metallic tin, or of phosphorous acid, or by passing the cacodyl through slightly heated tubes. It is insoluble in water and alcohol. (See *CACODYL*, i. 404.)

ERYTHRIN. A red substance, probably impure orcein, produced by the action of ammonia and air on erythric acid. (Heeren.)

ERYTHRELIC ACID. See the next article.

ERYTHRIC ACID, or ERYTHRIN. (Heeren, Schw. J. lix. 313. — Kane, Ann. Ch. Pharm. xxxix. 25. — Schunck, *ibid.* lxi. 69. — Stenhouse, *ibid.* lxxviii. 72; further, Proc. Roy. Soc. xii. 263. — Hesse, Ann. Ch. Pharm. cxvii. 304. — Gm. xii. 381.) — An acid discovered by Heeren in *Rocella tinctoria*; it appears also to be contained in most of the lichens from which archil is prepared. When either of these lichens — the *Rocella Montagnei*, for example — is exhausted with boiling water, the erythric acid is deposited as a crystalline powder, which may be purified by boiling alcohol. (The aqueous mother-liquor retains picroerythrin and orcein.) According to Stenhouse, it is better to exhaust the lichens with milk of lime; the quantity then obtained amounts to 12 per cent. of the weight of the lichen.

Erythric acid is white, crystalline, destitute of taste and odour, sparingly soluble in water (1 pt. of the acid requiring about 240 pts. of boiling water to dissolve it), easily soluble in alcohol, ether, and alkalis.

Erythric acid dried at $100^{\circ}C$. gives by analysis numbers agreeing nearly with either of the formulæ $C^{20}H^{22}O^{10}$ (Stenhouse), or $C^{28}H^{30}O^{14}$ (Hesse):

Calculation.				Hesse.		Stenhouse.		
C^{20}	240	56.87	C^{28}	336	56.95	56.9	56.84	56.94
H^{22}	22	5.22	H^{30}	30	5.08	5.4	5.56	5.33
O^{10}	160	37.91	O^{14}	224	37.97			5.62
	422	100.00		590	100.00			

Schunck found 58.70 per cent. carbon and 5.37 hydrogen, whence he deduced the formula $C^{24}H^{19}O^{13}$, or $C^{34}H^{38}O^{18}$ (59.5 C, 5.5 H); Gerhardt proposed $C^{61}H^{16}O^8$ (57.14 C, 4.77 H).

The air-dried substance was found by Hesse to contain 51.7 per cent. carbon and 5.4 hydrogen, agreeing exactly with the formula $C^{28}H^{30}O^{14}$, $2H^{2}O$. When heated to $100^{\circ}C$. it gives off 5.7 per cent. water, which also agrees exactly with 2 aq. At $137^{\circ}C$. it melts, and does not solidify in the crystalline form on cooling.

Decompositions.—1. Erythric acid may be heated to $200^{\circ}C$. without sensible alteration; but at a higher temperature it is decomposed, yielding orcein and carbonic anhydride.

2. By boiling for some time with water, or more readily, with alkalis, it is resolved into picroerythrin and orsellinic acid (formerly called erythrelin or erythrolesic acid):

and the orsellinic acid is resolved by longer boiling into orcein ($C^8H^6O^2$) and carbonic anhydride (CO^2).

3. Boiled for some time with alcohol, it yields in like manner picroerythrin and orsellinate of ethyl, $C^8H^7(C^2H^5)O^4$, and with methyl alcohol orsellinate of methyl.

4. Strong sulphuric acid dissolves erythric acid without alteration in the cold; but decomposes it when heated. Boiling hydrochloric acid likewise dissolves it. Nitric acid dissolves it in the cold without evolution of nitrous acid, forming a yellow substance soluble in alcohol and precipitated by water; no oxalic acid is produced. On heating it with nitric acid, nitrous acid is evolved.

5. Bromine converts erythric acid dissolved in water into a yellow resin. When the acid is covered with ether containing water, and bromine is slowly added, tetrabromerythric acid, $C^{28}H^{18}Br^4O^{14}$ (or $C^{20}H^{12}Br^4O^{10}$), is formed, in white crystalline spherules, nearly insoluble in cold water, soluble in alcohol, slightly in cold ether. The alcoholic solution is acid, forms a white precipitate with acetate of lead, purple with a small quantity of ferric chloride, brown-red with a larger quantity; hypochlorite of sodium imparts to it a transient blood-red colour. When boiled with alcohol it is resolved into dibromorsellate of ethyl and bromopicroerythrin. Bromerythric acid cakes together a little above $100^{\circ}C$., melts to a colourless frothy mass at 139° , and at a higher temperature gives off acid vapours and burns away. (Hesse.)

6. Chlorine decomposes erythric acid suspended in water, dissolving a considerable portion, and forming a yellow resinous substance. (Hesse.)

Erythrates. — Erythric acid is a very weak and unstable acid. It forms with *potash, soda, lime, and magnesia*, solutions which have an alkaline reaction, and from which, when recently prepared, carbonic acid throws down erythric acid; after a few days, however, no precipitate is formed. The alkaline solutions undergo decomposition when heated.

An alcoholic solution of erythric acid is not precipitated by nitrate of silver, but on adding ammonia a white precipitate is formed, which soon turns black and produces a specular deposit of silver. Chloride of gold is not altered by boiling with the alcoholic solution of erythric acid. *Sesquichloride of iron* imparts to the alcoholic solution a deep purple tint, and the addition of ammonia causes it to pass to yellow, but without precipitation, unless the liquid is boiled. The alcoholic solution of the acid is not precipitated by *neutral acetate of lead*, but with the *basic acetate* it yields a copious precipitate containing 59.12 per cent. of lead.

The compound ether obtained by boiling erythric acid with alcohol was originally regarded by Stenhouse as erythrate of ethyl, $C^{26}H^{22}(C^2H^5O)^{10}$. But as its formation is accompanied by that of picroerythrin, it appears to be orsellinate of ethyl (p. 502). It is remarkable, however, that when boiled with alkalis, it yields a solution containing both orcin and erythromannite, whereas the corresponding methylic ether treated in like manner yields orcin, but no erythromannite. The same difference is observed in the reactions of the ethylic and methylic ethers obtained from all the varieties of *Roseella tinctoria* (Stenhouse). The reaction requires further investigation.

Picroerythrin, $C^{22}H^{16}O^7$. — Produced by the action of boiling water on erythric acid. The acid boiled for some time with water dissolves slowly, and the liquid yields by evaporation a viscid brown mass, which, when treated with cold water, leaves picroerythrin (Schunck). Stenhouse boils erythric acid, after saturation with lime or baryta; saturates the liquid with hydrochloric acid (to precipitate erythreic acid); filters, and leaves the solution to itself. Picroerythrin is then deposited in yellowish crystals, which may be purified by means of boiling water and animal charcoal.

Picroerythrin is colourless, crystallisable, bitter, sparingly soluble in cold water, very soluble in boiling water. The solution reddens litmus slightly. It is not altered by prolonged boiling with water, and is not etherified by alcohol. Heated in a small tube, it yields a sublimate of orcin. It dissolves in *alkalis* without the aid of heat; the ammoniacal solution quickly reddens in contact with the air. Boiled with baryta it yields carbonate of barium, and a solution containing orcin and erythromannite:

The aqueous solution of picroerythrin is not precipitated by *neutral acetate of lead*, but abundantly by the *basic acetate*, the precipitate containing 68.94 per cent. lead. The aqueous solution acquires a fine purple tint when mixed with *sesquichloride of iron*. It does not reduce nitrate of silver even at the boiling heat, unless ammonia is added. It gradually reduces chloride of gold.

ERYTHRINE. Syn. with COBALT-BLOOM (l. 1057).

ERYTHRITE. A flesh-coloured felspar, containing 3 per cent. magnesia, found in amygdaloid. Specific gravity = 2.541. (Thomson, Phil. Mag. [3] xxii. 188.)

ERYTHROBETIC ACID. A very unstable acid obtained from red beet (*Beta vulgaris*). It is crystalline, easily soluble in cold water, insoluble in alcohol and ether; precipitated from its aqueous solution by nitrate of silver and neutral acetate of lead. (Meier, Pharm. Centralbl. 1847, p. 436.)

ERYTHRODANUM. The name given by Kuhlmann (Ann. Ch. Phys. [2] xxiv. 225) to a red crystalline substance obtained from madder, probably impure alizarin.

ERYTHROGEN. A substance originally colourless, but reddened by acids, supposed by Hope (J. pr. Chem. x. 269) to be contained in flowers. Filhol regards it as identical with cyanin (p. 274).

The same name was applied by Bizio (Schw. J. xxxvii. 10) to a crystalline substance which he obtained from the bile of a patient who died of jaundice, and which he described as capable of abstracting nitrogen from the air, from nitric acid, and from ammonia, and as being converted thereby into blood-red.

ERYTHROGENIC ACID. An oily liquid said by Bizio to be produced on heating the substance which he calls erythrogen in oxygen gas.

ERYTHROGLUCI-SULPHURIC ACID. Syn. with ERYTHROMANNI-SULPHURIC ACID (p. 506).

ERYTHROGLUCIN. Syn. with ERYTHROMANNITE.

504 ERYTHROLEIC ACID—ERYTHROMANNITE.

ERYTHROLEIC ACID. A purple semifluid substance said to exist in archil (Kane, Ann. Ch. Phys. ii. 1.)

ERYTHROLEIN and **ERYTHROLITMIN.** Red substances obtained from litmus (*q. v.*)

ERYTHROLEIC ACID. Syn. with **ERYTHRELIC ACID.**

ERYTHROLIC ACID. The name originally applied by Kane to a substance which he supposed to exist both in archil and in litmus; subsequently, however, he applied the name *erythrolein* to the substance found in litmus, and *erythroleic acid* to the one contained in archil, because it contained more oxygen.

ERYTHROMANNITE. $C^4H^{10}O^4$. *Erythroglycerin.* *Eryglucin.* *Erythrite.* *Phycite.* *Pseudorcin.* (Stenhouse, Phil. Trans. 1848, 76; 1849, 399.—Strecker, Ann. Ch. Pharm. lxxiii. 111.—Schunck, Phil. Mag. vii. 33, 254.—Lamy, Ann. Ch. Phys. [3] xxxv. 138; li. 232.—Wagner, J. pr. Chem. lxi. 125.—Hesse, Ann. Ch. Pharm. cxvii. 327.—Gm. xii. 385.) This substance exists ready formed in *Protococcus vulgaris*, and is produced by boiling erythric acid or picroerythrin, or the ethylic ethers obtained from any of the varieties of *Rocella tinctoria* with excess of baryta or lime (*p. 503*). The substance from *Protococcus vulgaris* was originally called phycite.

Preparation. 1. The extract of *Lecanora Montagnei*, obtained with milk of lime, is boiled down in an open pan to about one-third or one-fourth; carbonic acid passed into the cooled liquid as long as a precipitate continues to form; and the solution, after filtration, evaporated to a syrup over the water-bath. This syrup consists chiefly of orcin and erythromannite, mixed with a rather large quantity of red colouring matter and a resinous substance. The orcin and the greater part of the colouring matter are extracted by cold ether; or the syrup is mixed with three times its volume of strong alcohol, from which, after a while, the erythromannite separates in small crystals. These are collected on a cloth filter, pressed, washed with cold strong alcohol, which dissolves the orcin and the greater part of the colouring matter, and recrystallised two or three times from hot alcohol.—2. *Protococcus vulgaris* is boiled for some hours with water, and the filtered and decolourised solution is evaporated to a syrup, precipitated with alcohol or basic acetate of lead, and the filtrate left to crystallise.—Or, 1 lb. of *Protococcus vulgaris* is digested at a temperature between 50° and 100° C. with 2 lbs. of alcohol of 85° ; the liquid decanted; the green residue strongly pressed out; the liquid then filtered; and the alcohol distilled to one-half. The mother-liquor of the phycic acid which is deposited on cooling, separates, when the liquid is again heated, into two layers, the alcohol at the same time evaporating. The upper layer is strongly coloured; the lower, which is less coloured, yields by evaporation a crystalline mass saturated with a black syrup, which must be pressed between fine linen, washed with very cold water, and recrystallised from hot water. (Lamy.)

Properties.—Large colourless transparent crystals, having an adamantine lustre, and belonging to the dimetric system. Observed faces $P. \propto P \propto \frac{3P3}{2}$. Inclination of $P : P = 123^{\circ} 43'$; $P : \propto P \propto = 109^{\circ} 29'$; $3P3 : \propto P \propto = 138^{\circ} 42'$ (Miller). Specific gravity 1.59 (Lamy). Its taste is very sweet and cooling (Lamy). Index of refraction = 1.545 (Stenhouse). Does not exhibit circular polarisation (Lamy). Melts at 112° C. without giving off water, and volatilises partly undecomposed (Lamy). Melts at 120° C. (Hesse). Does not act on litmus. Its taste is sweet, but less so than that of orcin. It does not lose water at 100° C. (Stenhouse). It dissolves very readily in water, sparingly in cold alcohol, and is insoluble in ether; the aqueous solution yields the finest crystals.

The following analyses have been made of erythromannite:—

Calculation.			Stenhouse.	Schunck.	Lamy	
C^4	48	39.34	39.42	39.68	39.10	39.22
H^{10}	10	8.20	8.48	8.60	8.23	8.27
O^4	64	52.46	52.10	51.72	52.67	52.51
$C^4H^{10}O^4$	122	100.00	100.00	100.00	100.00	100.00

Stenhouse originally gave to erythromannite the formula $C^{10}H^{13}O^{10}$; Gerhardt proposed $C^{10}H^{12}O^{12}$, or $C^4H^{10}O^4$. According to the formula $C^4H^{10}O^4$, or $C^4H^{10}O^4$, which was first given by Strecker, and agrees best with all the reactions of erythromannite, this body may be regarded as a tetratomic alcohol, $\left\{ \begin{smallmatrix} (C^4H^4)^4 \\ H^4 \end{smallmatrix} \right\} O^4$. Berthelot regards it as a hexatomic alcohol, $C^{12}H^{13}O^{12} = \frac{C^{12}H^6}{H^7} O^{12}$; but this formula is improbable, on account of the uneven number of hydrogen-atoms.

Decompositions.—1. Erythromannite subjected to dry distillation gives off an odour of burnt sugar, and yields a liquid which does not crystallise on cooling, but dissolves in water and in alcohol (Stenhouse). It begins to boil at 160° C. without perceptible decomposition, giving off an odour of burnt flour; as the decomposition advances, the boiling point gradually rises to about 200°, but the mass does not swell up: the residue in the retort consists partly of unaltered erythromannite, partly of a substance analogous to glucose, and possessing the power of reducing copper-salts, a property not exhibited by erythromannite. Erythromannite thrown on red-hot coals gives off the odour of burnt sugar (Lamy). It burns on platinum-foil with a blue flame and an odour of caramel (Stenhouse).—2. It is not altered by aqueous potash, by ammonia, by bromine, or by chloride of lime.—3. Heated to 220° C. with solid hydrate of potassium, it yields acetate of potassium and hydrogen gas, $C^4H^8O^4 + 2KHO = 2C^2H^3KO^2 + 2H^2O + H^2$ (Stenhouse, Lamy).—4. Fuming nitric acid converts it into nitro-erythromannite; on heating the mixture, oxalic acid is produced (Stenhouse).—5. Erythromannite dissolves in cold sulphuric acid, and when heated therewith, is converted into an erythromanni-sulphuric acid (Hesse).—6. It is not fermentable. (Stenhouse, Lamy). It does not precipitate neutral or basic acetate of lead, copper-salts, or ammonio-nitrate of lead (Stenhouse).—7. Erythromannite heated to 120° C. for a day or two, with an equal weight of tartaric acid, yields an acid having the composition $C^{11}H^{10}O^{18}$ (Berthelot, Compt. rend. xlv. 268. See TARTARIC ACID).—8. Heated with hydriodic acid in a stream of carbonic anhydride, it yields iodide of tetryl (V. de Luynes, Compt. rend. lv. 624):

Nitro-erythromannite. $C^4H^6(NO^2)^4O^4$ (Stenhouse, Phil. Trans. 1849, 399).—Pulverised erythromannite adding by small portions to fuming nitric acid, which is kept cool, dissolves quickly with considerable rise of temperature; and if the solution be mixed with a quantity of sulphuric acid, equal in weight to the nitric acid, or rather more, the whole forms in half an hour a crystalline magma, which is collected on a funnel plugged with asbestos, washed with cold water, pressed between paper, and recrystallised from hot alcohol. The compound is not obtained by dissolving erythromannite in a mixture of nitric and sulphuric acids, and adding water.

It forms large shining crystalline laminae, which melt at 61° C., and solidify in the crystalline form at a temperature a few degrees lower. It gives by analysis, 15.89—16.03 per cent. carbon, 2.125—2.10 hydrogen, and 18.59 nitrogen (Stenhouse, *Epistolary communication*), the above formula requiring 15.89 C, 1.99 H, and 18.54 N.

The compound takes fire when strongly heated, and burns with a bright flame. The crystals, when thoroughly dried and mixed with sand, detonate under the hammer.

ERYTHROMANNITIC ETHERS. *Erythroglucides. Erythrides.* (Berthelot, *Chimie organique fondée sur la Synthèse*, ii. 222.—Hesse, *loc. cit.*)—Erythromannite heated with acids to 200°—250° C. forms acid and neutral compound ethers, analogous to those derived from mannite and glycerin. These compounds are decomposed by alkalis, erythromannite being separated, and the acid sometimes uniting with the alkali, sometimes suffering further decomposition.

The acetate is a neutral liquid, easily soluble in alcohol and ether.

Benzoates.—The dibenzoate, $C^{10}H^{12}O^{16}$ (Berthelot), more probably $C^{11}H^{10}O^8 = \frac{(C^4H^8)^2}{(C^2H^3O^2)^2} \cdot O^4$, is resinous when recently prepared, but gradually becomes crystalline. Insoluble in water, easily soluble in absolute alcohol and ether.

The hexbenzoate, $C^{18}H^{20}O^{24}$ (Berthelot); more probably

is obtained by heating the preceding compound with ten or fifteen times its weight of benzoic acid to about 200° C. It is neutral, insoluble in water, soluble in ether.

Orsellates.—Berthelot regards erythrin as diacid orsellate of erythromannite $[C^2H^2O^{10} = \frac{(C^4H^8)^2}{(C^2H^3O^2)^2} \cdot O^4]$, and picroerythrin as the mono-orsellate $[C^2H^2O^7 = \frac{(C^4H^8)^2}{(C^2H^3O^2)^2} \cdot O^4]$. The formulæ actually given by Berthelot, viz. for erythrin $C^4H^8O^{22} = C^2H^3O^2 \cdot H^2 \cdot O^4$, and for picroerythrin $C^2H^2O^{16} = C^2H^3O^2 + C^2H^3O^2 - 4HO$, are very improbable.

Stearate, $C^{16}H^{18}O^{16}$ (Berthelot); more probably $C^{16}H^{18}O^8 = \frac{(C^4H^8)^2}{(C^2H^3O^2)^2} \cdot O^4$. Solid, waxy, neutral body, resembling stearates in general; insoluble in water, soluble in ether.

Sulphate, Erythromannisulphuric or *Erythroglucisulphuric Acid*, $C^6H^{10}SO^{11} = (C^6H^{12})^{11} \left\{ O^8 = 2C^6H^{10}O^4 + 3H^2SO^4 - 6H^2O \right.$ —Produced by dissolving 1 pt. erythro

$(SO_2)^3.H^2 \}$ mannite in 20 or 30 pts. of strong sulphuric acid, and heating the solution to 60° or 70° C. It has not been prepared in the free state; but the barium or lead-salt may be obtained by diluting with water, saturating with carbonate of barium or lead, and evaporating the filtrate, first at a gentle heat, then in vacuo. The *barium-salt*, $C^{10}H^{22}Ba^2SO^{28} + 6H^2O$, forms a hard brittle mass, easily soluble in water, insoluble in alcohol. The *calcium-salt*, $C^{10}H^{22}Ca^2SO^{28} + 6H^2O$, dries up over oil of vitriol to a brittle deliquescent mass, sparingly soluble in alcohol, decomposing at 105° C. The *lead-salt*, $C^{10}H^{22}Pb^2SO^{28} + 12H^2O$, forms needle-shaped crystals, soluble in water and in alcohol. (Hesse.)

Tartrate, Erythromannitaric Acid.—Obtained by heating erythromannite with tartaric acid to 100° C. According to Bertholot, it consists of $C^{14}H^{28}O^{38} = C^{12}H^{18}O^{12} + 4C^2H^2O^2 - 4H^2O$, and is sexbasic, its calcium-salt having the composition $C^4H^8Ca^2O^{12}$. Hesse suggests that it may be formed from 3 at. erythromannite; perhaps $3C^4H^{10}O^4 + 8C^2H^2O^2 - 8H^2O = C^{14}H^{28}O^{32}$.

ERYTHRONIUM. The name applied by Del Rio to a metal, which he regarded as new, contained in a peculiar lead-ore from Zimapan in Mexico. After the discovery of vanadium by Sefström, Wöhler showed that this mineral was vanadate of lead. (*Kopp's Geschichte der Chemie*, iv. 80.)

ERYTHROPHYLL. The red colouring matter of leaves in autumn. It is soluble in water and alcohol, and dissolves with brown colour in alkalis. With lead-salts it forms a precipitate of a fine green colour (Gerh. *Traité*, iv. 527). According to Morren (*Dissertation sur les feuilles vertes et colorées, envisagées spécialement au point de vue des rapports de la chlorophylle et de l'érythrophylle*, Gand, 1858; also N. Arch. ph. nat. v. 84), the red and blue colouring matters of plants are not formed from chlorophyll. The blue colouring matter, *anthocyan*, is probably, like litmus, the alkali-salt of an acid, which in the free state constitutes erythrophyll.

ERYTHROPROTIDE. A red extractive matter obtained by Mulder from albumin and allied substances. (See ALBUMIN.)

ERYTHRORETIN. A resinous constituent of rhubarb-root, soluble with purple-red colour in alkalis. (See RHUBARB.)

ERYTHROSE. The name given by Garot (J. Pharm. [3] xvii. 5) to the yellow or orange-coloured substance obtained by treating rhubarb with nitric acid, which however he allows to be a mixture. It dissolves in alkalis, forming red solutions (salts of *erythrosic acid*), which produce very deep stains. (See RHUBARB.)

ERYTHROSIN. Städeler's name for a red substance produced by the action of nitric acid on tyrosine. (Ann. Ch. Pharm. cxvi. 87.)

ERYTHROXYLINE. A crystalline substance resembling theine, obtained in small quantity from the leaves of *Erythroxylon coca*. (Gaedeke, Arch. Pharm. [2] lxxxii. 141; Jahresber. d. Chem. 1855, p. 724.)

ERYTHROXYLON COCA. See COCA (i. 1059).

ERYTHROZYME. An azotised substance which exists in madder root, and gives rise to a peculiar transformation of rubian. It is extracted by macerating madder in water at 38° C. and precipitating the aqueous extract with alcohol. (See MADDER and RUBIAN.)

ERYTHRYLIN. Impure erythric acid. (Kane, Ann. Ch. Pharm. xxxix. 31.)

ESCHERITE. A variety of epidote from the St. Gothard (probably from the Maggia Valley in Ticino), where it occurs in tuft-like masses on felspathic rocks, associated with prehnite, rock-crystal, and adularia. Specific gravity = 3.384. Gives by analysis, 37.70 to 37.62 per cent. silica, 27.49 to 27.22 alumina, 9.12 to 8.67 ferric oxide, 23.87 to 23.94 lime, and 2.33 water. (Stöckar-Escher, Pogg. Ann. xcv. 501.)

ESCHHOLTZIA CALIFORNICA. This papaveraceous plant contains, according to Walz (Jahrb. pr. Pharm. vii. 282; viii. 147, 209), colouring matters, citric and malic acids, a peculiar acid, and three alkaloids, viz. 1. An alkaloid forming red salts, and perhaps identical with cholerethrine (i. 847).—2. An alkaloid soluble in alcohol and ether, and forming bitter sharp-tasting salts; its properties are essentially those of chelidonine (i. 849). These two alkaloids are extracted from the plant by acidulated water, and precipitated by ammonia.—3. An alkaloid precipitated from the mother-liquor of the other two by tannic acid. It is crystalline, has a nauseous taste,

dissolves in water, alcohol, and ether; melts at a gentle heat, and forms salts, which, even in dilute solution, assume a splendid violet colour on addition of sulphuric acid. All these bodies require further investigation.

ESCHWEGITE. A mineral examined by Döbereiner (*Glocker's Synopsis*, p. 86), and said to contain ferrous oxide and silica.

ESCULIN. See *ÆSCULIN*.

ESENBECKINE. An alkaloid obtained from the bark of *Esenbeckia febrifuga*, Mart. *Feodia febrifuga*, Aug. Saint Hilaire. (Buchner, *Repert. Pharm.* xxxi. 481; xxxvii. 1.)

ESMARKITE. A variety of hydrous dichroite from Brevig in Finland. The term is also used as a synonyme of datholite, and appears also to have been applied to an altered form of scapolite. (Danu, ii. 205.)

ESPARSETTE. See *HEDYSARUM*.

ESRAR. A narcotic substance resembling tobacco, extracted from the leaves of *Atropa Mandragora*. (Landerer, *Buchn. Repert.* lxxxi. 290.)

ESSENCES. A term sometimes applied to volatile oils.

ESSONITE. A variety of lime-garnet.

ESTER. L. Gmelin's name for compound ethers derived from oxygen acids, e. g. acetate of ethyl = *Essigsäure-vinester*; sulphate of methyl = *Schwefelsaures Formyl-ester*.

ETHAL. Syn. with *CETYLIC ALCOHOL* (i. 841).

ETHALIC ACID. Syn. with *PALMITIC ACID*.

ETHALOL. The name applied by Berzelius to the hydrocarbon (cetene) produced by the action of phosphoric anhydride on cetyl alcohol.

ETHALONE or *Cetylone*. Syn. with *PALMITONE*.

ETHALYL. Syn. with *CETYL*.

ETHAMIDE, ETHAMINE, ETHAMMINE. Syn. with *ETHYLAMINE*.

ETHAMINE-SULPHURIC ACID. Syn. with *SULPHRETHAMIC ACID*.

ETHENE. Syn. with *ETHYLENE*.

ETHENIDES. Laurent's name for *Primary Nuclei*. (See *NUCLEUS*.)

ETHER. See *ETHYL*, *OXIDE OF*; also *ETHERS*.

ETHERENE. Syn. with *ETHYLENE*.

ETHERIFICATION. The conversion of alcohols into ethers. (See *ALCOHOL*, i. 76; *ALCOHOLS*, i. 99; *CHEMICAL AFFINITY*, i. 867; *ETHERS*, ii. 508.)

ETHERIN and **ETHEROL.** (Marchand, *J. pr. Chem.* xv. 1.—Serullas, *Ann. Ch. Phys.* [2] xxxix. 152; *Pogg. Ann.* xiv. 20.—Liebig, *Handw. d. Chem.* 1^{re} Aufl. i. 121.) When heavy oil of wine, the oily body which sometimes occurs among the residues of the preparation of ether, is warmed with water, a light oily liquid rises to the surface, which is a mixture of two substances, both polymeric with ethylene, viz. etherin and etherol. On decanting this liquid and leaving it at rest, the etherin crystallises out, while the etherol remains liquid. The etherin may be freed from etherol by filtration and pressure between paper, and then recrystallised from alcohol or ether.

Etherin forms transparent, colourless, shining prisms, moderately hard, very friable and grating between the teeth; it has no taste, but when heated smells like etherol. Melts at 110° C. Boils at 260°, without alteration. Insoluble in water, but soluble in alcohol, and still more so in ether.

Etherol is a yellowish, viscid liquid of specific gravity 0.921 (Serullas), boiling at 280° C. By exposure to cold, it becomes more viscid, but does not solidify even at -35° C. It has a peculiar aromatic odour, is insoluble in water, but dissolves easily in ether, less easily in alcohol. Potassium immersed in it retains its lustre undiminished.

Heavy oil of wine, which passes over in the preparation of ether towards the end of the distillation, when sulphurous anhydride and olefant gas are given off, is, according to Liebig, an ethylsulphate of etherol. On treating it with water, the etherol (holding the isomeric body etherin in solution) separates out, and ethylsulphuric acid remains in solution. An oil of similar character and composition is obtained by the distillation of perfectly dry ethylsulphates, the best process, according to Liebig, being to distil the dry potassium-salt with an equal weight of freshly burned lime. Mar-

chand recommends the distillation of dry ethylsulphate of lead. The crude product is freed from alcohol, ether, and sulphurous acid, by agitation with cold water, and drying in vacuo over oil of vitriol.

Light oil of wine, which is also obtained in the preparation of ether on the large scale appears to be impure etherol. When the crude ether is rectified with milk of lime, this substance remains after the ether has passed over, floating on the watery residue, in the form of a thick yellow oil, which is blackened by strong sulphuric acid, but separates as a colourless oil on addition of water.

ETHERINAMONE. Syn. with ETHYLAMINE.

ETHERIPLATINIC ACID. Syn. with ETHYLENE-CHLORIDE OF PLATINUM.

ETHEROL. See ETHERIN.

ETHERONE. A very volatile liquid, boiling at about 30° C., which passes over with the heavy oil of wine produced by the distillation of the ethyl-sulphates (Marchand J. pr. Chem. xv. 1). It appears to be identical with amylene.

ETHERS. The term *ether*, originally applied to oxide of ethyl, the volatile liquid produced by the action of sulphuric acid upon common alcohol, is now extended to a large class of compounds, formed by the action of acids on alcohols, and includes all salts of alcohol-radicles, that is to say, all such derivatives of the alcohols as are comparable with ordinary metallic salts, in the same sense as the alcohols themselves are comparable with metallic hydrates.

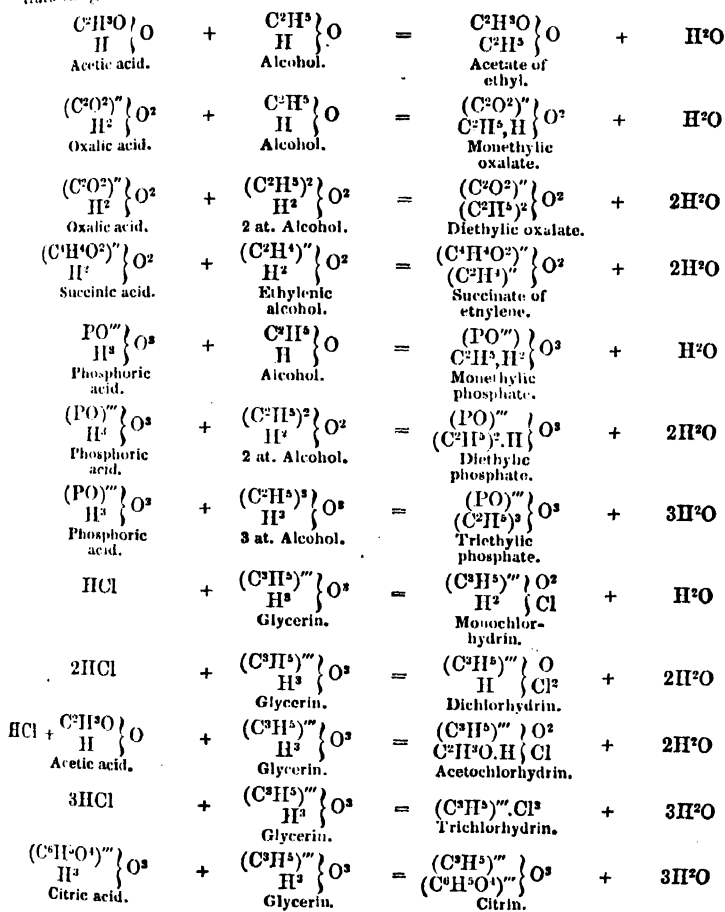

Some of these bodies, commonly called simple ethers (Gmelin's *Aether*), are the oxides of the alcohol-radicles, and may be regarded as the anhydrides of the alcohols, being related to them in the same manner as an anhydrous metallic oxide to its hydrate. With these may also be classed the sulphides, selenides, and tellurides of the alcohol-radicles. The remaining ethers, called compound ethers, which constitute by far the most numerous class, are analogous to metallic salts, and are usually subdivided into two groups, the one comprising the oxygen-salts of the alcohol-radicles (Gmelin's *Ester*), the other, the haloïd salts of those radicles, viz. the chlorides, bromides, iodides, fluorides, and cyanides (Gmelin's *Afer*). The former may be derived from a single or multiple molecule of water, in which part of the hydrogen is replaced by acid-radicles, and the remainder (not necessarily the whole) by alcohol-radicles, e.g.

The haloïd-compounds of the alcohol-radicles may be regarded as formed on the hydrogen-type nHH , the hydrogen being partly replaced by an alcohol-radicle, partly by chlorine, bromine, &c., e.g. *chloride of ethyl*, $\text{C}^2\text{H}^5\text{Cl}$, *dibromide of ethylene* $(\text{C}^2\text{H}^5)^2\text{Br}^2$, *tribromide of glyceryl* $(\text{C}^3\text{H}^5)''' \text{Br}^3$; or they may be derived from water regarded as H.HO , by supposing the HO replaced by an equivalent quantity of chlorine, &c., and the hydrogen by an alcohol-radicle. This mode of derivation may also evidently be extended to the oxygen-salts of the alcohol-radicles, the HO in the type being supposed to be replaced by the peroxide of an acid-radicle; in fact, it really amounts to regarding all the so-called compound ethers as formed upon the hydrogen or hydrochloric acid type: thus, *acetate of ethyl*, $\text{C}^2\text{H}^5\text{.C}^2\text{H}^5\text{O}^2$; *monethylic sulphate*, $\text{C}^2\text{H}^5 \left\{ \begin{matrix} \text{SO}^2 \end{matrix} \right\}$; *diethylic phosphate*, $\text{C}^2\text{H}^5 \left\{ \begin{matrix} \text{PO}^3 \end{matrix} \right\}$, &c. It is convenient in this respect—that it reduces all these compounds to the same type, which likewise includes a number of intermediate compounds, such as the chlorhydrins, chloracetins, &c.

The compound ethers contain the elements of an acid and an alcohol, *minus* a certain number of molecules of water. If the quantities of acid and alcohol concerned in the reaction are of equal atomicity, *i. e.* contain the same number of atoms of replaceable hydrogen, then the number of molecules of water eliminated in the formation of the ether corresponds for the most part to that number of hydrogen-atoms; but if the atomicities of the acid and alcohol are unequal, the number of molecules of water eliminated corresponds to the smaller atomicity of the two. With the monatomic alcohols, this rule is universally true, but the polyatomic alcohols present an exception to it, to be presently noticed. The following examples will suffice to illustrate the general rule:—

In all these cases, the resulting ether is of the same degree of atomicity as the higher of the two bodies concerned in its formation; but the polyatomic alcohols are capable of forming ethers, with elimination of a number of molecules of water greater than that indicated by the preceding rule, thereby yielding compounds of a lower type; thus:—

See also the BROMHYDRINS (i. 668), and GLYCIDE.

When the process of etherification is so conducted that the compound ether and the water produced remain in contact, they react upon each other, tending to reproduce the

original acid and alcohol. Unless, therefore, the water is removed as fast as it is formed, the quantity of the compound ether produced is always less than that which the given quantities of acid and alcohol are capable of yielding. The manner in which the quantity of ether ultimately formed, and the rapidity of the action, are affected by the nature of the acid and alcohol, their relative quantities, the temperature, and other conditions of the reaction, has been examined by Berthelot and Péan de Saint-Gilles (Compt. rend. liii. 474; lv. 39, 210 and 324; Rép. Chim. pure 1862, pp. 1, 325, 327, 369), who have obtained the following results:—

1. The quantities of acid and alcohol which *ultimately* enter into combination are independent of the temperature and pressure at which the reaction takes place, and are but little affected by the particular nature of the acid and alcohol concerned, the variations observed appearing to depend on accidental causes.

2. The *rapidity of combination*, or, in other words, the quantity of the compound ether formed in a given time, varies with the nature of the acid and the alcohol, and with the proportions in which they are mixed.

a. The rapidity of combination of an acid of the series $C^nH^{2n}O^2$ with an alcohol, is less in proportion as the atomic weight of the acid is greater, and its boiling point higher.

The same law applies to monobasic acids of different series; thus, acetic acid etherifies alcohol more quickly than benzoic acid.

Polybasic acids etherify alcohols more quickly than monobasic acids.

b. Alcohols of the same series, $C^nH^{2n+2}O$, for example, are etherified by any given acid with nearly equal rapidity, how much soever their molecular weights may differ. This is not true, however, with regard to alcohols of different series; thus, glycerin unites with acetic acid at common temperatures much more readily than common alcohol.

c. With a given quantity of acid, the quantity of ether ultimately produced increases with the quantity of alcohol present; but the rapidity of combination is diminished by an excess of alcohol at the beginning of the action, and increased thereby as it approaches the limit.

d. With a given quantity of alcohol, the quantity of ether ultimately formed increases with the proportion of acid present. At ordinary temperatures, the rapidity of combination is for the most part diminished by excess of acid at first and accelerated afterwards. With 5 at. of a monobasic acid to 5 at. of a monatomic alcohol, the rate of combination is accelerated, even from the beginning. At $100^\circ C$. the accelerating influence of an excess of acid is still more marked.

3. The ethers of monobasic acids resist the action of water longer than those of polybasic acids. The amount of resistance which a compound ether offers to the decomposing action of water is determined by the nature of the acid, not of the alcohol, concerned in its formation. In general, the ethers corresponding to acids which are most difficult to etherify, are likewise those which offer the greatest resistance to the action of water; thus butyrate of ethyl is less easily decomposed than the acetate, and this less easily than the formate.

The quantity of an ether decomposed by water increases with the quantity of water present; but ethers are never completely decomposed, even by a very great excess of water; neither can such an excess completely prevent the combination of an alcohol and an acid, though it diminishes the total quantity of ether produced.

4. Pressure appears to influence the phenomena of etherification, as well as of other kinds of chemical action, not directly, but only so far as it affects the proximity of the molecules of the acting substances. Hence when both bodies are in the liquid state, which admits of but little variation in the molecular intervals, the result is but slightly affected even by great variations of pressure; but when the acting bodies are wholly or partly in the gaseous state, as when acetic acid and alcohol are heated together in closed vessels to $200^\circ C$., the action is retarded by diminution of pressure. On the other hand, the authors' experiments have brought out the somewhat unexpected result that the limit of the quantity of ether producible from a given quantity of an acid and alcohol, becomes greater as the intermolecular distance is increased.

We proceed to enumerate some of the principal ethers, and give a general view of their formation and reactions.

Ethers containing Monatomic Alcohol-radicles.

1. Oxides.

Methylic oxide	$\left. \begin{matrix} CH^* \\ CH^* \end{matrix} \right\} O$	Ethylic oxide	$\left. \begin{matrix} C^*H^* \\ C^*H^* \end{matrix} \right\} O$
Methyl-ethylic oxide	$\left. \begin{matrix} CH^* \\ C^*H^* \end{matrix} \right\} O$	Ethyl-tetrylic oxide	$\left. \begin{matrix} C^*H^* \\ C^*H^* \end{matrix} \right\} O$

Tetrylic oxide	$\left. \begin{matrix} C^4H^9 \\ C^4H^9 \end{matrix} \right\} O$	Octylic oxide	$\left. \begin{matrix} C^8H^{17} \\ C^8H^{17} \end{matrix} \right\} O$
Methyl-amylie oxide	$\left. \begin{matrix} C^6H^9 \\ C^5H^{11} \end{matrix} \right\} O$	Ethyl-cetylic oxide	$\left. \begin{matrix} C^2H^5 \\ C^{16}H^{33} \end{matrix} \right\} O$
Ethyl-amylie oxide	$\left. \begin{matrix} C^2H^5 \\ C^5H^{11} \end{matrix} \right\} O$	Cetylic oxide	$\left. \begin{matrix} C^{16}H^{33} \\ C^{16}H^{33} \end{matrix} \right\} O$
Amylic oxide	$\left. \begin{matrix} C^5H^{11} \\ C^5H^{11} \end{matrix} \right\} O$	Allylic oxide	$\left. \begin{matrix} C^3H^5 \\ C^3H^5 \end{matrix} \right\} O$
Methyl-octylic oxide	$\left. \begin{matrix} C^8H^9 \\ C^8H^{17} \end{matrix} \right\} O$	Ethyl-allylic oxide	$\left. \begin{matrix} C^2H^5 \\ C^3H^5 \end{matrix} \right\} O$
Ethyl-octylic oxide	$\left. \begin{matrix} C^2H^5 \\ C^8H^{17} \end{matrix} \right\} O$	Phenylic oxide	$\left. \begin{matrix} C^6H^5 \\ C^6H^5 \end{matrix} \right\} O$
Amyl-octylic oxide	$\left. \begin{matrix} C^5H^{11} \\ C^8H^{17} \end{matrix} \right\} O$	Benzylic oxide	$\left. \begin{matrix} C^7H^7 \\ C^7H^7 \end{matrix} \right\} O$

The compounds obtained by the action of potassium or sodium on the alcohols, such as *ethyl-sodic oxide*, *ethylate of sodium*, or *sodium-alcohol*, C^2H^5NaO , are bodies of analogous constitution; but as the metal is easily replaceable by an alcohol-radicle, they are perhaps more like alcohols than ethers. The oxides of some of the organo-metallic bodies, such as oxide of cacodyl (C^2H^5As) 2O , are also analogous in composition to those in the preceding lists, but they are not usually classed as ethers.

The simple ethers are produced: 1. By the action of the iodides, bromides, or chlorides of the alcohol-radicles on the potassium- or sodium-alcohols, *e.g.*:

2. By distilling an alcohol or a mixture of two alcohols with sulphuric acid (i. 76, 78).

Oxide of methyl is gaseous; oxide of cetyl and ethyl-cetylic oxide are solid and crystalline; all the other ethers in the preceding list are liquids, more or less mobile, and capable of volatilising without decomposition. They are all neutral to vegetable colours. With *acids* they behave, for the most part, like the alcohols; thus oxide of ethyl treated with sulphuric acid, yields acid sulphate of ethyl, and with hydrochloric acid, chloride of ethyl. *Persulphide of phosphorus* transforms them into sulphides. Altogether, however, they are less energetic in their chemical relations than the alcohols, just as anhydrous metallic oxides act, for the most part, less energetically than the corresponding hydrates.

The simple ethers, treated with *chlorine*, yield chlorinated ethers, such as $(CH^2Cl)^2O$, $(CHClCl)^2O$, &c. By treating dichlorethylie ether $(C^2H^3Cl)^2O$ with *zinc-ethyl*, an atom of chlorine is removed, and its place supplied by ethyl, forming the compound $C^2H(C^2H^3)\{O\}$; and this product again treated with zinc-ethyl, yields the compound $C^2H(C^2H^3)\{O\}$. (Lieben and Bauer, Ann. Ch. Pharm. cxxiii. 130.)

2. Sulphides, Selenides, and Tellurides of Monatomic Alcohol-radicles.

The protosulphides of the monatomic alcohol-radicles, called *sulphydric ethers*, are exactly analogous in composition to the oxides, *e.g.* *sulphide of ethyl* = $C^2H^3\{S\}$. They are produced by the action of the chlorides, iodides, or sulphates of the corresponding alcohol-radicles on the protosulphides of the alkali-metals, *e.g.*:

Also by the action of pentasulphide of phosphorus on the corresponding oxygen-ethers:

By these means, the sulphides of *methyl*, *ethyl*, *amyl*, *octyl*, *cetyl*, and *allyl* have been obtained; the last-mentioned sulphide is also the essential constituent of volatile oil of garlic (i. 143).

These compounds, which are the ethers of the sulphydric alcohols, or mercaptans, are fetid oils or crystalline solids, insoluble in water. Treated with *nitric acid*, they yield monobasic acids containing sulphur and oxygen: sulphide of ethyl, for example, yields ethyl-sulphurous acid, $\begin{matrix} \text{C}^2\text{H}^5\text{H} \\ (\text{SO})'' \end{matrix} \text{O}^2$. With *chlorine*, they yield substitution-products.

Sulphides containing two alcohol-radicles, analogous to methyl-ethyl oxide, &c., are obtained by heating in a sealed tube a mixture of an alcohol with the disulphophosphate of another alcohol-radicle, thus:

Ethyl-amylic sulphide, $\text{C}^2\text{H}^5\text{C}^3\text{H}^{11}\text{S}$, is obtained in a similar manner. These compounds are volatile liquids, resembling the simple alcoholic sulphides in their physical and chemical properties. (Carius, Ann. Ch. Pharm. cxix. 313.)

The mercaptans treated with metals or metallic oxides, yield sulphides containing a metal and an alcohol-radicle; thus ethylic mercaptan treated with sodium yields *ethylo-sodic sulphide*, $\text{C}^2\text{H}^5\text{NaS}$. Such compounds treated with the iodide of another alcohol-radicle, appear to yield mixed alcoholic sulphides, like those above mentioned. See Ann. Ch. Pharm. cxx. 62.

Persulphides of alcohol-radicles, such as CH^3S , $\text{C}^2\text{H}^5\text{S}$, analogous to peroxide of hydrogen, are obtained by the action of the chlorides or acid sulphates of those radicles on the persulphides of the alkali-metals. They are related to the protosulphides above mentioned in the same manner as peroxide of hydrogen to water. They are fetid liquids, heavier than water, and volatile without decomposition. With nitric acid, they yield the same products as the protosulphides. Their alcoholic solutions yield white precipitates with acetate of lead and mercuric chloride.

The selenides and tellurides of the alcohol-radicles, e.g. $(\text{C}^2\text{H}^5)_2\text{Se}$ and $(\text{C}^2\text{H}^5)_2\text{Te}$, are obtained like the corresponding sulphides, viz. by distilling a metallic selenide or telluride with an ethyl-sulphate, or homologous salt, e.g.:

The *methyl*-, *ethyl*-, and *amyl*-compounds of *selenium* and *tellurium* have been obtained. They are extremely fetid oily liquids, heavier than water. By exposure to the air, they are converted into basic oxides, e.g. $(\text{C}^2\text{H}^5)_2\text{SeO}$, capable of forming salts with acids. They are likewise oxidised by nitric acid and converted into nitrates. This basic property of the alcoholic selenides and tellurides, which is possessed in a slight degree only by the corresponding sulphides, approximates them to the organo-metallic bodies, the arsenethylys, stannethylys, &c.

3. Oxygen-salts of Monatomic Alcohol-radicles.

a. Containing Monatomic Acid-radicles.

These ethers may be derived from monobasic acids by the substitution of an alcohol-radicle for the basic hydrogen. They are very numerous; in fact, every monobasic acid appears to be capable of forming such compounds, at least with the alcohol-radicles containing but a small number of carbon-atoms, such as methyl and ethyl. They are produced:

1. By the action of a silver-salt on the iodide, bromide, or chloride of an alcohol-radicle:

2. By the reaction of an acid with an alcohol, especially with aid of heat:

3. By distilling a metallic salt with sulphuric acid and an alcohol, or by passing hydrochloric acid gas into an alcoholic solution of an acid.—4. By the dry distillation of a metallic salt of an acid ether (e.g. ethyl-sulphate of potassium) with the salt of another acid:

5. By the solution of an acid anhydride in an alcohol:

6. By the action of an acid chloride on an alcohol:

The stronger mineral acids, such as sulphuric and nitric acid, etherify the alcohols directly; oxalic acid etherifies ethylic alcohol when the latter is added drop by drop to the acid at a high temperature. Sometimes the etherification takes place gradually when the acid and the alcohol are mixed together, and exposed for some days to a gentle heat; such, according to Liebig, is the case with oxalic acid. Generally speaking, however, organic acids etherify the alcohols only when assisted by sulphuric or hydrochloric acid, or when heated for a long time with the alcohol in sealed tubes. The mineral acid probably acts by abstracting the water set free in the etherification; or its influence may be similar to that which, according to Berthelot and Péan de Saint-Gilles (p. 510), is produced by an excess of the etherifying acid. The alcohols are etherified by anhydrides much more quickly than by acids, and still more easily by the chlorides of the acid radicles. Some organic acids (benzoic, butyric, palmitic) produce compound ethers when heated with the simple ethers (oxides) to 360° or 400° C. in a sealed tube. (Berthelot.)

The monatomic oxygen-ethers are liquid or solid bodies volatile without decomposition. The boiling point of a monatomic methyl-ether is about 63° C. below that of the corresponding acid, that of an ethyl-ether about 44° C. below that of the acid. They are insoluble or sparingly soluble in water, but mix in all proportions with common alcohol and ether. They do not immediately exhibit the reactions of the acids from which they are derived; but by prolonged contact with water, they are resolved more or less quickly, especially at the boiling heat, into acid and alcohol, *e.g.*:

This transformation is more quickly effected by boiling with *caustic alkalis*, especially in alcoholic solution; it is likewise produced by the stronger acids, such as sulphuric or hydrochloric acid. The ethers may be distinguished one from the other by the properties of the acid and alcohol thus obtained from them.

The monatomic compound ethers are converted by ammonia into an alcohol and an amide, *e.g.*:

The ethers are likewise decomposed by the more basic *anhydrous oxides*, when heated therewith in sealed tubes, the action being similar to that which takes place with the alkaline hydrates, excepting that, instead of an alcohol, a metallic alcoholate is formed in the first instance, and this, when treated with water, yields the alcohol and a metallic hydrate. The following equations exhibit the reactions with a hydrated and an anhydrous oxide.

(Berthelot and Fleuriu, Compt. rend. li. 1020).

The cyanates of the alcohol-radicles form a group of monatomic ethers, which are distinguished by particular reactions, inasmuch as, under the influence of water and alkalis, they split up as if they were formed on the ammonia-type instead of the water-type; thus cyanate of ethyl may be represented either as $\begin{array}{c} \text{C}^2\text{H}^5 \\ \text{CN} \end{array} \text{O}$ or as

$\text{N} \begin{array}{c} \text{C}^2\text{H}^5 \\ (\text{CO}) \end{array}$. Accordingly, when treated with water, they yield compound ureas; also when treated with ammonia, ethylamine, phenylamine, and other organic bases. When distilled with caustic alkalis, they yield an alkaline carbonate and an amine. (See CYANIC ETHERS, p. 195.)

Another class of monatomic ethers requiring special notice are the amethanes, or

ethers of amic acids. They are obtained by the action of ammonia on the neutral ethers of the dibasic acids, from which the amic acids are derived; thus

The alcoholic carbamates, or carbamethanes, or urethanes, may also be obtained by the action of ammonia on the chlorocarbonic ethers (i. 916), e. g.:

or by the action of cyanic acid vapour, or gaseous chloride of cyanogen, on the alcohols:

The oxamates of methyl, ethyl, and amyl have been obtained; also the carbamates of the same radicles, together with carbamate of tetryl.

The amethanes are solid, crystallisable bodies, which are converted by ammonia into an alcohol and a diamide:

They are decomposed by alkalis, by boiling mineral acids, and partially by water, the carbamethanes yielding an alcohol, ammonia, and carbonic anhydride, the oxamethanes the same products, with addition of carbonic oxide:

The acids formed from carbamic acid by the substitution of an alcohol-radicle for part of the hydrogen in the ammonium-molecule may also be mentioned here: e.g. ethyl-carbamic acid, $\left\{ \begin{array}{c} \text{NH}(\text{C}^2\text{H}^5)(\text{CO}) \\ \text{H} \end{array} \right\} \text{O}$ (i. 751).

A few monatomic compound ethers are known, in which the oxygen is wholly or partly replaced by sulphur, viz. *thiacetate of ethyl*, $\left\{ \begin{array}{c} \text{C}^2\text{H}^5 \\ \text{C}^2\text{H}^5\text{O} \end{array} \right\} \text{S}$, and the *sulphocyanic ethers*, such as *sulphocyanate of ethyl*, $\left\{ \begin{array}{c} \text{C}^2\text{H}^5 \\ \text{Cy} \end{array} \right\} \text{S}$, and *sulphocyanate of allyl*, $\left\{ \begin{array}{c} \text{C}^2\text{H}^5 \\ \text{Cy} \end{array} \right\} \text{S}$, which is the principal constituent of volatile oil of mustard.

b. Containing Diatomic Acid-radicles.

These ethers may be derived from dibasic acids by the partial or total replacement of the typic hydrogen by a monatomic alcohol-radicle. The ether is acid or neutral, according as half or the whole of the typic hydrogen is thus replaced.

The neutral diatomic ethers of monatomic alcohol-radicles are produced by the same reactions as the monatomic compound-ethers (p. 512). When the corresponding acids are not volatile without decomposition, these ethers (those of malic and tartaric acids, for example) are decomposed by distillation, and cannot therefore be prepared by that process. They are usually obtained by passing hydrochloric acid gas into a solution of the organic acid in the alcohol, neutralising the resulting liquid with carbonate of sodium, then shaking it up with common ether, which dissolves the compound ether produced, and evaporating the solvent.

The following are examples of these ethers:

There are also diatomic ethers containing two different alcohol-radicles: they are obtained by distilling a salt of an acid diatomic ether with a salt of ethyl-sulphuric or an analogous acid (Chancel), *e.g.*:

The *neutral diatomic ethers of monatomic alcohol-radicles* are resolved by the action of water, or more quickly by that of a *caustic alkali*, into an alcohol and a salt of an acid ether, or into an alcohol and a salt of the corresponding acid:

Ammonia, according to the proportion in which it is added, converts the diatomic ethers into an alcohol and an ether of an amic acid (an amethane), or into an alcohol and a diamide:

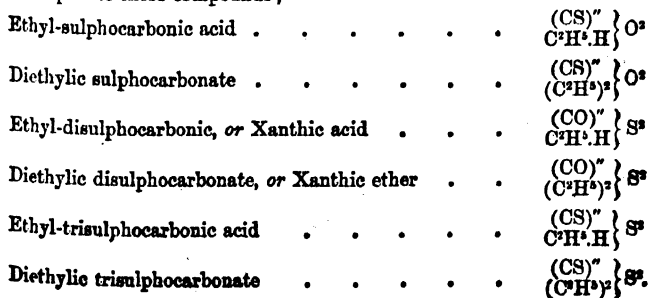

The *diatomic acid ethers of monatomic alcohol-radicles* are produced by heating the alcohols with certain dibasic acids, or by treating a neutral diatomic ether (oxalate of ethyl for example) with only half the quantity of alkali required to resolve it completely into acid and alcohol (see above).

These acid ethers in the free state are for the most part rather unstable, being easily resolved into acid and alcohol by boiling with water or with an alkali. Most of them are decomposed by distillation. They are monobasic acids, and form salts which are usually more stable than the acids themselves, and serve for the preparation of other ethers by double decomposition; *e.g.*:

The *sulphocarbonic ethers* are diatomic ethers, similar in constitution to those just described, but having the oxygen more or less replaced by sulphur. The following are examples of these compounds;

The disulphocarbopates, acid and neutral, of *methyl* and *amyl*, are known; also *cetyl*disulphocarbonic acid.

These ethers may also be regarded as compounds of carbonic anhydride, or of disulphide of carbon, with the protoxides, protosulphides, hydrates, or sulphydrates of alcohol-radicles; *e.g.* *xanthic acid* = $\text{CS}^2.(\text{C}^2\text{H}^5.\text{H}.\text{O})$; *xanthic ether* = $\text{CS}^2.(\text{C}^2\text{H}^5)^2\text{O}$.

There are likewise ethers consisting of carbonic anhydride or disulphide of carbon combined with an alcoholic persulphide; *e.g.*

Ethyl-sulphocarbonic persulphide or Dicarbonate of ethylic persulphide $\text{CO}^2.\text{C}^2\text{H}^5\text{S}$.

Ethyl-disulphocarbonic persulphide or Dioxysulphocarbonate of ethyl $\text{C}_\text{S}^{\text{O}}\}\text{C}^2\text{H}^5\text{S}$.

The *methyl*- and *amyl*-disulphocarbonic persulphides are also known.

For the formation and properties of all these compounds, see SULPHOCARBONIC ETHERS.

The chlorocarbonic ethers (i. 916), derived from the carbonic ethers by the substitution of an atom of chlorine for a molecule of the peroxide of an alcohol-radicle, *e.g.* *carbonate of ethyl* = $(\text{CO})^2.\text{C}^2\text{H}^5\text{O}.\text{C}^2\text{H}^5\text{O}$; *chlorocarbonate of ethyl* = $(\text{CO})^2.\text{C}^2\text{H}^5\text{O}.\text{Cl}$, also belong to this place.

c. Containing Triatomic Acid-radicles.

These ethers are derived from tribasic acids by the partial or total substitution of an alcohol-radicle for the basic hydrogen. Every tribasic acid is capable of forming three such ethers, which are dibasic, monobasic, or neutral, according as 1, 2, or 3 at. hydrogen are thus replaced. Thus from citric acid are formed

Ethers of aconitic, arsenic, boric, chelidonic, citric, cyanuric, meconic, phosphorous and phosphoric acids have likewise been obtained. The mode of formation and the reactions of these ethers are, for the most part, similar to those of the diatomic ethers (p. 515).

The diethylic and triethylic phosphates are produced simultaneously by heating alcohol with phosphoric anhydride in sealed tubes:

and in like manner, alcohol heated with sulphophosphoric anhydride (pentasulphide of phosphorus) yields diethylic and triethylic disulphophosphates:

A precisely similar reaction is obtained with *methylic alcohol* and the pentasulphide. With *amyllic alcohol*, however, the products are diamyllic disulphophosphate, and triamyllic tetrasulphophosphate, $\text{PS}(\text{C}^2\text{H}^{11})^2\text{S}^2$, probably thus:

All these sulphophosphoric ethers are oily, disagreeable-smelling liquids; the neutral ethers are insoluble, or nearly so, in water; the acid ethers soluble; they are all soluble in common alcohol and ether. The acid ethers form crystalline salts with metals. (Carius, Ann. Ch. Pharm. cxii. 190; Kowalevsky, *ibid.* cxix. 303.)

4. Haloïd Salts of Monatomic Alcohol-radicles.

The chlorides, bromides, &c., of these radicles may be regarded as formed from the alcohols by the substitution of Cl, Br, &c., for HO; *e.g.* methylic alcohol $\text{CH}^3.\text{HO}$; chloride of methyl $\text{CH}^3.\text{Cl}$. They are produced by the action of the chlorides, bromides, and iodides of hydrogen, the metals, or phosphorus on the alcohols. They are mostly liquid at ordinary temperatures; chloride of methyl, however, is gaseous. They are decomposed by potash, especially in alcoholic solution, and by moist oxide of silver, yielding the corresponding alcohols, and a metallic

These compounds are isomeric with the aldehydes of the fatty acids, *e.g.* oxide of ethylene with acetic aldehyde (i. 105).

Oxide of ethylene, produced by the action of potash on glycolic chlorhydrin $(C^2H^4)^{\cdot}HO.Cl$, is a very volatile liquid, possessing strong basic properties, and capable of uniting directly with a considerable number of bodies, *viz.* with hydrogen, oxygen, bromine, water, ammonia (Wurtz), and sulphydric acid (Foster). Its vapour-density shows that its molecule contains the same quantity of ethylene as the molecule of the corresponding alcohol $(C^2H^4)^{\cdot}.H^2.O^2$. In this respect it differs from the ethers of the monatomic alcohols, whose molecules contain twice as much of the alcohol-radicle as those of the alcohols themselves, *e.g.* ethylic alcohol = $C^2H^5.H.O$, ethylic ether = $C^2H^5.C^2H^5.O$.

The oxides of tritylone and amylene are obtained in like manner, exhibit corresponding relations, and their molecules likewise contain the same quantity of the alcohol-radicles as the alcohols from which they are derived. It appears, then, that the ethers of both monatomic and diatomic alcohols are related to those alcohols in the same manner as the anhydrides of the monobasic and dibasic acids are related to those acids, thus :

Monatomic.		Diatomic.	
Ethylic alcohol.	Ethylic ether.	Ethylene alcohol.	Ethylene ether.
$\begin{array}{c} C^2H^3 \\ H \end{array} \left. \vphantom{\begin{array}{c} C^2H^3 \\ H \end{array}} \right\} O$	$\begin{array}{c} C^2H^4 \\ C^2H^4 \end{array} \left. \vphantom{\begin{array}{c} C^2H^4 \\ C^2H^4 \end{array}} \right\} O$	$\begin{array}{c} (C^2H^4)^{\cdot} \\ H^2 \end{array} \left. \vphantom{\begin{array}{c} (C^2H^4)^{\cdot} \\ H^2 \end{array}} \right\} O^2$	$(C^2H^4)^{\cdot}O$.
Acetic acid.	Acetic anhydride.	Sulphuric acid.	Sulphuric anhydride.
$\begin{array}{c} C^2H^3O \\ H \end{array} \left. \vphantom{\begin{array}{c} C^2H^3O \\ H \end{array}} \right\} O$	$\begin{array}{c} C^2H^3O \\ C^2H^3O \end{array} \left. \vphantom{\begin{array}{c} C^2H^3O \\ C^2H^3O \end{array}} \right\} O$	$\begin{array}{c} (SO^2)^{\cdot} \\ H^2 \end{array} \left. \vphantom{\begin{array}{c} (SO^2)^{\cdot} \\ H^2 \end{array}} \right\} O^2$	$(SO^2)^{\cdot}O$.

The molecule of a diatomic anhydride differs from that of the corresponding hydrate, by 1 at. water; thus: $C^2H^4O^2 - H^2O = C^2H^3O$; and $SH^2O^2 - H^2O = SO^2$. In the corresponding monatomic compounds, this relation does not exist.

A body having the percentage composition of oxide of methylene, CH^2O , is obtained by the action of iodide of methylene on oxide or oxalate of silver, or of acetate of methylene on oxide of lead (Buttlerow); but it is not analogous to oxide of ethylene, for its vapour-density shows that its molecule contains 2 at. of methylene $(CH^2)^2O^2$. Moreover, it is a crystalline solid, much less volatile than oxide of ethylene, and apparently quite destitute of basic properties. It cannot, therefore, be regarded as the first term of the series of diatomic ethers $(C^2H^{2n})^{\cdot}O$.

2. Oxygen-salts of Diatomic Alcohol-radicles.

These are the compound ethers of the glycols or diatomic alcohols, and may be derived from two (or $2n$) molecules of water by the substitution of diatomic alcohol-radicles for one portion of the hydrogen, and of acid radicles for the remainder or for a portion of it. The following are examples of the formulæ:—

Diacetate of methylene (neutral)	$\begin{array}{c} (CH^2)^{\cdot} \\ (C^2H^3O)^{\cdot} \end{array} \left. \vphantom{\begin{array}{c} (CH^2)^{\cdot} \\ (C^2H^3O)^{\cdot} \end{array}} \right\} O^2$
Monoacetate of ethylene (basic)	$\begin{array}{c} (C^2H^4)^{\cdot} \\ C^2H^3O.H \end{array} \left. \vphantom{\begin{array}{c} (C^2H^4)^{\cdot} \\ C^2H^3O.H \end{array}} \right\} O^2$
Diacetate of ethylene (neutral)	$\begin{array}{c} (C^2H^4)^{\cdot} \\ (C^2H^3O)^{\cdot} \end{array} \left. \vphantom{\begin{array}{c} (C^2H^4)^{\cdot} \\ (C^2H^3O)^{\cdot} \end{array}} \right\} O^2$
Aceto-butyrate of ethylene (neutral)	$\begin{array}{c} (C^2H^4)^{\cdot} \\ C^2H^3O \\ C^2H^3O \end{array} \left. \vphantom{\begin{array}{c} (C^2H^4)^{\cdot} \\ C^2H^3O \\ C^2H^3O \end{array}} \right\} O^2$
Monoethylate of ethylene (basic)	$\begin{array}{c} (C^2H^4)^{\cdot} \\ C^2H^5.H \end{array} \left. \vphantom{\begin{array}{c} (C^2H^4)^{\cdot} \\ C^2H^5.H \end{array}} \right\} O^2$
Diethylate of ethylene (neutral)	$\begin{array}{c} (C^2H^4)^{\cdot} \\ (C^2H^5)^{\cdot} \end{array} \left. \vphantom{\begin{array}{c} (C^2H^4)^{\cdot} \\ (C^2H^5)^{\cdot} \end{array}} \right\} O^2$
Oxalate of ethylene	$\begin{array}{c} (C^2H^4)^{\cdot} \\ (C^2O^2)^{\cdot} \end{array} \left. \vphantom{\begin{array}{c} (C^2H^4)^{\cdot} \\ (C^2O^2)^{\cdot} \end{array}} \right\} O^2$

The following have likewise been obtained:—The *monobutyrate*, *monovalerate*, *dibutyrate*, *divalerate*, *aceto-valerate*, *diacetate*, and *dibenzoate of ethylene*; and the *monoacetate of tritylene*, *tetrylene* and *amylene*; also several polyethylenic acetates of the general formula, $\begin{array}{c} (C^2H^4)^{\cdot} \\ (C^2H^3O)^{\cdot} \end{array} \left. \vphantom{\begin{array}{c} (C^2H^4)^{\cdot} \\ (C^2H^3O)^{\cdot} \end{array}} \right\} O^{n+1}$. *Sulphocyanate of ethylene* $\begin{array}{c} (C^2H^4)^{\cdot} \\ C_2^2 \end{array} \left. \vphantom{\begin{array}{c} (C^2H^4)^{\cdot} \\ C_2^2 \end{array}} \right\} S^2$, may also be mentioned as analogous in constitution to the neutral ethers in the preceding table.

The compounds of benzylene, C^6H^4 (i. 577), are likewise analogous in composition to the glycol-ethers; but they are perhaps not strictly comparable therewith; for they are all formed by double decomposition from the chloride of benzylene $(C^6H^4)''Cl^2$, which is produced by the action of pentachloride of phosphorus on hydride of benzoyl. Now it is known that aldehyde (hydride of acetyl), treated with the same reagent, yields not chloride of ethylene (Dutch liquid), but an isomeric body called chloride of ethyldene (i. 107). Hence it is probable that chloride of benzylene (chlorobenzol), and the compounds produced from it, are not true glycol-ethers. Similar observations apply to the compounds of allylene, C^3H^4 (i. 147).

The neutral ethers of diatomic alcohol-radicles are obtained by the action of silver-salts on the bromides or iodides of the corresponding alcohol-radicles, *e. g.* :

They are oily liquids, miscible in all proportions with common alcohol and ether; the acetates of methylene, ethylene, and tritylene are soluble in water, the rest are nearly or quite insoluble. They are easily decomposed by alkalis into a diatomic alcohol and a metallic salt of the acid.

3. Haloid Salts of Diatomic Alcohol-radicles.

The chlorides, bromides, &c., of these radicles may be derived from the diatomic alcohols in the same manner as the monatomic chlorides, &c., from their corresponding alcohols, viz. by the substitution of Cl, Br, &c., for an equivalent quantity of peroxide of hydrogen. But as there are 2 at. HO to be thus replaced, the substitution may be total or partial, producing in the one case a neutral, in the other a basic chloride, bromide, &c., *e. g.* :

Glycol	$(C^2H^4)''HO.HO$
Glycolic Chlorhydrin	$(C^2H^4)''HO.Cl$
Dichloride of Ethylene	$(C^2H^4)''Cl.Cl$

In the basic compounds, the remaining atom of hydrogen may be replaced by an acid radicle (or the remaining HO by the peroxide of an acid radicle), *e. g.* :

Glycolic Iodacetin	$(C^2H^4)''C^2H^3O^2.I$
Glycolic Chlorobutyryn	$(C^2H^4)''C^4H^7O^2.Cl$

The dichlorides, &c., of the diatomic alcohol-radicles are produced by the direct combination of these radicles with chlorine, bromine, and iodine, or by the action of perchloride or bromide of phosphorus on the corresponding diatomic alcohols or their basic haloid salts. The first mentioned reaction is characteristic of the diatomic alcohol-radicles, and serves to separate those which are gaseous from mixtures of gases and vapours in which they occur. Most of these compounds are oily liquids; but iodide of ethylene and its higher homologues are solid at common temperatures. Alcoholic potash converts them into the chlorides of monatomic radicles.

The basic haloid compounds of ethylene are oily liquids, whose reactions are similar to those of the monatomic alcoholic chlorides, bromides, &c.; but when treated with alkalis, they yield the corresponding diatomic oxides (p. 617).

Ethers containing Triatomic Alcohol-radicles.

The only compounds of this group at present known are the glycerides, which are derived from a molecule of glycerin, $(C^3H^5)''' \left\{ \begin{smallmatrix} O^2 \\ H \end{smallmatrix} \right\}$, by the substitution of acid radicles for 1, 2, or 3 at. hydrogen, *e. g.* :

Monostearin.	Distearin.	Tristearin.
$(C^3H^5)''' \left\{ \begin{smallmatrix} O^2 \\ H \end{smallmatrix} \right\} O^2$	$(C^3H^5)''' \left\{ \begin{smallmatrix} O^2 \\ H \end{smallmatrix} \right\} O^2$	$(C^3H^5)''' \left\{ \begin{smallmatrix} O^2 \\ O^2 \\ O^2 \end{smallmatrix} \right\} O^2$

These glycerides are produced by heating glycerin with the respective acids in sealed tubes in the required proportions. Most of those which have hitherto been formed contain only monatomic acid radicles; many of those in which 3 at. hydrogen are thus replaced, exist as natural fats.

A few glycerides have also been formed containing diatomic and triatomic, as well as monatomic acid radicles (Van Bemmelen, J. pr. Chem. lxxix. 84), *e. g.* :

All these glycerides are oily liquids or solid fats, which, when boiled with alkalis, are resolved into glycerin and an alkali-salt of the acid contained in them. This is the reaction which takes place in the ordinary process of soap-making or saponification.

Glycerides are also known containing monatomic alcohol-radicles, *e. g.* :

For the preparation and properties of these compounds, see GLYCERIDES.

Berthelot obtained oxide of glyceryl, or glyceric ether, $\left\{ \begin{array}{c} \text{C}^6\text{H}^5 \\ \text{C}^3\text{H}^3 \end{array} \right\} \text{O}^2$, by the action of potash upon iodhydrin.

The triatomic haloid-compounds of the alcohol-radicles resemble the corresponding diatomic compounds (p. 518) in their constitution and many of their properties.

The haloid-compounds of glycerin are obtained by heating that liquid with hydrochloric, hydrobromic acid, &c., in sealed tubes. They are derived from glycerin, $\text{C}^6\text{H}^5(\text{HO})^3$, by the partial or total replacement of the HO by Cl, Br, &c., *e. g.* :

By heating glycerin with a mixture of hydrochloric acid, &c., and an oxygen-acid, similar compounds are obtained, in which the HO is replaced partly by Cl, &c., partly by the peroxide of an acid radicle, *e. g.* :

These ethers are oily liquids which, when boiled with alkalis, reproduce the acid or acids and glycerin.

The formation of all the glycerides above mentioned is attended with the elimination of a number of atoms of water equal to the number of atoms of a monobasic acid, or double that number of a dibasic acid, or three times that number of a tribasic acid, which enter into the combination, thus :

See also page 509. There are, however, a number of glycerides whose formation is attended with the elimination of a number of atoms of water greater or less than that indicated by the preceding rule, *e. g.* :

The dulcitanides have the same composition as the mannitanides, being derived from dulcitan, $\left\{ \begin{smallmatrix} \text{C}^6\text{H}^9\text{O}^2 \\ \text{H}^2 \end{smallmatrix} \right\} \text{O}^2$. In fact, Wanklyn and Erlenmeyer have shown (Rép. Chim. pure 1862, p. 361; Chem. Soc. J. xv. 466) that mannite and dulcite, $\text{C}^6\text{H}^{14}\text{O}^4$, are hexatomic, their rational formula being $\left\{ \begin{smallmatrix} \text{C}^6\text{H}^9\text{O}^2 \\ \text{H}^2 \end{smallmatrix} \right\} \text{O}^2$; and from this formula that of mannitan (and dulcitan), $\left\{ \begin{smallmatrix} \text{C}^6\text{H}^9\text{O}^2 \\ \text{H}^4 \end{smallmatrix} \right\} \text{O}^2$, is derived by simple elimination of water.

The formulæ of the mannitanides and dulcitanides cannot however be considered as established with certainty. In fact they are uncrystallisable compounds, which by evaporation can only be obtained in the state of syrups, not admitting of exact analysis.

Polyethylenic, Polyglyceric Ethers, &c.

The polyatomic alcohols differ from the monatomic alcohols in this respect, that they are capable of undergoing dehydration in various degrees. Common alcohol, which is monatomic, can form only one anhydride, viz.:

But glycol, which is diatomic, is capable of forming an indefinite number of anhydrides, e. g.:

Glycerin, in like manner, forms polyglyceric alcohols, thus:

All these compounds may be regarded as ethers, inasmuch as, like common ether, they are formed by the union of two or more molecules of an alcohol, with elimination of water, but those which still contain replaceable hydrogen are usually regarded as alcohols.

When, in such an equation as the above, a molecule of a polyatomic alcohol is replaced by one or more molecules of an acid, compound ethers result, of different atomicity from the alcohol from which they are derived: *e. g.*—

A single molecule of a di- or tri-atomic alcohol can undergo only one degree of dehydration; viz. by the abstraction of 1 at. water:

But a single molecule of an alcohol of higher atomicity may undergo several degrees of dehydration. Thus, from mannite, $\left(\begin{array}{c} \text{C}^6\text{H}^8 \\ \text{H}^4 \end{array} \right)^{\sim} \text{O}^4$, there are formed by successive abstraction of H^2O , the compounds *mannitan*, $\left(\begin{array}{c} \text{C}^6\text{H}^8 \\ \text{H}^4 \end{array} \right)^{\sim} \text{O}^4$, *mannide*, $\left(\begin{array}{c} \text{C}^6\text{H}^8 \\ \text{H}^2 \end{array} \right)^{\sim} \text{O}^4$, and the theoretically possible *oxide of mannityl*, $(\text{C}^6\text{H}^8)^{\sim} \text{O}^3$.

ETHERS, ACETIC. These and the ethers of other oxygen-acids are described after the several acids.

ETHERS, BROMHYDRIC or HYDROBROMIC. These and the ethers of other halogen-acids are described under the several alcohol-radicles, ALLYL, AMYL, ETHYL, &c.

ETHIDE, BORIC. See ETHYL, BORIDE OF (p. 526).

ETHIONIC ACID. $\text{C}^2\text{H}^4\text{S}^2\text{O}^7 = \text{C}^2\text{H}^4.2\text{SO}^3.\text{H}^2\text{O}$. (Magnus, Pogg. Ann. xxvii. 378; xlvii. 514.—Marchand, *ibid.* xxxii. 466.)—Produced by the action of water on ethionic anhydride; also by saturating anhydrous alcohol or ether with sulphuric anhydride and diluting with water. Or the barium-salt may first be prepared by adding absolute alcohol to ethionic anhydride, then diluting with water and saturating with carbonate of barium, evaporating the filtrate at 100°C . till precipitation commences, and completing it by addition of absolute alcohol; and from the barium-salt the acid may be obtained by precipitating the barium with dilute sulphuric acid. The aqueous acid cannot be evaporated without decomposition, even in vacuo, as it splits up into sulphuric and isethionic acids:

At the boiling heat this change takes place rapidly.

The ethionates appear to contain, in the dry state, $\text{C}^2\text{H}^4\text{M}^2\text{S}^2\text{O}^7$, the acid being dibasic. The ammonium-, potassium-, sodium-, and barium-salts crystallise readily. The potassium-salt, $\text{C}^2\text{H}^4\text{K}^2\text{S}^2\text{O}^7 + \frac{1}{2}\text{H}^2\text{O}$, does not give off any water in vacuo, or even when heated, before decomposition takes place. At a high temperature, it blackens and yields a sublimate of sulphur. Heated with hydrate of potassium, it yields sulphate and sulphite of potassium. The barium-salt, $\text{C}^2\text{H}^4\text{Ba}^2\text{S}^2\text{O}^7 + \text{H}^2\text{O}$, gives off $\frac{1}{2}$ at. water in vacuo, and decomposes at 100°C . Heated in a tube, it yields a sublimate of sulphur. It dissolves in about 10 pts. of water at 20°C .

ETHIONIC ANHYDRIDE, Sulphate of Carbonyl, $\text{C}^2\text{H}^4.2\text{SO}^4$ (Regnault, Ann. Ch. Phys. lrv. 98; Magnus, Pogg. Ann. xlvii. 509), is obtained by bringing together olefant gas and vapour of sulphuric anhydride in a tube; also when absolute alcohol is left for some time exposed to the vapour of sulphuric anhydride. It forms crystals, which melt at 80°C ., and deliquesce in the air. They mix with water

and alcohol, producing rise of temperature, and yielding a solution of ethionic acid. If, however, the heat produced by the reaction is very great, isethionic acid is likewise produced.

Ethion anhydride and ethionic acid may be represented typically as follows:

Type.	Ethion anhydride.	Type.	Ethionic acid.
H^2	$(\text{C}^2\text{H}^4)'' \text{O}$	H^2	H^2
H^2O	$(\text{SO}^2)'' \text{O}$	H^2O	$(\text{C}^2\text{H}^4)'' \text{O}$
H^2O	$(\text{SO}^2)'' \text{O}$	H^2O	$(\text{SO}^2)'' \text{O}$
		H^2O	$(\text{SO}^2)'' \text{O}$

ETHYL. C^2H^4 , often denoted by the shorter symbol, E; in the free state, $\text{C}^2\text{H}^4 = \text{E}^2$. — The radicle of ordinary alcohol and ether. It was first obtained in the free state by Frankland in 1849 (Chem. Soc. Qu. J. ii. 263). It is produced from iodide of ethyl by the action of zinc at high temperatures; also by the action of light.

Preparation.—1. Pure iodide of ethyl is heated with finely divided zinc in a strong sealed glass tube immersed in an oil-bath. The granulated zinc is first introduced into the tube; the upper extremity of the tube then drawn out and bent twice at right angles; the iodide is introduced by heating and afterwards cooling the tube, while its open extremity dips into the liquid; the air is then exhausted by the air-pump; and the tube is sealed and immersed in an oil-bath. The decomposition of the iodide of ethyl begins at about 100°C .; white crystals are deposited on the glass (probably consisting of a compound of iodide of zinc and zinc-ethyl), together with a colourless mobile liquid, equal in bulk to about half the iodide of ethyl used, and consisting of condensed ethyl, hydride of ethyl, and ethylene. These compounds are separated by their different degrees of volatility. The tube when cold is immersed in a mixture of ice and salt, and the narrow end is broken off under water.

The ethylene and hydride of ethyl being more volatile than the ethyl itself, escape in greatest abundance when the tube is first opened; and by collecting apart the gas which comes over after the evolution has become slow and regular, a gas is obtained, which, when freed from ethylene and undecomposed iodide of ethyl by means of sulphuric anhydride, and from sulphurous acid by potash, is found to be pure ethyl, C^2H^4 .

In the preceding reaction three distinct chemical changes occur, viz.:

i. The decomposition of iodide of ethyl by zinc, with formation of ethyl and iodide of zinc:

ii. The decomposition of iodide of ethyl by zinc, with formation of zinc-ethyl and iodide of zinc:

iii. The reaction of the zinc-ethyl thus formed on the undecomposed iodide of ethyl, by which hydride of ethyl, ethylene, and iodide of zinc are formed:

2. A few drops of iodide of ethyl are introduced into an inverted glass globe filled with mercury and exposed to sunshine; or, better, the sun's rays are concentrated on the iodide of ethyl at the top of the mercury by a parabolic mirror. The iodide of ethyl is then decomposed, iodide of mercury is formed, and the globe becomes filled with gas, which is a mixture of ethyl, hydride of ethyl, and ethylene, the two latter being produced by the decomposition of a portion of the ethyl: $\text{C}^2\text{H}^4 = \text{C}^2\text{H}^4 + \text{C}^2\text{H}^4$. In this process, however, only one-fifth of the ethyl is thus decomposed, whereas in the decomposition by zinc, the quantity thus lost is about one-third of the whole. The ethyl is freed from the other two gases as in the preceding process. (Frankland, Ann. Ch. Pharm. lxxvii. 221.)

Ethyl is at ordinary temperatures a colourless gas, having a slightly ethereal odour (if perfectly pure, it would probably be inodorous); it burns with a white and very luminous flame. Its specific gravity was found by a diffusion-experiment, according to Graham's law (see GASES, DIFFUSION OF), to be 2.0. This shows that its molecule in the gaseous state is represented by the formula C^2H^4 ; for $\frac{4.12 + 10.1}{2} \times 0.0693 = 2.009$ (see ALCOHOL-RADICLES, i. 97). It does not condense at -18°C . (0°Fah .); but in an Oersted's condensing apparatus, it condenses at $+3^\circ$, and under a pressure of 2 atmospheres, to a transparent, colourless, very mobile liquid: hence its boiling point under the ordinary pressure is probably about -23°C .

Ethyl is nearly insoluble in water, but soluble in absolute alcohol. 1 vol. absolute alcohol at 14° C., and under a pressure of 744·8 mm. dissolves 18·13 vol. of the gas, but gives it up again on the addition of a small quantity of water. (See GASES, ABSORPTION OF.)

1 vol. ethyl-gas (containing C^2H^3) requires $6\frac{1}{2}$ vol. oxygen to burn it completely: for 5 at. or 6 vol. H require $2\frac{1}{2}$ vol. O, and 2 at. C require 4 at. (or 4 vol.) O. The products of the combustion are water and 4 vol. CO^2 . Mixed with half its volume of oxygen, and passed over spongy platinum, it remains unaltered at ordinary temperatures; but on the application of a gentle heat, the platinum becomes red-hot, a small quantity of charcoal is deposited, and water, together probably with marsh-gas, produced. It is not acted upon by nitric, chromic, or fuming sulphuric acid. With iodine and sulphur it does not combine even when moderately heated; but at a red heat, sulphuretted hydrogen is formed, and charcoal separated. Chlorine does not act upon ethyl in the dark; but a dry mixture of the two gases in equal volumes, exposed to diffused light, undergoes a change of volume and forms a colourless liquid. Bromine acts upon ethyl when the two are gently heated together in the direct rays of the sun, but the products of the decomposition have not yet been examined.

Ethyl enters into the composition of a large number of compounds, in which it plays the part of a monatomic basylous radicle, analogous to hydrogen or potassium, so that the chloride, bromide, nitrate, acetate, &c., contain 1 at. C^2H^3 ; the oxide, sulphide, neutral sulphate, and other neutral ethyl-salts of dibasic acids contain 2 at. C^2H^3 ; the neutral salts of tribasic acids, such as the phosphate or cyanurate, 3 at. C^2H^3 , &c. &c. It likewise unites with other alcohol-radicles, viz. tetryl and amyl, producing compound alcohol-radicles, which, in their constitution and mode of formation, are exactly analogous to ethyl itself, regarded as $C^2H^3.C^2H^3$. (See ALCOHOL-RADICLES, i. 97.)

ETHYL-AMYL. $C^2H^{10} = C^2H^3.C^2H^7$. (Wurtz, Ann. Ch. Phys. [3] xlv. 275.)—This compound is obtained by decomposing 60 pts. of iodide of ethyl and 70 pts. of iodide of amyl with 14 pts. of sodium in a flask provided with an upright condensing tube cooled by ice-cold water, so that the condensed vapours may run back into the flask. The action begins in the cold, and is attended with evolution of heat; towards the end, however, it requires to be sustained by external heating. The action is then kept up by adding quantities of the materials about equal to the former, and when it is complete, the product is distilled in an oil-bath, the portion which goes over below 120° C. being collected apart, and heated to 120° with excess of sodium in a sealed tube to complete the decomposition. By fractional distillation of the products, ethyl-amyl is obtained as a liquid boiling at 88° C., of specific gravity 0·7069 at 0°, and vapour-density = 3·522, corresponding with a condensation to two volumes $\left(\frac{7 \cdot 12 + 16 \cdot 1}{2} \times 0 \cdot 0693 = 3 \cdot 465\right)$. It is but slightly attacked by pentachloride of phosphorus at its boiling point; but in sealed tubes decomposition takes place: the products have not, however, been examined.

ETHYL-TETRYL. $C^2H^{14} = C^2H^3.C^2H^9$. (Wurtz, loc. cit.)—Prepared, like the preceding compound, by decomposing 40 grms. iodide of tetryl, and 34 grms. iodide of ethyl with 11 grms. sodium. It is a mobile liquid, boiling at 62° C., of specific gravity 0·7011 at 0°, and vapour-density = 3·053 (calc. $\frac{6 \cdot 12 + 14 \cdot 1}{2} \times 0 \cdot 0693 = 2 \cdot 980$).

The compounds of ethyl with oxygen, sulphur, chlorine, bromine, and other elementary bodies, will be described here in alphabetical order; the oxygen-salts, such as the acetate, benzoate, &c., are described after the corresponding acids.

ETHYL, ANTIMONIDES OF. *Antimonethyls, Stibethyls, Ethylstibines.* See ANTIMONY-RADICLES, ORGANIC, i. 339.

ETHYL, ARSENIDES OF. *Arsenethyls, Ethylarsines.* See ARSENIC-RADICLES, ORGANIC, i. 397.

ETHYL, BORIDE OF. *Boric Ethide, Borethyl.* $C^2H^3B = B(C^2H^3)^3 = BE^3$. (Frankland, Phil. Trans. 1862, p. 167; Chem. Soc. J. xv. 363.)—Produced by the action of zinc-ethyl on triethyllic borate (i. 650):*

Preparation.—Several ounces of boric ether were placed in a capacious flask closed

* Frankland prepares triethyllic borate by distilling about 2 lbs. of a mixture of 2 pts. dried borax and 3 pts. ethylsulphate of potassium in a Papin's digester; agitates the crude distillate from several such operations, consisting of boric ether and a large excess of alcohol, with fused chloride of calcium to remove the latter; decants the upper layer of liquid thus produced, which consists of boric ether, with only a little alcohol, from the alcoholic solution of chl. ride of calcium below it; and subjects it to distillation, collecting the liquid which passes over between 118° and 125° C.

by a doubly perforated cork. Through one of the perforations passed a thermometer, and through the other a short glass tube, one fourth of an inch in diameter, and open at both ends: the bulb of the thermometer dipped into the boric ether. Successive quantities of pure zinc-ethyl were introduced through the short glass tube by means of a pipette, the elevation of temperature after each addition being allowed to subside before the next portion was added. The failure of a further addition of zinc-ethyl to produce any rise of temperature was regarded as evidence of the completion of the reaction, which was not attained until a comparatively very large amount of zinc-ethyl had been added.

The liquid in the flask was now submitted to distillation in an oil-bath. It began to boil at 94°C ., and between this temperature and 140°C . a considerable quantity of a colourless liquid distilled over. The distillation then suddenly stopped, and, to avoid secondary products of decomposition by the application of a greater heat, the operation was interrupted. On cooling, the materials remaining in the flask solidified to a mass of large crystals of ethylate of zinc and zinc-ethyl. On rectification, the distillate began to boil at 70°C ., but the thermometer rose rapidly to 95° , at which temperature the last two-thirds of the liquid passed over and were received apart. The product thus collected exhibited a constant boiling-point on re-distillation.

Properties.—Borethyl is a colourless mobile liquid having a pungent odour; its vapour is very irritating to the mucous membrane, and provokes a copious flow of tears. The specific gravity of borethyl at 23°C . is 0.6961; it boils at 95°C . Its vapour-density, as determined by Gay-Lussac's method, is 3.4006; by calculation, for a condensation to two volumes, it is 3.306 $\left(= \frac{11 + 6 \cdot 12 + 15 \cdot 1}{2} \times 0.0693\right)$.

The density of borethyl vapour increases more considerably than is usual, as the temperature approaches the boiling-point; thus a determination made at 132°C . gave the number 3.6979, whilst a second showed the specific gravity of the vapour at 101.6°C . to be no less than 3.757.

Borethyl is insoluble in water, and is very slowly decomposed by prolonged contact with it. Iodine has scarcely any action upon it, even at 100°C . It floats upon concentrated nitric acid for several minutes without change; but suddenly a violent reaction takes place, and crystals of boric acid separate. When borethyl vapour comes in contact with air, it produces slight bluish-white fumes, which in the dark are seen to proceed from a lambent blue flame. The liquid is spontaneously inflammable in air, burning with a beautiful green and somewhat fuliginous flame. In contact with pure oxygen it explodes. Excluded from the air, borethyl is quite a stable body; a quantity of it kept in a sealed tube for two years exhibited, on examination, no evidence of alteration.

When borethyl is heated to 99°C . with strong hydrochloric acid over mercury, a considerable quantity of hydride of ethyl is slowly evolved, and chloroborethyl is formed:

When borethyl is heated with water to 99°C . for several hours, it also appears to suffer an analogous decomposition, although with extreme slowness; even with hydrochloric acid, the action is very tedious. In the cold, a strong solution of hydrofluoric acid has no action upon borethyl, which also suffers scarcely any change by being heated to 99°C . for four hours with concentrated sulphuric acid. Gently heated for fourteen days with sodium in a sealed tube, borethyl underwent no visible change.

Ammonio-Borethyl, $\text{NH}^3\text{B}(\text{C}^2\text{H}^5)^3$.—When a few drops of borethyl are passed up into a dry eudiometer filled with mercury, and dry ammoniacal gas is admitted into the same tube, each bubble of gas collapses with a shock, like that produced by a bubble of steam projected into cold water. A large quantity of ammonia is thus absorbed by borethyl with extreme energy. To prepare the compound thus formed in larger quantity, several grammes of borethyl were placed in a small flask filled with nitrogen and surrounded with ice; a current of dry ammoniacal gas was now passed into the flask as long as it was absorbed; finally, the product thus obtained was warmed to expel excess of ammonia, and then exposed in vacuo over sulphuric acid for twenty-four hours. It did not crystallise, and could not be distilled, except in vacuo, without decomposition.

Ammonio-borethyl is a somewhat oily liquid, possessing an aromatic odour and an alkaline reaction. Carbonic acid has no action upon it, even in presence of water, but other acids decompose it instantly and liberate borethyl. When it is exposed to a measured quantity of atmospheric air, there is scarcely any perceptible absorption of oxygen, even after the lapse of several hours.

Oxide of Borethyl, $B(C^2H^3)^2O = B \begin{Bmatrix} C^2H^3 \\ C^2H^3O \\ C^2H^3O \end{Bmatrix}$.—When borethyl is placed in a

flask and allowed to oxidise gradually, first in dry air and finally in dry oxygen, it forms a colourless liquid, which boils at $125^\circ C$, but cannot be distilled under atmospheric pressure without partial decomposition. At the ordinary temperature, this product of oxidation evaporates without residue in a stream of carbonic anhydride. It can be distilled in vacuo without decomposition.

This body, which is the oxide of borethyl, may be regarded, as shown by the second of the above formulæ, as dioxethylo-borethyl, i.e. as borethyl in which 2 at. ethyl are replaced by 2 at. peroxide of ethyl; and this view of its constitution is supported by its behaviour with water: for when placed in contact with water, it is instantly decomposed, yielding alcohol and dioxhydro-borethyl, a compound derived from borethyl by the substitution of 2 at. peroxide of hydrogen for 2 at. ethyl:

Dioxhydro-borethyl may be conveniently prepared in the pure state by agitating its aqueous solution with ether, which dissolves the boric compound. The ethereal solution must then be decanted; and on evaporation at common temperatures in a stream of carbonic anhydride, the compound is left behind as a white and very volatile crystalline mass, very soluble in water, alcohol, and ether. It has an agreeable ethereal odour, and a most intensely sweet taste. Exposed to the air it evaporates at ordinary temperatures, undergoing at the same time partial decomposition, and invariably leaving a slight residue of boric acid. It may be sublimed without change at about $40^\circ C$, in a current of carbonic anhydride, and then condenses in magnificent crystalline plates resembling naphthalin. It melts at a gentle heat, and at a higher temperature boils with partial decomposition. Its vapour tastes intensely sweet. It reddens litmus, but does not appear to be capable of forming definite salts with metallic bases; oxide of borethyl may, however, as already observed, be regarded as its ethyl-salt.

Frankland gives also another view of the composition of these bodies. He regards borethyl as boric anhydride, BO^2 or B^2O^3 , in which the whole of the oxygen is replaced by an equivalent quantity of ethyl (1 at. C^2H^3 for each at. $O = 8$, or 2 at. C^2H^3 for each at. $O = 16$), and supposes that when this compound is exposed to the action of the air or of oxygen gas, 2 at. ethyl are removed, and their place supplied by an

equivalent quantity of oxygen, producing dioxyborethyl, or boric dioxethide, $B \begin{Bmatrix} C^2H^3 \\ O \\ O \end{Bmatrix}$, or

$B \begin{Bmatrix} C^2H^3 \\ O^2 \end{Bmatrix}$, which remains combined with the oxide of ethyl formed at the same time,

producing diethylate of boric dioxethide, $B \begin{Bmatrix} C^2H^3 \\ O^2 \end{Bmatrix} \cdot (C^2H^3)^2O$, or $B \begin{Bmatrix} C^2H^3 \\ C^2H^3O \\ C^2H^3O \end{Bmatrix}$; and this,

when subjected to the action of water, yields dihydrate of boric dioxethide,

$B \begin{Bmatrix} C^2H^3 \\ O^2 \end{Bmatrix} \cdot H^2O$, or $B \begin{Bmatrix} C^2H^3 \\ HO \\ HO \end{Bmatrix}$, which may be regarded as a dibasic acid, of which the hy-

pothetical compound, $B \begin{Bmatrix} C^2H^3 \\ O^2 \end{Bmatrix}$, is the anhydride.

An argument in favour of the supposition that borethyl is produced by the substitution of ethyl for oxygen in boric anhydride, is deduced from the formation of the analogous compound, bormethyl, or boric methide, $B(CH^3)^2$, or BMe^2 , by the action of zinc-methyl on triethyllic borate, which takes place as shown by the equation:

Here the methyl evidently goes to the boron and the oxygen to the zinc; whereas if, as supposed by Kekulé (*Lehrbuch*, p. 489), the action consisted in a simple deoxidation of the boric ether, the products would be methylete of zinc, $ZnMeO$, and borethyl, BE^2 : hence it may be inferred that the decomposition of boric ether by zinc-ethyl is likewise, not a mere deoxidation of the former, but a process of substitution. It must be observed, however, that the interchange which takes place in the formation of the methyl-compound is not that of methyl for oxygen, but of methyl for peroxide of ethyl, EO , the reaction being most clearly represented in the form:

Moreover, Frankland finds that zinc-ethyl has no action whatever on boric anhydride at any temperature to which a mixture of the two may be exposed. This may indeed be due to the insolubility of the boric anhydride in the zinc-ethyl; but it may also indicate that the association of an alcohol-radicle with the boron is an essential condition of the reaction.

ETHYL BROMIDE OF. C^2H^5Br . *Hydrobromic or Bromhydric Ether.* (Serullas, Ann. Ch. Phys. xxxiv. 99.—Löwig, Ann. Ch. Pharm. iii. 291.)—Discovered by Serullas in 1827. Produced by the action of bromine, hydrobromic acid, or bromide of phosphorus, on alcohol.

Preparation.—1. One part of phosphorus and 40 pts. of alcohol of 38° Bm. are introduced into a tubulated retort, and 7 to 8 pts. of bromine gradually added, whereupon the mixture becomes heated and hydrobromic and phosphorous acids are produced; the tubulus is then closed, the mixture distilled at a gentle heat, the distillate collected in a cooled receiver, and the hydrobromic ether separated from it by water, to which, if the distillate contains acid, a small quantity of potash is added (Serullas).—2. Absolute alcohol gradually mixed in a distillatory apparatus with a treble quantity of bromine and heated from without towards the end of the process, yields a distillate consisting of two layers. The lower reddish stratum, which consists of bromide of ethyl, a small quantity of bromide of carbon (C^2Br^4), and free bromine, is freed from the latter by agitation with dilute potash till it loses its colour, and then from bromide of carbon by distillation (Löwig).—3. According to De Vrij, it is easily prepared by distilling 4 pts. pulverised bromide of potassium with 5 pts. of a mixture of 2 pts. strong sulphuric acid and 1 pt. alcohol of 96 per cent.

Properties.—Transparent and colourless liquid, heavier than water (Serullas). Specific gravity 1.40 (Löwig); 1.4733 at 0° (Pierre). Vapour-density = 3.754 (R. Marchand, J. pr. Chem. 188). Very volatile. Boiling point 40.7° C. when the barometer stands at 757 mm. (Pierre). Has a strong ethereal odour and a pungent taste (Serullas). According to Löwig, its taste is strongly and disagreeably sweetish, with a somewhat burning after-taste. The vapour, when inhaled, exerts an anæsthetic action, like chloroform (Robin, Compt. rend. xxxii. 649). It is sparingly soluble in water, but mixes in all proportions with alcohol and ether.

Decompositions.—1. Vapour of hydrobromic ether passed through a glass tube at a low red heat is resolved into ethylene and hydrobromic acid gas; if the tube be more strongly ignited, charcoal is deposited (Löwig).—2. It burns with difficulty, but with a beautiful green flame which does not smoke, a strong odour of hydrobromic acid being at the same time evolved (Löwig).—3. It is not decomposed by nitric acid, oil of vitriol, or potassium (Löwig).—4. With ammonia, it yields hydrobromate of ethylamine:

Similarly with ethylamine, it forms hydrobromate of diethylamine; and with the latter hydrobromate of triethylamine. With phenylamine, $NH^2.C^6H^5$, it yields hydrobromate of ethyl-phenylamine, $C^2H^5N.HBr$ (Hofmann).—6. With alcoholic potash-solution it forms bromide of potassium and oxide of ethyl:

(Berthelot, Ann. Ch. Pharm. xcii. 351.)

ETHYL CHLORIDE OF. C^2H^5Cl . *Chlorhydric or Hydrochloric Ether, Light Muriatic Ether.* (Robiquet and Colin, Ann. Ch. Phys. [2] i. 343.—Regnault, *ibid.* lxxi. 355.—Kuhlmann, Ann. Ch. Pharm. xxxiii. 108.—Löwig, Pogg. Ann. xlv. 346.—Gm. viii. 367.—Gerh. ii. 308.)—This compound in an impure state was known to many of the older chemists, especially Rouelle; its composition was first correctly ascertained by Robiquet and Colin.

Chloride of ethyl is easily formed from alcohol and hydrochloric acid: $C^2H^5O + HCl = C^2H^5Cl + H^2O$; also by distilling alcohol with various chlorides, e.g. chloride of aluminium, antimonie chloride, ferric chloride, pentachloride of phosphorus, dichloride of platinum, chloride of sulphur, stannic chloride, chloride of zinc, &c., its formation, especially by the action of metallic chlorides, being usually accompanied by that of oxide of ethyl (see ALCOHOL, i. 77). It is likewise produced by the action of chlorine on iodide of ethyl, by that of hydrochloric acid on acetate of ethyl, and, according to Berthelot, by heating oxide of ethyl with hydrochloric acid in sealed tubes.

Preparation.—1. Absolute, or at least very strong alcohol, is saturated with hydrochloric acid gas, the liquid distilled in the water-bath, and the distillate passed first into a bottle containing water, and immersed in water at 20° – 25° C., then into a receiver surrounded with ice. The product is washed either with pure or with saline water to remove free alcohol, and then rectified over magnesia.

2. Chloride of ethyl may also be prepared by distilling a mixture of 5 pts. alcohol, 5 pts. strong sulphuric acid, and 12 pts. common salt, or by distilling alcohol with the perchlorides of tin, bismuth, antimony, arsenic, or iron.

3. A convenient method of preparing chloride of ethyl in a state of purity is to act on absolute (or nearly absolute) alcohol by means of pentachloride of phosphorus. The pentachloride is contained in a flask, and, by help of a suitable arrangement, the alcohol is allowed to flow upon it in quantities of a few drops at a time, care being taken that each quantity has reacted before more is added. The mixture of hydrochloric acid gas and chloride of ethyl vapour thus formed is passed, first through a U-tube containing pieces of pentachloride of phosphorus, in order to decompose any alcohol vapour that may accompany it; then through a vessel containing water, to absorb the hydrochloric acid; next through one or two U-tubes containing fused chloride of calcium; and lastly, into a receiver cooled by a mixture of ice and salt. All the parts of the apparatus, between the generating flask and the receiver, should be kept at a temperature of 25° or 30° C., to prevent the condensation of the chloride of ethyl.

Properties.—Chloride of ethyl is a thin colourless liquid, of specific gravity 0.920 at 0° C. (Pierre). It boils at 11° C., and does not solidify at -29° . Its vapour-density, as determined by Thénard, is 2.219; by calculation for a condensation to 2 vol. it is 2.235 ($= \frac{2 \cdot 12 + 5 \cdot 1 + 35.5}{2} \times 0.0693$). It has a pungent ethereal odour and a sweetish

aromatic taste, with somewhat alliaceous after-taste. It is very inflammable, and burns with a green-edged flame, evolving hydrochloric acid.

Chloride of ethyl dissolves sparingly in water, but mixes in all proportions with alcohol and ether. It dissolves sulphur, phosphorus, fats, volatile oils, many resins and colouring matters. It unites with several metallic chlorides.

Pentachloride of antimony absorbs the vapour of chloride of ethyl, with evolution of heat, and forms a colourless liquid, which fumes in the air, and in a dry atmosphere solidifies to a crystalline mass; this, however, gradually becomes liquid and brown, and slowly deposits crystals of trichloride of antimony, whereupon water throws down a brown oil from the brown mother-liquid (Kuhlmann). Stannic chloride likewise yields, with evolution of heat, a liquid which fumes in the air, and when set aside over lime under a bell jar containing air, effloresces on the edge of the basin in plumose vegetations. Water decomposes the compound, separating part of the ether in the undecomposed state, and if the compound is not recently prepared, precipitating a white substance, probably stannic oxide (Kuhlmann). Sesquichloride of iron in dry air forms with chloride of ethyl a compound which crystallises indistinctly, and from which water throws down a large quantity of ferric oxide and separates hydrochloric ether. (Kuhlmann, Ann. Ch. Pharm. xxxiii. 108.)

Chloride of ethyl is used in medicine for the same purposes as common ether; it has been recommended in catarrhal affections. As its great volatility would interfere with its application, it is usually mixed with an equal weight of alcohol, the mixture constituting the alcoholised muriatic ether of the pharmacopœias.

Decompositions. 1. By heat.—Chloride of ethyl passed through a red-hot porcelain tube is resolved into ethylene and hydrochloric acid; at a stronger heat, carbon is separated, and marsh-gas and hydrogen are obtained as well as hydrochloric acid.

2. Cold nitric acid of specific gravity 1.3 exerts no action on chloride of ethyl; but when the vapour of that compound is passed through the boiling acid, hydrochloric acid is evolved, together with a small quantity of nitrous ether (Thénard, Boullay).

—3. Sulphuric anhydride absorbs the vapour of hydrochloric ether abundantly, and converts it into a liquid, which fumes in the air, boils at 130° C., and passes over partly undecomposed, whilst the residue turns brown and gives off sulphurous acid (Kuhlmann, loc. cit.). The compound thus formed is $\text{SO}^2 \cdot \text{C}^2\text{H}^5\text{Cl}$, and may be regarded as chlorethylsulphuric acid (SO^2) $\left\{ \begin{array}{l} \text{C}^2\text{H}^5\text{O} \\ \text{Cl} \end{array} \right.$, that is, as sulphuric acid

(SO^2) $\left\{ \begin{array}{l} \text{HO} \\ \text{HO} \end{array} \right.$ in which 1 at. HO is replaced by peroxide of ethyl and the other by

chlorine (R. Williamson, Chem. Soc. Qu. J. x. 100). Strong sulphuric acid likewise absorbs vapour of chloride of ethyl, but does not afterwards yield an oil on addition of water (Kuhlmann). It does not exert any decomposing action at medium temperatures, but when the vapour of hydrochloric ether is passed through it at a high temperature, hydrochloric acid gas is evolved (Thénard), together with ethylene gas, and ultimately also with sulphurous anhydride (Boullay).—4. In an aqueous solution of nitrate of silver, chloride of ethyl, whether in the gaseous or liquid state, forms no precipitate at first, a very slight one after an hour, and even in three months but a small quantity of chloride of silver (Thénard, Boullay); according to Thénard, it acts in a precisely similar manner on mercurous nitrate, but, according to Boullay, it immediately throws

down a large quantity of calomel from a solution of that salt. Chloride of silver is rapidly precipitated when hydrochloric ether is heated to 100°C . in a sealed tube with aqueous solution of nitrate of silver (G. C. Foster).—6. *Ammoniacal gas* and the aqueous solution of ammonia act but very slowly at ordinary temperatures on chloride of ethyl, either in the gaseous or liquid state, taking up a small quantity of chlorine from it (Thénard). A mixture of 1 vol. chloride of ethyl vapour and 2 vol. ammoniacal gas heated over the flame of a spirit-lamp, soon diminishes in volume, deposits a large quantity of sal-ammoniac, and, after being heated for some time, leaves a mixture of ammoniacal and ethylene gas (Dumas and Stas, Ann. Ch. Phys. lxxiii. 154): $\text{C}^2\text{H}^4\text{Cl} + \text{NH}^3 = \text{C}^2\text{H}^4 + \text{NH}^4\text{Cl}$. Chloride of ethyl acts slowly on an ethereal solution of ammonia. When the mixture is allowed to stand in stoppered bottles exposed to sunlight at the beginning of the reaction, fine crystals of hydrochlorate of ethylamine are deposited (Stas, *Kekulé's Lehrbuch*, i. 455). Chloride of ethyl, mixed with three times its volume of alcohol saturated with ammonia-gas, and heated to 100°C . for six or seven hours in a sealed tube, yields a large quantity of chloride of ethylammonium ($\text{N}^1\text{H}^3\text{C}^2\text{H}^4$).Cl, together with small quantities of the chlorides of diethyl- and tetraethyl-ammonium (Groves, Chem. Soc. Qu. J. xiii. 331).—6. *Aqueous potash* at ordinary temperatures takes but a small quantity of chlorine from chloride of ethyl, even in the course of three months (Thénard). According to Boullay, the vapour of hydrochloric ether passed through a bent tube into potash-ley heated in a tubulated retort, is almost wholly decomposed, chloride of potassium being formed and alcohol having the taste and smell of rum distilling over:

A saturated alcoholic solution of potash decomposes hydrochloric ether, between 14° and 25°C ., more rapidly than aqueous potash, beginning, in fact, to deposit chloride of potassium after the lapse of twenty-four hours; but the decomposition is not complete even in a week (Thénard). A mixture of alcoholic potash and hydrochloric ether inclosed in a strong glass tube and heated to 100°C . deposits chloride of potassium and forms a liquid containing common ether (Balard, Ann. Chim. Phys. [3] xii. 302). When vapour of chloride of ethyl is passed through a tube in which a mixture of lime and hydrate of potassium is gently heated, chloride of potassium is obtained, together with very pure ethylene gas (Dumas and Stas).—7. Vapour of chloride of ethyl passed into a heated alcoholic solution of *protosulphide of potassium*, is converted into sulphide of ethyl; similarly, with an alcoholic solution of sulphide of hydrogen and potassium, it forms mercaptan (Regnault):

8. *Potassium* acts rapidly on chloride of ethyl, producing an evolution of heat, whereby part of the ether is volatilised, with ebullition. If the potassium be freed by repeated pressure from the crust which forms upon it, the whole of it is ultimately converted into a white powder. This powder, when subjected to dry distillation, gives off combustible gases and leaves a carbonaceous residue, which immediately burns away on exposure to the air. It dissolves in water, with evolution of hydrogen, forming a liquid which contains a large quantity of chloride of potassium; ether shaken up with this liquid dissolves out an oil which remains behind when the ether is evaporated in vacuo, but likewise evaporates itself when left for some time in the vacuum. This oil has a peculiar odour, a soapy and somewhat burning taste, and burns with a bright flame. The white powder contains carbon and hydrogen in the proportion of 82.79 pts. to 17.21 pts.; therefore in the proportion of ethyl, C^2H^4 . Hence the white powder appears to be a compound of chloride and ethylide of potassium, KC^2H^4 , and the oil is perhaps a hydrate of ethyl. (Löwig, Pogg. Ann. xlv. 346.)

CHLORINATED DERIVATIVES OF CHLORIDE OF ETHYL.

Chlorine does not act on chloride of ethyl in the dark, and but slowly in diffused daylight; but in sunshine the action is very rapid, the liquid sometimes taking fire and depositing charcoal. If the action be set up in direct sunshine, then continued in diffused daylight, and finally completed in sunshine, the following substitution-products are formed, with evolution of hydrochloric acid:

Monochlorinated Chloride of Ethyl	.	.	$\text{C}^2\text{H}^4\text{Cl}^1$	=	$\text{C}^2(\text{H}^4\text{Cl}^1)\text{.Cl}$
Dichlorinated	"	"	$\text{C}^2\text{H}^4\text{Cl}^2$	=	$\text{C}^2(\text{H}^4\text{Cl}^2)\text{.Cl}$
Trichlorinated	"	"	$\text{C}^2\text{H}^4\text{Cl}^3$	=	$\text{C}^2(\text{H}^4\text{Cl}^3)\text{.Cl}$
Tetrachlorinated	"	"	C^2HCl^4	=	$\text{C}^2(\text{H}^4\text{Cl}^4)\text{.Cl}$
Pentachlorinated	"	"	C^2Cl^5	=	$\text{C}^2\text{Cl}^5\text{.Cl}$

The last of these products is identical with trichloride of carbon (i. 786); the first is isomeric with dichloride of ethylene; the second, and those which follow it, with chloride of vinyl and its derivatives. (Regnault, Ann. Ch. Phys. [2] lxxi. 365.)

Monochlorinated Chloride of Ethyl, $C^2H^4Cl^2 = C^2 \left\{ \begin{smallmatrix} H^1 \\ Cl \end{smallmatrix} \right\}. Cl$.—Isomeric with

dichloride of ethylene; sometimes called *Chloraldehyde*.
The apparatus used for the preparation of this compound is similar to that which serves for the preparation of chloride of ethylene (*q. v.*). Chloride of ethyl, evolved by heating in a flask a mixture of equal volumes of alcohol and fuming hydrochloric acid, is passed through three wash-bottles, the first containing water, the second sulphuric acid, and the third water, to free it from hydrochloric acid and alcohol, and then into a glass globe, which is connected on its opposite side with another flask in which chlorine is evolved. The globe has at the bottom a narrow neck fitted into the cork of a wide-mouthed bottle, which is further connected by a bent tube with another bottle standing in a vessel of cold water, this second bottle being also provided with an escape-tube for the hydrochloric acid gas evolved. The chlorine and hydrochloric ether meeting in the glass globe are at first exposed to the rays of the sun concentrated on the vessel by a lens or mirror; but when the action has thus been set up, the vessel is placed in the shade, and the action left to go on by itself, care being taken to keep up a good stream of the vapour of chloride of ethyl, so as to prevent, as far as possible, the formation of the more highly chlorinated products. The monochlorinated hydrochloric ether thus produced, condenses, partly in the globe, partly in the wide-mouthed bottles. It is purified by shaking it up several times with water, then distilling over the water-bath, and finally rectifying over quicklime, the first drops of the distillate, which contain unaltered chloride of ethyl, being rejected, and likewise the last fourth, which generally contains the more highly chlorinated products.

Monochlorinated chloride of ethyl is a transparent, colourless, very thin liquid, of specific gravity 1.174 at 17° C. Boils at 64°. Vapour-density, by experiment 3.478, by calculation (2 vol.) 3.42. It is insoluble in water, but miscible in all proportions with alcohol and ether. Smells like Dutch liquid, and has a sweet, fiery taste. (Regnault.)

When distilled with *alcoholic potash*, it passes over for the most part unaltered; but the residue contains a small quantity of chloride of potassium, and on addition of water deposits a brown sticky resin, probably resin of aldehyde.—It may be distilled undecomposed in contact with *potassium*, the metal retaining its lustre. (Regnault.)

Monochlorinated hydrochloric ether is distinguished from Dutch liquid, which is isomeric with it, by its smaller specific gravity, lower boiling point, and difficult decomposibility by potash.

Preparation of the more highly chlorinated products.—These are obtained by the action of chlorine on the compound just described. In diffused daylight chlorine does not exert any perceptible decomposing action on the monochlorinated chloride, but dissolves in it abundantly, imparting to the liquid an intense yellow colour. If the liquid thus saturated be exposed to sunshine, a very violent action is set up, torrents of hydrochloric acid being evolved, and the liquid often thrown out of the vessel.

On pouring a small quantity of the monochlorinated chloride into a large bottle filled with chlorine, and exposing it to sunshine, crystals of the perchlorinated compound, C^2Cl^6 , are obtained after a while. The preparation of the intermediate products is somewhat difficult, but may be effected by operating as follows with a large quantity of material:

600 or 700 grammes of the monochlorinated chloride are placed in a large test-tube and covered with a layer of water. A stream of chlorine is then passed to the bottom of the tube, which is connected with a cooled receiver, and placed at first in the shade, so that the chlorine may saturate the liquid without decomposing it. The vessel is afterwards placed in a stronger light, or even in sunshine, and after the action has gone on for about two days, the liquid is distilled, and the first half of the distillate is again subjected for a while to the action of chlorine, then united with the second half, and the whole distilled in a retort fitted with a thermometer, the first and last fourths of the distillate being set aside, and the medium portion, which ought to boil at a tolerably constant temperature, being collected apart. By further fractionating this medium product into several parts, products of constant boiling point and composition will at length be obtained in a state of purity. The other fractions, which do not exhibit constant boiling points, may be used for the preparation of the more highly chlorinated products, for which purpose they are returned to the test-tube, to be again submitted to the action of chlorine, the least chlorinated being treated first.

The liquid, which condenses in the cooled receiver during the action of the chlorine, is preserved for the preparation of the perchlorinated compound, C^2Cl^6 .

The lower products are obtained with tolerable facility; but the preparation of those which contain the larger proportions of chlorine is much more difficult, because the quantity of liquid subjected to the action of the chlorine diminishes considerably during the operation, whereby the difficulty of separating the products by distillation

is increased. It is necessary to analyse the products from time to time, so as to make sure that the required degree of chlorination is not exceeded.

Dichlorinated Chloride of Ethyl, $C^2H^3Cl^2 = C^2 \left\{ \begin{smallmatrix} H^2 \\ Cl^2 \end{smallmatrix} \right\} .Cl$.—Isomeric with *chloride of vinyl*. Specific gravity 1.372 at $0^\circ C$. Boiling point 76° . Vapour-density 4.530. Its odour resembles that of Dutch liquid. It is scarcely altered by an alcoholic solution of potash, even at the boiling heat; but after the treatment has been repeated several times, chloride and acetate of potassium are produced:

It is not decomposed by alcoholic sulphhydrate of potassium.

Trichlorinated Chloride of Ethyl, $C^2H^2Cl^3 = C^2 \left\{ \begin{smallmatrix} H^2 \\ Cl^3 \end{smallmatrix} \right\} .Cl$.—Resembles the two preceding products in external characters. Specific gravity 1.530 at $17^\circ C$. Boiling point 102° . Vapour-density 5.799. Heated with alcoholic potash, it yields a certain quantity of chloride of potassium. Not attacked by sulphhydrate of potassium.

Tetrachlorinated Chloride of Ethyl, $C^2HCl^4 = C^2 \left\{ \begin{smallmatrix} H \\ Cl^4 \end{smallmatrix} \right\} .Cl$.—Difficult to obtain pure. A product not quite pure had a specific gravity of 1.644. Boiling point $146^\circ C$. Vapour-density = 6.975. It is more easily attacked than the preceding products by alcoholic potash, heat being evolved and chloride of potassium deposited; the distilled liquor diluted with water deposits an oily substance. Potassium does not act upon the tetrachlorinated compound in the cold, but on applying heat, a violent explosion takes place and carbon is deposited.

Perchlorinated Chloride of Ethyl, $C^2Cl^6 = C^2Cl^5.Cl$.—Identical with trichloride of carbon (i. 766).

Heavy Hydrochloric Ether, the product obtained by passing chlorine into alcohol, not long enough to convert it into chloral, and washing the product with water and potash, or by saturating alcohol with hydrochloric acid gas and distilling with peroxide of manganese, or by passing chlorine into ether and precipitating with water,—is a mixture of several products, viz. acetate of ethyl, aldehyde, chloral, chloride of ethyl, and perhaps also chloride of ethylene. (Gm. viii. 273.)

ETHYL, CHLOROPLATINATE OF. See ETHYLENE-CHLORIDE OF PLATINUM.

ETHYL, CHLOROSULPHATE OF, or *Chlorethyl-sulphuric Acid*. See p. 529; also SULPHURIC ETHERS.

ETHYL, CYANIDE OF. $C^2H^3N = C^2H^3.Cy$.—The preparation and most of the reactions of this compound are described under CYANIDES (p. 211). We have here to speak of the products of its decomposition by *chlorine*, as described by R. Otto. (Ann. Ch. Pharm. cxvi. 195.)

When dry chlorine gas is passed into cyanide of ethyl in a vessel exposed to diffused daylight, a large quantity of hydrochloric acid is evolved, and at the end of the reaction, which requires at last to be assisted by heat, the viscid liquid, if exposed to the temperature of a freezing mixture, deposits a crystalline substance (a), having the composition $C^2H^3Cl^3N^2O^2$. This substance is soluble in water, alcohol, and ether, melts at $110.5^\circ C$, and solidifies to a radio-crystalline mass at 86° . The aqueous solution is neutral, is not precipitated by nitrate of silver, and when boiled with potash gives off a large quantity of ammonia and leaves chloride of potassium.

The liquid separated from this crystalline substance (a) yields by distillation a liquid distillate (b) and a brown residue (c), which solidifies to a crystalline mass on cooling. The distillate, after repeated rectification, boils with slight decomposition at $104^\circ - 107^\circ C$, and exhibits the composition of cyanide of dichlorethyl, $C^2H^2Cl^2N = C^2H^2Cl^2.Cy$. Specific gravity = 1.431 at $15^\circ C$. Vapour-density, by experiment = 4.26; by calculation = 4.29. It is colourless, insoluble in water, miscible in all proportions with alcohol and ether. When kept in loosely stoppered vessels, it decomposes with abundant formation of hydrochloric acid; and when heated with potash or baryta, gives off ammonia and yields chloride of potassium or barium, together with the salt of a non-volatile acid.

The crystals which separate from the residue (c) likewise exhibit, after recrystallisation from alcohol, the composition of cyanide of dichlorethyl. They have sometimes the form of scales, sometimes that of large tables or prisms; they are colourless and inodorous, melt at $74.5^\circ C$, sublime with difficulty, and with partial decomposition, are insoluble in water, dissolve at $26^\circ C$ in 7.17 pts. of anhydrous alcohol and in 0.77 pts. ether. With alkalis they behave like the isomeric liquid compound.

ETHYL FLUORIDE OF. *Hydrofluoric or Fluorhydric Ether.* C^2H^5F (?)—Produced by distilling a mixture of fluor-spar, sulphuric acid, and alcohol, or by passing dry hydrofluoric acid gas into absolute alcohol contained in a leaden or platinum vessel surrounded with ice and salt. On distilling off about one-fourth of the saturated liquid, and mixing the distillate with water, a light ethereal liquid rises to the surface, which appears to be fluoride of ethyl. It is very volatile, colourless, has a peculiar odour, like that of horse-radish, and burns with a bluish flame, giving off vapours of hydrofluoric acid. It cannot be preserved in glass vessels, at least not in contact with water, being then decomposed, with formation of alcohol and silicofluoride of potassium. It has not been obtained sufficiently pure for exact analysis. (Reinsch, J. pr. Chem. xix. 514.)

ETHYL HYDRATE OF. See ALCOHOL (i. 72).

ETHYL HYDRIDE OF. *Ethylide of Hydrogen.* $C^2H^4 = C^2H^5.H$.—This compound, which is isomeric with methyl, was originally obtained by Frankland and Kolbe in 1848 (Chem. Soc. Qu. J. i. 60) by the action of potassium on cyanide of ethyl, and was at that time regarded as methyl. Afterwards, in 1850 (Chem. Soc. Qu. J. iii. 338), Frankland obtained it by the action of water on zinc-ethyl, and showed that it is distinct from the true methyl (discovered by Kolbe in 1849), which is obtained by the electrolysis of acetic acid, and by the action of zinc on iodide of methyl.

Hydride of ethyl is produced: 1. By the resolution of a molecule of ethyl:

This decomposition takes place when iodide of ethyl is heated with zinc in a sealed tube, also when it is decomposed by light in presence of mercury (p. 525).—2. When iodide of ethyl is decomposed by zinc in presence of water or of alcohol:

The formation of hydride of ethyl by the action of potassium on cyanide of ethyl (not quite dry), as above mentioned, was probably due to both these modes of decomposition.

Preparation.—When equal parts of water and iodide of ethyl are heated with zinc in a sealed and exhausted glass tube, in the manner described on page 524, decomposition takes place at a lower temperature than when zinc is heated with iodide of ethyl alone; the decomposition is complete in about two hours. The liquid portion of the contents of the tube is thick, and solidifies on cooling to a white amorphous mass. On opening the tube under water containing sulphide of potassium, a large quantity of gas escapes, which, by combustion with oxygen, is found to have the composition of hydride of ethyl, C^2H^4 .

This gas is colourless, nearly insoluble in water, but soluble in alcohol, which at $88^\circ C$, and under a pressure of 665.5 mm., dissolves 1.22 of its own volume of it. (See GASES, ABSORPTION OF.) Specific gravity, by observation 1.075; by calculation for a condensation to 2 vol. it is 1.039. It has at first a faint ethereal smell, but becomes quite inodorous after being treated with alcohol and fuming sulphuric acid. It does not liquefy at $-18^\circ C$, or even under a pressure of 20 atmospheres at $+3^\circ$. Chlorine does not act upon it in the dark; but on exposing the mixture to diffused daylight, the colour of the chlorine disappears altogether. 2 vol. chlorine with 1 vol. hydride of ethyl yield 2 vol. hydrochloric acid, together with an *oily liquid* having the same composition per cent. as Dutch liquid. This reaction distinguishes hydride of ethyl from methyl: for when 1 vol. of the latter is mixed with 2 vol. chlorine, the products are 2 vol. hydrochloric acid and 1 vol. of a gas having the composition CH^2Cl .

ETHYL IODIDE OF. C^2H^5I . *Hydriodic or Iodhydric Ether.* (Gay-Lussac [1816], Ann. Chim. xci. 89.—Serullas, Ann. Ch. Phys. [2] xxv. 323; xlii. 119.—E. Kopp, J. Pharm. [3] vi. 109.—R. Marchand, J. pr. Chem. xxxiii. 186.—Frankland, Chem. Soc. Qu. J. ii. 263; iii. 322.—Gm. viii. 359.)—This compound is produced: 1. By distilling absolute alcohol with hydriodic acid containing free iodine.—2. By the action of iodine and phosphorus on alcohol:

The phosphoric acid, at the moment of its production, acts on a sixth molecule of alcohol, in such a manner as to form ethyl-phosphoric acid, $C^2H^5.H^2.PO^4$.

Preparation.—The second reaction is almost invariably used for the preparation of iodide of ethyl. The iodine and phosphorus are either added to the alcohol in alternate small portions, or the alcohol is poured upon the whole of one of these substances,

and the other is then added by small portions. Frankland pours 36 pts. absolute alcohol on 7 pts. phosphorus in a vessel surrounded with ice-cold water; then adds gradually 32 pts. of iodine; decants the liquid from the undissolved portion, and distils it over the water-bath; washes the distillate, and mixes it with more iodine, till it exhibits a faint colour; then dries it over chloride of calcium; and rectifies it repeatedly over a mixture of chloride of calcium, mercury, and oxide of lead, to free it from the remaining water, and from iodine and hydriodic acid. Lautemann (Ann. Ch. Pharm. cxiii. 241) proceeds in a similar manner, pouring 10 pts. absolute or 95 per cent. alcohol on an equal weight of iodine, and very gradually adding 1 pt. of phosphorus. Hofmann (Chem. Soc. Qu. J. xiii. 69), to avoid the explosive action which takes place, even when the phosphorus is very gradually added to the mixture of iodine and alcohol, occasioning loss of material, and sometimes dangerous combustion, introduces the phosphorus, together with about one-fourth of the alcohol to be used, into a retort connected with an efficient cooler, and having inserted into its tubulus a glass globe provided with tube and stopcock. The rest of the alcohol is then poured upon the iodine, and the solution thus obtained is poured into the glass globe; the retort is heated by a sand- or water-bath till the phosphorus melts; and the alcoholic solution of iodine is then suffered to flow gradually into it. Iodide of ethyl is thus produced and distils over, together with alcohol. The rest of the iodine is then dissolved in the distillate, in which it dissolves much more freely than in pure alcohol, and the concentrated solution of iodine thus obtained is poured back into the retort, where it is immediately converted into iodide of ethyl. In preparing large quantities of iodide of ethyl by this method, it is found more advantageous to pour the whole of the alcohol at once on the phosphorus in the retort, then dissolve the iodine in previously prepared iodide of ethyl, in which it is extremely soluble, and allow this solution to flow gradually from the globe into the retort. Good proportions are 1000 grms. iodine, 700 grms. alcohol of specific gravity 0.84, and 60 grms. phosphorus. The iodide of ethyl distils over at once perfectly colourless, and requires only to be washed with water to free it from traces of alcohol. The product amounts to 96 or 98 per cent. of the theoretical quantity. It is remarkable that none of the proportions of the materials recommended for the actual preparation agree with those required by the equation above given, the theoretical quantities being about 8 pts. alcohol to 20 pts. iodine and 1 pt. phosphorus. In Hofmann's process, the quantity of phosphorus used is only $\frac{1}{2}$ of the alcohol.

De Vrij (J. Pharm. [3] xxxi. 169) dispenses with the use of phosphorus altogether; he saturates absolute alcohol with hydrochloric acid gas in a vessel surrounded with a freezing mixture; then, having determined the proportion of hydrochloric acid in the liquid, adds this liquid to pulverised iodide of potassium contained in a tubulated retort, in quantity just sufficient to convert the whole of the iodide into chloride of potassium. The liquid containing the iodide of ethyl thus produced is distilled off next day, then washed and rectified. (See ADDENDA, p. 967.)

Properties.—Iodide of ethyl is a colourless liquid, having a strong, peculiar ethereal odour. Specific gravity 1.9206 at 23° C. (Gay-Lussac), 1.97546 at 0° (Pierre), 1.9464 at 16° (Frankland). It boils at 70° (Pierre), with the barometer at 751 mm.; at 72.2° (Frankland), barometer at 746.6 mm. Vapour-density, by experiment = 5.475 (Gay-Lussac), by calculation (2 vol.) = 5.405. It is but slightly soluble in water, but mixes readily with alcohol and ether.

Decomposition.—1. Iodide of ethyl is but slightly inflammable; when dropped on red-hot coals, it gives off violet vapours without taking fire.—2. When its vapour is passed through a porcelain tube heated to dull redness, hydrogen, ethylene, and iodide of ethylene are obtained, and sometimes iodine is set free (E. Kopp):

3. When exposed to light, it turns red or brown, from separation of the iodine and ethyl, the decomposition taking place slowly in diffused daylight, quickly in sunshine. If the iodine be removed by mercury, the compound is at length completely decomposed, yielding, in sunshine, ethyl and iodide of mercury, the former being partly resolved into ethylene and hydride of ethyl. In diffused light, the chief product of the decomposition is iodide of mercuriethyl, $C^2H^5Hg^2I$.—4. Chlorine converts iodide of ethyl into chloride, separating the iodine if the action is rapid, but forming chloride of iodine if it is slower.—5. Strong nitric acid also separates iodine from iodide of ethyl. Strong sulphuric acid blackens it.—6. Aqueous potash acts upon it but slowly.—7. When the vapour is passed over hot soda-lime, pure ethylene is set free, and iodide of sodium is formed (Dumas and Stas):

8. Metals decompose iodide of ethyl under the influence of light or heat, with various

degrees of facility; generally speaking, the metal unites, partly with the iodine, partly with the ethyl; sometimes, however, the organo-metallic compound thus formed acts further on the metallic iodide, or on the undecomposed iodide of ethyl, giving rise to new products.

The reactions with zinc and zinc-ethyl have been already described (pp. 524, 532). Sodium-ethyl acts in the same manner as zinc-ethyl, without the aid of heat, evolving a pure mixture of ethylene and hydride of ethyl (Frankland):

Iodide of ethyl enclosed in a sealed tube, with thin strips of *tin-foil*, and heated to 180°C ., or exposed to the sun's rays concentrated by a lens or mirror, is partly decomposed, yielding ethyl and iodide of tin, while the rest unites with the metal, forming iodide of stannethyl (C^2H^5) $_2\text{Sn}^{\text{I}^2}$ (Frankland, Chem. Soc. Qu. J. vi. 67). According to Cahours (Ann. Ch. Phys. [3] lviii. 5), iodide of tristannethyl, $\text{Sn}^{\text{I}^2}(\text{C}^2\text{H}^5)_3$, is formed at the same time. When an alloy of tin and sodium is used, several other stannides of ethyl are likewise produced (Löwig, J. pr. Chem. lxxv. 386; Jahresber. f. Chem. 1852, p. 577). Arsenide of sodium or of potassium, heated with iodide of ethyl, yields the compounds $\text{As}(\text{C}^2\text{H}^5)_2$, $\text{As}(\text{C}^2\text{H}^5)_3$, and $\text{As}(\text{C}^2\text{H}^5)_4\text{I}$; antimony or antimonide of sodium yields stibtriethyl $\text{Sb}(\text{C}^2\text{H}^5)_3$. Arsenide of zinc or arsenide of cadmium, heated with iodide of ethyl in sealed tubes, yields a compound of iodide of zinc or cadmium with iodide of tetraethylarsonium, $2\text{As}(\text{C}^2\text{H}^5)_4\text{I} \cdot \text{Zn}^{\text{I}^2}$ or $2\text{As}(\text{C}^2\text{H}^5)_4\text{I} \cdot \text{Cd}^{\text{I}^2}$. Phosphide of zinc yields a similar compound, containing phosphorus in place of arsenic. Plumbide of sodium yields $\text{Pb}^2(\text{C}^2\text{H}^5)_4$, together with several other compounds (Löwig); bismuthide of sodium forms $\text{Bi}(\text{C}^2\text{H}^5)_3$.

Aluminium, heated with iodide of ethyl, yields a fuming liquid, which boils at 340°C ., and exhibits the composition $\text{Al}^2(\text{C}^2\text{H}^5)_3\text{I}^2$ or $\text{Al}^{\text{I}^2} \cdot \text{Al}^2(\text{C}^2\text{H}^5)_3$. This iodide decomposes explosively in contact with water, forming alumina, hydriodic acid, and hydride of ethyl; in an atmosphere of chlorine or oxygen it takes fire. Zinc-ethyl acts strongly on it, producing iodide of zinc, and a very inflammable liquid, which has not been obtained pure, but appears to have the composition of aluminium-ethyl, $\text{Al}^2(\text{C}^2\text{H}^5)_3$. (Cahours.)

Similar results have been obtained by Hallwachs and Schafarik (Ann. Ch. Pharm. cxix. 206).

Glucium reacts with iodide of ethyl like aluminium, and appears to form similar products. (Cahours.)

Magnesium, in the form of filings, acts spontaneously and with rise of temperature on iodide of ethyl. If the tube, after cooling, be sealed, and then heated for some hours to 120°C .— 130°C ., a white mass is formed which, when distilled, yields magnesium-ethyl mixed with iodide of ethyl. The magnesium-ethyl, separated by fractional distillation, is a colourless, allicaceous, spontaneously inflammable liquid, which decomposes water with violence. (Cahours, loc. cit.; see also Hallwachs and Schafarik, loc. cit.)

Pulverised vanadium acts slowly on iodide of ethyl at 180°C ., forming a deep red liquid. (Hallwachs and Schafarik.)

The action of mercury on iodide of ethyl has been already described (pp. 524, 525).

9. When pulverised *white precipitate* $(\text{NH}^2\text{Hg}^2)\text{Cl}$, triturated with water, is heated with iodide of ethyl for several days at the temperature of the water-bath, no gas is evolved, but gold-yellow crystals are formed, consisting of a compound of mercuric iodide with iodide of tetraethylammonium and iodide of mercuriotetraethylammonium; these crystals are surrounded by a dark brown liquid containing compounds of mercuric iodide with the iodides of ethylammonium, diethylammonium, and triethylammonium, and on this there floats a nearly colourless aqueous solution containing mercuric chloride, sal-ammoniac, and a crystallisable compound of mercuric chloride and chloride of ethylammonium [$\text{Hg}=100$]:

(Sonnenschein, Ann. Ch. Pharm. ci. 20.)

10. Iodide of ethyl dissolved in alcohol is decomposed by most *silver-salts*, in the same manner as the iodides of the alkali-metals, iodide of silver being precipitated, and the solution containing the ethyl-salt of the acid previously united with the silver. A similar decomposition takes place, and with greater facility, when a silver-salt is heated with dry iodide of ethyl in a sealed tube. This is a very convenient way of preparing many compound ethers: thus *orthophosphate*, *pyrophosphate*, *sulphate*, *sulphide*, *cyanide*, and *sulphocyanate of silver*, heated in sealed tubes with iodide of ethyl, yield the corresponding ethyl-ethers. According to Gössmann (Ann. Ch. Pharm. ci. 213) *tungstate of silver* and iodide of ethyl, enclosed together in a sealed tube, act upon

each other strongly at ordinary temperatures, evolving great heat, forming iodide of silver and oxide of ethyl, and liberating tungstic anhydride. According to H. N. Nason (Ann. Ch. Pharm. civ. 126) iodide of ethyl acts in a precisely similar manner, but with various degrees of facility, on *molybdate*, *arsenite*, *arsenate*, *antimonit*, *stannate*, *borate*, and *tellurate* of silver. With neutral or acid *chromate* of silver, it yields a small quantity of aldehyde.

The *cyanides* of *potassium* and *barium*, heated with iodide of ethyl in sealed tubes, yield an iodide of the metal and cyanide of ethyl; *cyanide* of *zinc* does not appear to act upon it at 140° — 160° C. *Cyanide* of *mercury* and iodide of ethyl decompose each other to a slight extent, even when their alcoholic solutions are simply mixed and evaporated; in sealed tubes at 120° C. the decomposition is more complete. The *metallic sulphocyanates*, heated with iodide of ethyl in sealed tubes to 100° — 160° , yield sulphocyanate of ethyl; *sulphocyanate* of *mercury* produces a more complicated reaction, the products of which have not been examined. The *acetates* of *potassium*, *barium*, *lead*, *mercury*, and *silver*, heated to 200° C. with iodide of ethyl in sealed tubes, yield metallic iodide and acetate of ethyl. With the *formates*, the decomposition is less easy; but it is facilitated by the presence of a certain quantity of alcohol. The *oxalates* are decomposed in like manner, but the resulting oxalate of ethyl is decomposed at the high temperature of the reaction, yielding carbonic oxide and carbonic anhydride, which burst the tubes when they are opened, with a loud detonation. (Schlagdenhauffen, Ann. Ch. Pharm. cvii. 234; ex. 256.)

11. A mixture of 2 pts. iodide of ethyl and 1 pt. *disulphide of carbon*, shaken up in a corked flask with *sodium-amalgam*, yields, as principal product, a fetid liquid having the composition of trisulphide of allyl ($C^3H^3S^3$). This liquid has a specific gravity of 1.012 at 16° C.; boils at 188° C.; is insoluble in water; mixes in all proportions with alcohol, ether, and disulphide of carbon; is decomposed with violence by fuming nitric acid, chlorine, bromine, and hypochlorite of calcium; is not decomposed by sodium, potash, alkaline sulphides, or mercuric oxide, but yields with alcoholic mercuric chloride, a white precipitate having the composition $12HgCl.(C^2H^2)^{2S^2}$.

12. Iodide of ethyl, heated with *alcoholic ammonia* in such a manner that the volatilised portions may condense and run back again, yields a mixture of the iodides of ammonium, and of ethyl-, diethyl-, triethyl-, and tetrethyl-ammonium (Weltzien, Ann. Ch. Pharm. lxxvi. 202). With *triethylamine* it solidifies to a crystalline mass of iodide of tetrethylammonium; and with triamines in general it forms the iodide of an ammonium containing ethyl, in addition to the radicles of the triamine. (Hofmann.)

ETHYL, NITRIDES OF. See ETHYLAMINES.

ETHYL, OXIDE OF. $C^2H^2O = \begin{matrix} C^2H^2 \\ C^2H^2 \end{matrix} O$. Ether, *Ethylic ether*, *Vinic ether*;

formerly called *Sulphuric ether*, *Phosphoric ether*, &c., according to the acid used in its preparation. (Gm. viii. 17.—Görh. ii. 270.—Kekulé, *Lehrb. der org. Chemie*, p. 100.)

Valerius Cordius, in 1540, first described the preparation of ether, which he called *Oleum vitrioli dulce*. Frobenius, who first called it *ether*, again directed attention to it in 1730. Afterwards the ether prepared by the action of sulphuric acid upon alcohol was called *sulphuric ether*; but Valentin Rose (Scher. J. iv. 263) showed that it does not contain sulphur. Fourcroy suggested that ether is alcohol deprived of a certain portion of oxygen and hydrogen; a suggestion which was confirmed, so far as regards the percentage composition, by the analyses made by Saussure and by Dumas and Boullay (Ann. Ch. Phys. xxxvi. 294).—Boullay discovered the preparation of ether by phosphoric acid (Ann. Chim. lxii. 192), and by arsenic acid (*ibid.* lxxviii. 284); he likewise first practised the preparation of ether by the continuous process (J. Pharm. i. 97).—Desfosses prepared it with fluoride of boron (Ann. Ch. Phys. [2] xvi. 72); Masson with chloride of zinc; Kuhlmann with tetrachloride of tin, and other metallic chlorides. The constitution of ether was further studied by Liebig (Ann. Ch. Pharm. ix. 1; xxx. 138).—Malaguti (Ann. Ch. Phys. [2] lxx. 338; [3] xvi. 5), and Regnault (*ibid.* [2] lxxi. 362), investigated the products of its decomposition by chlorine. Graham in 1850 (Chem. Soc. Qu. J. iii. 24) made some important experiments on the formation of ether by the action of acids and salts on alcohol under pressure; and Williamson in the same and the following year (Phil. Mag. [3] xxxvii. 360; Chem. Soc. Qu. J. iv. 106) established the views of the constitution and formation of ether now universally adopted. Lastly, Reynoso in 1856 published an elaborate series of investigations on the etherification of alcohol by acids, salts, &c. (Ann. Ch. Phys. [3] xlviii. 386.)

Formation.—1. By the action of iodide (bromide or chloride) of ethyl on ethylate of potassium or sodium. (Williamson.)

2. By heating a mixture of alcohol and strong sulphuric acid to a temperature between 140° and 150° C. (about 280° to 300° F.). The formation of ether here takes place by two stages; the first consisting in the formation of ethylsulphuric acid and water:

the second in the production of ether, and reproduction of sulphuric acid, by the mutual action of ethylsulphuric acid and another molecule of alcohol:

The sulphuric acid being thus reproduced in its original state, is ready to etherify fresh quantities of alcohol, so that, if the supply of alcohol is made continuous, the process goes on without interruption. The water formed in the first stage of the reaction does not, however, distil over quite so fast as it is formed, and consequently the sulphuric acid becomes continually more dilute, and at last too weak to etherify the alcohol.

The action of phosphoric and of arsenic acid is similar to that of sulphuric acid.

The formation of ether by the action of these and other dehydrating substances was formerly attributed to the simple abstraction of water, ether being represented by the formula $\text{C}^4\text{H}^{10}\text{O}$, and alcohol by $\text{C}^2\text{H}^5\text{O}^2$ or $\text{C}^2\text{H}^5\text{O.HO}$; but the manner in which the reaction takes place, and its relation to other reactions in which ethylic ether or analogous products are formed, clearly show that this is not the right view of it. In the first place, during the whole of the distillation, ether and water go off together, the quantity of water thus evolved being nearly equal to the whole of that which, according to the old view of the reaction, should be separated from the alcohol and taken up by the sulphuric acid. *Secondly*, ethyl-sulphuric acid is always formed on heating together alcohol and sulphuric acid; and ethyl-sulphuric acid, heated with alcohol, does actually give off ether. *Thirdly*, if, in the first mode of formation, the ethylate of potassium be mixed with iodide of methyl or amyl instead of iodide of ethyl, the product is an intermediate ether, $\text{C}^2\text{H}^5 \left\{ \text{O} \right.$ or $\text{C}^2\text{H}^5 \left\{ \text{O} \right.$; or if, in the second, a stream of ethylic alcohol be made to flow into a heated mixture of sulphuric acid and amyl alcohol, ethyl-amyl ether, $\text{C}^2\text{H}^5 \left\{ \text{O} \right.$, distils over, and ethyl-sulphuric acid remains in the vessel. These reactions are precisely analogous to those by which oxide of ethyl is produced, and show that this compound differs from the double ethers, $\text{C}^2\text{H}^5 \left\{ \text{O} \right.$, for example, only in containing 2 at. ethyl instead of 1 at. ethyl and 1 at. amyl. *Fourthly*, the vapour-densities of alcohol and ether show that a given volume of ether in the state of vapour contains twice as much ethyl as the same volume of alcohol-vapour, and therefore, according to the general law of vapour-volumes, the molecule of ether must be $(\text{C}^2\text{H}^5)^2\text{O}$, if that of alcohol is $\text{C}^2\text{H}^5\text{H.O}$. *Fifthly*, if the simple and double ethers are represented by corresponding (2-volume) formulæ, their formulæ constitute an ascending series, corresponding very nearly with their differences of boiling point; thus:

		Boiling point.
Methylic ether	$\text{C}^2\text{H}^4\text{O} = \text{CH}^3.\text{CH}^3.\text{O}$	— 21° C.
Methyl-ethylic ether	$\text{C}^3\text{H}^8\text{O} = \text{CH}^3.\text{C}^2\text{H}^5.\text{O}$	+ 11
Ethylic ether	$\text{C}^4\text{H}^{10}\text{O} = \text{C}^2\text{H}^5.\text{C}^2\text{H}^5.\text{O}$	+ 34
Methyl-amyl ether	$\text{C}^6\text{H}^{14}\text{O} = \text{CH}^3.\text{C}^4\text{H}^{11}.\text{O}$	+ 92
Ethyl-tetrylic ether	$\text{C}^8\text{H}^{20}\text{O} = \text{C}^2\text{H}^5.\text{C}^6\text{H}^{15}.\text{O}$	+ 80
Ethyl-amyl ether	$\text{C}^7\text{H}^{16}\text{O} = \text{C}^2\text{H}^5.\text{C}^5\text{H}^{11}.\text{O}$	+ 112
Tetrylic ether	$\text{C}^8\text{H}^{18}\text{O} = \text{C}^4\text{H}^8.\text{C}^4\text{H}^8.\text{O}$	+ 104
Amylic ether	$\text{C}^{10}\text{H}^{22}\text{O} = \text{C}^5\text{H}^{11}.\text{C}^5\text{H}^{11}.\text{O}$	+ 176

If the simple ethers are represented by one-volume formulæ, and the double ethers by two-volume formulæ, this gradation no longer exists. *Sixthly*, when bromide of ethyl is heated with an alcoholic solution of potash, the products formed are bromide of potassium and ether. Now, if the ether were $\text{C}^4\text{H}^{10}\text{O}$, the reaction must take place according to the equation: $\text{C}^4\text{H}^{10}\text{Br} + \text{KO} = \text{C}^4\text{H}^{10}\text{O} + \text{KBr}$, the alcohol acting merely as a solvent; whereas if ether is $(\text{C}^2\text{H}^5)^2\text{O}$ or $(\text{C}^2\text{H}^5)^2\text{O}$, the alcohol must take part in the reaction, in the manner shown by the equation:

Now Berthelot found (Ann. Ch. Pharm. xcii. 131) that 22 grms. of bromide of ethyl thus treated yielded 12 grms. of ether, the theoretical quantity being 7.6 according to the first supposition, and 15 according to the second. Hence, allowing for an avoidable loss in rectifying the product, the result may be taken as a proof that the alcohol reacts in the manner shown by the second of the above equations, and that the molecule of ether contains 2 at. ethyl. (See the articles ALCOHOL, i. 76; and CHEMICAL AFFINITY, i. 867.)

Ether is also produced by the following reactions:—

3. By the action of iodide (bromide or chloride) of ethyl on dry oxide of silver:

Other ethyl-salts—the nitrate for example—act in a similar manner.

4. By heating alcohol with bromide or iodide of ethyl to 200°C . (Reynoso.)

5. By heating bromide or iodide of ethyl with water to $150^\circ\text{--}200^\circ\text{C}$. (Frankland, Reynoso). In this case, alcohol is first formed, according to the equation:

and this alcohol, acting on the excess of iodide or bromide of ethyl, forms ether, as in 4.

6. By heating alcohol to $200^\circ\text{--}240^\circ\text{C}$. with hydrochloric, hydrobromic, or hydriodic acid. Chloride, bromide, or iodide of ethyl is then formed, which acts upon the remaining alcohol as in 4, converting it into ether.

7. The same action is exerted by metallic chlorides, when distilled with alcohol, or better, when heated with it in sealed tubes, *e. g.* by chloride of zinc, tetrachloride of tin, the chlorides of manganese, cobalt, nickel, and cadmium, ferrous chloride, mercuric chloride, &c. (Reynoso.) Even chloride of calcium and chloride of strontium convert alcohol into ether, when heated with it to 300°C . (Berthelot, Ann. Ch. Pharm. lxxxiii. 104.)

The etherifying actions of iodide of mercury (Reynoso), of fluoride of boron, and of fluoride of silicon, belong to the same category.

8. Many sulphates also convert alcohol into ether when heated with it to $200^\circ\text{--}230^\circ\text{C}$, ethylsulphuric acid being first formed, and then producing ether with the rest of the alcohol; etherification is thus effected by the sulphates of magnesium, zinc, and cadmium, by ferrous, cobaltous, and uranic sulphate, also by sulphate of aluminium, common alum, ammonia-, iron-, and chrome-alum. (Reynoso.)

Preparation.—Ether is always prepared by heating a mixture of alcohol and sulphuric acid. The best mode of conducting the operation is that introduced by Boullay, in which the alcohol is supplied in a constant stream and the formation of ether goes on uninterruptedly (p. 537). A mixture of 5 pts. alcohol of 90%, and 9 pts. strong sulphuric acid is introduced, after cooling, into a wide-mouthed flask closed with a cork having three apertures, through one of which there passes a bent tube proceeding from a reservoir of alcohol, and terminating in a narrow mouth below the surface of the liquid in the flask; the reservoir is provided with a stop-cock to regulate the flow of spirit. Through the second aperture is inserted another bent tube, terminating just below the cork, and passing to a Liebig's condenser or a worm-tub connected with a receiver. The third aperture is for the insertion of a thermometer. The flask is heated in a sand-bath, and as soon as it begins to boil, the alcohol from the reservoir is allowed to flow in, the stream being regulated so as to keep the temperature of the liquid at about 140°C . (284°F .); below this temperature, the distillate consists chiefly of alcohol, and at higher temperatures large quantities of olefant gas are evolved. The process may be continued till the quantity of alcohol run in amounts to about six times that which was originally mixed with the sulphuric acid, making in all 35 pts. alcohol to 9 pts. acid. After this the sulphuric acid becomes too dilute to etherify the alcohol effectually. The alcohol which remains mixed with the sulphuric acid at the end of the process, may be recovered by mixing the liquid with water and distilling. On the large scale, a still of cast-iron lined with lead is generally used; it has, however, the disadvantage of not allowing the course of the operation to be watched. To moderate the great heat evolved on mixing large quantities of alcohol and sulphuric acid, the mixture is made in a metallic vessel surrounded with cold water or ice, and the sulphuric acid is poured down the side, so that it may form a layer below the alcohol. The two liquids are then slowly mixed by stirring with a wooden spatula, and the mixture when sufficiently cool, is transferred to the still. The distillation is conducted in the manner above described.

The first portions of the distillate separate spontaneously into two layers, the upper consisting of ether, mixed with comparatively small quantities of alcohol and water,

the lower of water, containing ether and alcohol in solution; but towards the latter part of the distillation, when the sulphuric acid has become weaker, more alcohol passes over unchanged, and the separation of the ether no longer takes place. The distillate also contains sulphurous acid, acetic acid, and a little oil of wine. To purify it, the whole of the distillate is introduced, together with an equal volume of milk of lime, into a large separating globe, having a descending tube and stopcock like a tap-funnel; the mixture is frequently agitated, and then left to itself till the ether has risen to the top, after which the lime-solution is run off by the stopcock, and the ether which remains is rectified over a water-bath. Nearly pure ether, amounting to one-third of the crude ether in the retort, then passes over first; afterwards ether containing alcohol; then alcohol containing oil of wine; and lastly water.

The rectified ether still retains a little water and alcohol; but it is pure enough for most purposes; it should, however, be quite free from sulphurous acid, and therefore should not redden litmus paper. 100 pts. alcohol containing 85 pts. by weight of absolute alcohol (after deducting that which remains in the flask) yield, in a well conducted process, 59 or 60 pts. by weight of ether, of specific gravity 6.725, or 70% of the (absolute) alcohol used. If the whole of the alcohol were converted into ether, the yield would be 80 per cent.

Soubéiran (J. Pharm. [3] xvi. 321) describes an apparatus for the preparation of ether on the large scale, by which the ether is at once obtained in the rectified state, the first condensing vessels being kept (as in the more recently invented apparatus for the distillation of brandy) at a sufficiently high temperature to maintain the pure ether in the state of vapour. He recommends that the temperature of the etherifying mixture be kept constantly at 130° C., because at 140° a gaseous hydrocarbon is constantly produced. An apparatus for the rectification of ether has also been described by Hoyer (Arch. Pharm. [2] xiii. 140).

The ordinary ether, obtained as above, may be completely freed from water and alcohol, and converted into absolute ether, either by placing it in contact with lumps of fused chloride of calcium, which takes up the water and alcohol, and separates from the ether in the form of a thick heavy liquid, or by agitating it repeatedly with 2 pts. of water, separating the upper layer of liquid by a pipette or tap-funnel, then leaving it for some time in contact with quick-lime or chloride of calcium, and rectifying.

Absolute ether should form a clear mixture in all proportions with oil of copaiba; ether containing water or alcohol forms an emulsion with considerable quantities of the oil. (Blanchet, Ann. Ch. Pharm. vii. 157.)

Properties.—Pure ether is a colourless, transparent, very mobile liquid, having a peculiar exhilarating odour and sharp, burning taste, with cooling after-taste. It is perfectly neutral to vegetable colours; refracts light strongly. Specific gravity 0.723 at 12.5° C. Boiling point 35.6° C. (96° F.) under a pressure of 760 mm. Vapour-density 2.586 (Gay-Lussac); by calculation for the formula $(C^2H^5)^2O$, representing a condensation to 2 volumes, it is 2.564 ($= \frac{4 \cdot 12 + 10 \cdot 1 + 16}{2} \times 0.0693$). Cooled

to - 31° C. it crystallises in white shining laminae. It is very inflammable, and its vapour, when mixed with air, detonates with great violence on the approach of a burning body. As the vapour of ether has a considerable tension at ordinary temperatures, and consequently diffuses quickly to a considerable distance, great danger is incurred in pouring the liquid from one vessel to another, in the neighbourhood of a gas-light or any burning body. The decantation of any considerable quantity of ether should always be performed in a room where there are no lights burning.

Ether mixes in all proportions with alcohol, wood-spirit, chloroform, acetone, and many other liquids, and to a certain extent also with water. When ether is shaken up with water, two layers are formed, the upper consisting of ether containing a little water, and the lower of water which has dissolved $\frac{1}{10}$ of ether. Ether dissolves iodine and bromine, and small quantities of sulphur and phosphorus; also chloride of gold, chloride of iron, mercuric chloride, and mercuric nitrate. It dissolves with facility most organic bodies containing a large proportion of hydrogen, such as fats and resins, which are but sparingly dissolved by alcohol, whereas it acts but little on those which are easily soluble in alcohol.

Ether unites directly with tetrachloride of tin, forming the compound $2C^2H^5 \cdot O \cdot SnCl_4$, which crystallises in shining rhomboidal plates, volatile without decomposition, dissolving easily in excess of ether, and decomposing in contact with water.

Decompositions.—1. By Heat. Ether-vapour, passed through a red-hot tube, yields nearly the same products as alcohol, viz. olefiant gas, carbonic oxide, water, aldehyde, &c.—2. By Combustion. When ether burns rapidly in the air or in oxygen gas, it is completely converted into water and carbonic anhydride; but when ether-vapour mixed with air comes in contact with platinum-black, slightly heated platinum-sponge,

or other bodies heated not quite to redness, it undergoes a slow and imperfect combustion, like alcohol under similar circumstances, yielding various products of oxidation, viz. aldehyde, acetic acid, formic acid, carbonic acid, water, and a peculiar volatile, pungent substance, which has been called *acetyloous, aldehydic, or lampic acid*, but has not been isolated: it is probably only a mixture of the products just mentioned (see *Acetyloous Acid*, i. 36; *Alcohol*, i. 74; *Combustion*, i. 1093). Ether exposed to the air in contact with potash yields a small quantity of acetate of potassium.—3. Ether mixed with strong *sulphuric acid* and heated to 120° C. does not give off any gas, and if water be then added, a solution is formed containing nothing but ethyl-sulphuric acid. If, on the other hand, the heat be raised above 120° C. the liquid begins to boil at 130° , and at 150° gives off sulphurous anhydride; at 180° it is in full ebullition, gives off oil of wine impregnated with sulphurous acid, and blackens considerably; the residue contains isethionic and ethionic acids.—4. Ether is decomposed by heated *nitric acid*, yielding carbonic anhydride, acetic acid, and oxalic acid.—5. *Chloric* and *bromic acids* likewise oxidise it rapidly, acetic acid being formed, and chlorine or bromine evolved.—6. With *hydrochloric acid gas* it forms chloride of ethyl.—7. Dry *chlorine* passed into anhydrous ether, forms three substitution products, $\text{C}_2\text{H}_5\text{Cl}$, $\text{C}_2\text{H}_4\text{Cl}_2$, and $\text{C}_2\text{H}_5\text{ClO}$, besides aldehyde, chloral, chloride of ethyl, and hydrochloric acid. If water is present, acetic acid and other products of oxidation are formed.—8. *Bromine* appears to act upon ether like chlorine. The red solution of bromine in ether becomes colourless after a few days, with formation of hydrobromic acid, bromide of ethyl, bromal, and other products, forming together a mixture analogous to heavy hydrochloric ether (p. 532). With *chloride of bromine*, ether yields hydrochloric acid and an organic compound rich in bromine.—9. *Iodine* acts but slightly upon ether. *Chloride of iodine* forms hydrochloric acid, the iodine dissolving in the ether.—10. *Phosphorus* converts ether into several phosphorised acids, which have not been accurately studied.—11. *Potassium* and *sodium* slowly decompose ether, eliminating hydrogen (Thénard.) [Was the ether quite free from water and alcohol?].—12. When ether-vapour is passed over heated *potash-* or *soda-lime*, hydrogen and marsh-gas are given off, and an alkaline carbonate is formed.—13. Ether decomposes many *metallic chlorides*, abstracting the chlorine, and yielding products which are probably the same as those produced by the action of free chlorine on ether. *Sesquichloride of iron* is decolorised and reduced to protochloride, with formation of hydrochloric acid; *cupric chloride* to cuprous chloride; *mercuric chloride* to mercurous chloride, which is precipitated; from *chloride of gold*, in sunshine, metallic gold is deposited.

CHLORINATED AND SULPHURETTED DERIVATIVES OF ETHYLIC ETHER.

Anhydrous ether treated with chlorine yields three substitution-products, containing 1, 2, and 4 at. chlorine in place of hydrogen, according to the manner and duration of the action. These compounds have been investigated chiefly by Regnault (*Ann. Ch. Phys.* [2] lxxi. 392), Malaguti (*ibid.* [2] lxx. 338; [3] xvi. 6 and 19), and Lieben (*Ann. Ch. Pharm.* cxi. 121).

Monochlorethyllic Ether, $\text{C}_2\text{H}_5\text{ClO} = \begin{Bmatrix} \text{C}_2\text{H}^*\text{Cl} \\ \text{C}_2\text{H}^*\text{Cl} \end{Bmatrix} \text{O}$.—This compound, originally called *chlorethral*, was discovered in 1837 by D'Arcet (*Ann. Ch. Pharm.* xxviii. 82), who obtained it by the action of chlorine on olefant gas. Regnault, however, suggested that its production was due to the presence of ether-vapour in the gas; and Lieben has since shown that the same compound is the chief product of the action of chlorine on ether at temperatures not exceeding 20° — 30° C. It is a very mobile, limpid, colourless liquid, having a sweet, ethereal odour, and boiling between 140° and 147° . Vapour-density = 4.93. Water decomposes it, yielding a substance which appears to be isomeric with aldehyde or acetate of ethyl. With potash it yields alcohol and acetic acid:

Dichlorethyllic Ether, $\text{C}_2\text{H}_4\text{Cl}_2\text{O} = \begin{Bmatrix} \text{C}_2\text{H}^*\text{Cl} \\ \text{C}_2\text{H}^*\text{Cl} \end{Bmatrix} \text{O}$.—Discovered by Malaguti in 1839. Produced when pure ether is saturated with chlorine in diffused daylight, the liquid being cooled at first, and afterwards heated to 100° C. A large quantity of hydrochloric acid is formed in the reaction, together with chloride of ethyl and chloral; the hydrochloric acid, acting on the ether, forms chloride of ethyl and water, and the chlorine, in presence of the water, exerts an oxidising action, resulting in the formation of chloral.

Dichlorethyllic ether is a limpid liquid, of specific gravity 1.5008, having an odour like that of fennel. It is decomposed by heat, even below its boiling point, with ev

tion of hydrochloric acid. It is slowly decomposed by water and by aqueous potash, quickly by alcoholic potash, yielding chloride and acetate of potassium:

Potassium decomposes it at a gentle heat, forming a chloride of potassium, and eliminating a gas, which burns with a green flame. Chlorine, in sunshine, converts dichlorethylic into perchlorethylic ether.

Sulphuric acid decomposes dichlorethylic ether, with evolution of hydrochloric acid and formation of an oily liquid, which solidifies in a few days to a soft crystalline mass, separable by crystallisation from boiling alcohol into the two following compounds containing respectively 1 and 2 at. sulphur in place of 2 and 4 at. chlorine:

Sulphethylic Ether, $\text{C}^4\text{H}^4\text{S}^2\text{O}$ (Malaguti's *ether sulfuré*), crystallises out first in prismatic needles, having a faint odour like that of chloride of sulphur, melting between 120° and 123° C., insoluble in water, but soluble in alcohol and ether; decomposed by alcoholic potash, yielding sulphide and acetate of potassium.

Chlorosulphethylic Ether, $\text{C}^4\text{H}^4\text{Cl}^2\text{SO}$ (Malaguti's *ether chlorosulfuré*), crystallises from the mother-liquor of the preceding, in unctuous fetid scales, melting between 70° and 72° C., insoluble in water, soluble in alcohol and ether. Alcoholic potash converts it into sulphide, chloride, and acetate of potassium.

These sulphuretted compounds, as well as the dichlorinated ether from which they are formed, may be regarded as intermediate in composition between ethylic ether and acetic anhydride, and as derived from the latter by the substitution of chlorine or sulphur for an equivalent quantity of oxygen in the acetyl:

All these compounds, when treated with potash, yield acetate of potassium.

Perchlorethylic Ether, $\text{C}^4\text{Cl}^4\text{O} = \frac{\text{C}^2\text{Cl}^2}{\text{C}^2\text{Cl}^2}\text{O}$.—Discovered by Regnault in 1830.

Produced by the prolonged action of chlorine on ether, in sunshine. In preparing this and the other chlorinated derivatives of ether, it is advisable not to cool the liquid too much at the beginning, so as to allow the hydrochloric ether, which is produced in large quantity, to escape; otherwise the reaction is apt to become very complicated, and to yield especially large quantities of perchlorinated chloride of ethyl or trichloride of carbon (p. 532).

Perchlorethylic ether crystallises in dimetric octahedrons, differing but little from regular octahedrons. Length of principal axis = 0.952. P : P in the lateral edges = $106^\circ 46'$. Terminal summits truncated by the face oP. Cleavage parallel to oP (Nicklès, Ann. Ch. Phys. [3] xxii. 28). Specific gravity = 1.9 at 14.5° C. (Malaguti). Melts at 69° C. (Regnault), and boils at about 300° , being resolved at the same time into trichloride of carbon and chloride of trichloroacetyl, $\text{C}^4\text{Cl}^4\text{O} = \text{C}^2\text{Cl}^2 + \text{C}^2\text{Cl}^2\text{O}$.

Sulphuric acid acts slowly on perchlorethylic ether at 210° C., emitting vapours, which when condensed in water, form a solution of trichloroacetic, sulphuric, and hydrochloric acids (Malaguti). The decomposition is probably as follows:—

Potassium acts violently on perchlorethylic ether, but only near the temperature at which spontaneous decomposition begins (Malaguti). The ether is attacked by alcoholic potash, but the reaction appears to be complicated by the presence of the alcohol. (Regnault.)

An alcoholic solution of *protosulphide of potassium* converts perchlorethylic ether into chloroxethose (i. 924):

and this compound, when subjected to the action of chlorine, is reconverted into perchlorethylic ether. (Malaguti.)

Perchlorobromethylic Ether, $\text{C}^4\text{Cl}^4\text{Br}^2\text{O}$, *Bromide of Chloroxethose*.—Obtained by exposing chloroxethose to the action of bromine in sunshine (Malaguti).

Crystallises in octahedrons, isomorphous with those of perchlorethyllic ether (Nickla, *loc. cit.*). Colourless, inodorous. Specific gravity = 2.5 at 18° C. Melts at 96°, and is resolved at the same time into bromine and chlorozethose. The same decomposition takes place under the influence of sulphides. (Malaguti.)

This compound and the preceding exhibit towards ethylic ether and acetic anhydride, relations similar to those previously noticed with respect to dichlorethyllic ether and its sulphuretted derivatives; thus:

The interest of these relations is increased by the facility with which perchlorethyllic ether is converted into compounds of the acetic acid series, e.g. chloride of trichloroacetyl and trichloroacetic acid.

Double Ethers containing Ethyl: Ethylates.

ETHYLATE OF AMYL. $\text{C}^5\text{H}^{10}\text{O} = \begin{matrix} \text{C}^2\text{H}^5 \\ \text{C}^3\text{H}^{11} \end{matrix} \left. \vphantom{\begin{matrix} \text{C}^2\text{H}^5 \\ \text{C}^3\text{H}^{11} \end{matrix}} \right\} \text{O}$.—See AMYL, OXIDE OF (i. 205).

ETHYLATE OF CETYL. $\text{C}^{18}\text{H}^{38}\text{O} = \begin{matrix} \text{C}^2\text{H}^5 \\ \text{C}^{16}\text{H}^{33} \end{matrix} \left. \vphantom{\begin{matrix} \text{C}^2\text{H}^5 \\ \text{C}^{16}\text{H}^{33} \end{matrix}} \right\} \text{O}$.—See CETYL, OXIDE OF (i. 842).

ETHYLATE OF BENZYLENE. $\text{C}^{11}\text{H}^{16}\text{O}^2 = \left(\begin{matrix} \text{C}^2\text{H}^5 \\ \text{C}^7\text{H}^9 \end{matrix} \right)^2 \text{O}^2$.—See BENZYLENIC ETHER (l. 578).

ETHYLATES OF ETHYLENE. $\begin{matrix} \text{C}^2\text{H}^5\text{H} \\ \text{C}^2\text{H}^4 \end{matrix} \left. \vphantom{\begin{matrix} \text{C}^2\text{H}^5\text{H} \\ \text{C}^2\text{H}^4 \end{matrix}} \right\} \text{O}^2$ and $\left(\begin{matrix} \text{C}^2\text{H}^5 \\ \text{C}^2\text{H}^4 \end{matrix} \right)^2 \text{O}^2$.—See ETHYLENE, OXIDE OF (p. 579).

ETHYLATE OF METHYL. $\text{C}^3\text{H}^8\text{O} = \begin{matrix} \text{C}^2\text{H}^5 \\ \text{CH}^3 \end{matrix} \left. \vphantom{\begin{matrix} \text{C}^2\text{H}^5 \\ \text{CH}^3 \end{matrix}} \right\} \text{O}$. *Methylate of Ethyl; Ethylmethylic.*

Methylethylic, or Vinomethylic Ether; Vinomethylide. (Williamson [1850], Phil Mag [3] xxxvii. 350; Chem. Soc. Qu. J. iv. 106, 229.—Chancel, Compt. rend. xxxi. 152.)—Produced: 1. By the action of iodide of methyl on ethylate of sodium, or of iodide of ethyl on methylate of sodium:

The second process is to be preferred, because the product is more easily purified by rectification than in the first. The apparatus should be arranged so that the distillate may constantly flow back into the retort till the decomposition is finished; the double ether may then be distilled off from the fixed products (Williamson).—2. By the action of methylsulphate on ethylate of potassium (Chancel):

It is a transparent, colourless, very mobile liquid, boiling at 11° C. Vapour-density = 2.168, corresponding with a condensation to 2 vol. (Williamson). The vapour has a peculiar ethereal odour, and is highly inflammable. (Chancel.)

ETHYLATE OF OCTYL. $\text{C}^{10}\text{H}^{20}\text{O} = \begin{matrix} \text{C}^2\text{H}^5 \\ \text{C}^8\text{H}^{17} \end{matrix} \left. \vphantom{\begin{matrix} \text{C}^2\text{H}^5 \\ \text{C}^8\text{H}^{17} \end{matrix}} \right\} \text{O}$. *Ethyl-octylic ether.* (Wills, Chem. Soc. Qu. J. vi. 312.)—Produced by the action of octylate of sodium on iodide of ethyl. It is a colourless mobile liquid, having a specific gravity of 0.791 at 16° C., and boiling at 177°. Vapour-density by observation = 5.095; by calculation from the preceding formula (2 vol.) = 5.47.

Wills regards this compound as *ethyl-heptylic ether*, $\text{C}^9\text{H}^{18}\text{O} = \text{C}^2\text{H}^5\text{C}^7\text{H}^{13}\text{O}$. The vapour-density, 4.99, deduced from this formula, certainly agrees better with the observed density than that deduced from the formula $\text{C}^{10}\text{H}^{20}\text{O}$; and so likewise does the analysis, which gives 75.16 per cent. carbon and 14.44 hydrogen, the formula $\text{C}^9\text{H}^{18}\text{O}$ requiring 75.00 C. and 13.88 H., whereas $\text{C}^{10}\text{H}^{20}\text{O}$ requires 75.95 C. and 13.92 H. But the experiments of Bouis and others tend to show that castor-oil alcohol, from which this compound is derived, contains 8 rather than 7 at. carbon. (See ALCOHOLS, i. 98; also OCTYLIC ALCOHOL.)

ETHYLATE OF POTASSIUM. $\text{C}^2\text{H}^5\text{K.O}$. *Potassium-alcohol.*—Produced by treating absolute alcohol with potassium; 1 at. hydrogen is then given off and its place supplied by potassium. The ethylate of potassium separates from the saturated liquid in colourless crystals, which, if protected from moisture and carbonic acid, may be preserved without alteration. Water converts the compound into alcohol and hydrate of potassium. Its other reactions are similar to those of the following compound.

ETHYLATE OF SODIUM. C^2H^5NaO . *Sodium-alcohol*.—Produced like the potassium-compound.—Crystallises in broad laminae. This compound, and the preceding, exhibit precisely similar reactions, and both form very convenient reagents for the preparation of a great number of organic bodies, serving to introduce ethyl by substitution into many compounds. Ethylate of sodium is, however, generally preferred to the potassium-compound, because sodium is cheaper than potassium, and acts less violently upon alcohol.

Ethylate of sodium, treated with the *iodide, bromide, or chloride* of an alcohol-radicle, forms iodide, bromide, or chloride of sodium, and an ether containing one or two alcohol-radicles, according to the particular reagent used (Williamson, *loc. cit.*). With *nitrate of ethyl* it acts in like manner, yielding ethylic ether, and nitrate of sodium; but with the ethers of organic acids, a different reaction takes place. With *acetate of ethyl* it forms a very insoluble compound, which absorbs water greedily from the air, yielding alcohol and acetate of sodium:

Benzoate and oxalate of ethyl act upon it in a somewhat similar manner (Beilstein, Ann. Ch. Pharm. cxii. 121).—*Carbonic anhydride* passed into a solution of ethylate of sodium forms a white precipitate of ethyl-carbonate of sodium (Beilstein, *loc. cit.*).—*Carbonic oxide* does not act on ethylate of sodium (Wanklyn, Ann. Ch. Pharm. cx. 111) unless a trace of moisture is present; in which case a small quantity of formic acid is produced by the action of the carbonic oxide on hydrate of sodium. (Geuther, *ibid.* cix. 73; Lieben, *ibid.* cxii. 326.)

Cyanate of ethyl, heated in a sealed tube with ethylate of sodium, generally yields triethylamine; sometimes, however, the greater part of the cyanate is converted into cyanurate, which acts on the ethylate of sodium in the manner explained on page 293, yielding hydrate of carbetriethyltriimine. (Hofmann, Proc. Roy. Soc. xi. 282.)

With *iodoform*, ethylate of sodium yields iodide of methylene and a body having the composition of aldehyde:

With *iodine*, it yields iodide of sodium, formate of sodium, and iodoform; which last compound acts upon it in the manner just mentioned. *Chloroform* converts ethylate of sodium into chloride of sodium, and a body having the composition $C^2H^5O^2$:

(Kay, Chem. Soc. Qu. J. vii. 224.)—Wurtz (Compt. rend. xliii. 478) suggests that this compound may be the triethylic ether of a triatomic alcohol homologous with glycerin; $C^2H^5O^3 = \left\{ \begin{smallmatrix} CH \\ C^2H^5 \end{smallmatrix} \right\}^3 O^3$.

With *monochloroacetic acid*, ethylate of sodium yields the sodium-salt of ethylox-acetic acid (an acid isomeric with ethylglycollic acid), together with alcohol and chloride of sodium:

(Heintz, Pogg. Ann. cix. 301; Jahresber. d. Chem. 1859, p. 360.—See OXACETIC Acn.)

With *nitrobenzene*, ethylate of sodium (and likewise alcoholic potash) yields azobenzene, azoxybenzene, phenylamine, oxalic acid, and other products. (Béchamp and Saint-Pierre, Compt. rend. xlvii. 24.)

ETHYLATE OF TETRYL. $C^2H^5O = \begin{smallmatrix} C^2H^5 \\ C^4H^9 \end{smallmatrix} O$, *Ethylate of Butyl, Ethyl-tetrylic or Ethyl-butylic ether*. (Wurtz, Ann. Ch. Phys. [3] xlii. 129.)—Produced by the action of iodide of ethyl on tetrylate of potassium, C^4H^9KO . Colourless, mobile, fragrant liquid, of specific gravity 0.751, boiling between 78° and $80^\circ C$.

ETHYL, PHOSPHIDES OF. See PHOSPHORUS-BASES.

ETHYL, PLUMBIDES OF. See PLUMBETHYLS.

ETHYL, SELENHYDRATE OF. $C^2H^5Se = \begin{smallmatrix} CH^2 \\ H \end{smallmatrix} \} Se$. *Selenium-mercaptan*. (Wöhler and Siemens, Ann. Ch. Pharm. lxi. 360.)—This compound is obtained by saturating aqueous potash with selenhydric acid gas in an apparatus filled with hydrogen, and distilling the resulting solution of selenide of hydrogen and potassium with concentrated ethylsulphate of potassium, the air being as much as possible ex-

cluded. Selenhydric acid gas is first given off, and afterwards water passes over, together with a heavy, yellow, intolerably stinking liquid. This liquid, after being separated from the watery distillate, is placed in contact with chloride of calcium and distilled into a fresh receiver, whereupon selenium-mercaptan passes over first, and afterwards selenide of ethyl.

Selenium-mercaptan is a thin, transparent, colourless liquid, heavier than water, and insoluble therein, but soluble in alcohol. It boils considerably above 100°C ., and has an extremely repulsive odour, resembling that of the cacodyl-compounds.

It burns with a bright blue flame, giving off thick white and red vapours of selenious acid and selenium. The vapour passed through a tube heated to low redness is decomposed, with separation of selenium. A mixture of selenium-mercaptan and chlorate of potassium takes fire and explodes on the addition of hydrochloric acid. Selenium-mercaptan appears not to be completely oxidised by chlorine or nitric acid. When passed in the state of vapour over red-hot copper wire, it is completely decomposed, forming crystalline selenide of copper, emitting an odour like that of benzene, and depositing a small quantity of charcoal.

In contact with mercuric oxide, it becomes heated, makes a hissing noise, and forms a yellow, easily fusible substance, which dissolves in hot alcohol, and separates from it in an amorphous condition on cooling. The alcoholic solution of selenium-mercaptan also forms a thick yellow precipitate with mercuric chloride.

ETHYL, SELENIDE OF, or SELENETHYL. $\text{C}_2\text{H}_5\text{Se} = (\text{C}_2\text{H}_5)_2\text{Se}$. Selenhydric or Hydroselenic ether. (Löwig, Pogg. Ann. xxxvii. 552; *Chemie der organischen Verbindungen*, Aufl. 2, ii. 432.—Joy, Ann. Ch. Pharm. lxxvi. 35.—Gm. viii. 366.)

Finely powdered selenide of potassium mixed to the consistence of a thick paste with pure oxalic ether, then gently heated in a retort for some hours, and afterwards distilled, yields a liquid which smells and tastes like sulphide of ethyl, and when set on fire burns with an odour of horse-radish, and deposits selenium. (Löwig.)—Joy obtains the compound by distilling selenide of potassium with aqueous ethylsulphate of calcium. It appears also to be produced in small quantity, in the preparation of selenium-mercaptan. (Siemens, Ann. Ch. Pharm. lxi. 360.)

Selenethyl is a clear, pale-yellow liquid, having a most insufferable odour; it is much heavier than water, and does not mix with it. When set on fire, it burns continuously, emitting red vapours of selenium.

Selenethyl is an organic basis forming definite salts with acids. Nitric acid converts it into a nitrate, from which the chloride, bromide, and iodide may be obtained by double decomposition. (Joy.)

Bromide of Selenethyl, separates in the form of a lemon-yellow oil, heavier than water, when a solution of the nitrate is mixed with hydrobromic acid. It dissolves readily in ammonia, and forms an oxybromide. (Joy.)

Chloride of Selenethyl. $\text{C}_2\text{H}_5\text{SeCl}^2$.—The solution of selenide of ethyl in nitric acid mixed with hydrochloric acid becomes milk-white, and immediately afterwards deposits drops of an oily body which is the chloride of selenethyl. It is a transparent light yellow liquid which sinks in water; when quite pure, it appears to be inodorous. It is somewhat soluble in water and more so in hydrochloric acid, which circumstance renders some care necessary in preparing it.

On leaving it for a considerable time in contact with the liquid containing hydrochloric and nitric acid, in which it has been produced, a number of well-defined transparent and colourless crystals are formed at the separating surface of the two liquids. These crystals dissolve readily in water and alcohol, and separate unchanged on evaporation. The aqueous solution is acid, and forms with ammonia a crystalline mass, from which the ammonia is separated by potash. Sulphurous acid added to it separates selenethyl. The crystals give by analysis 13.7 per cent. carbon, 4.3 hydrogen, and 20.05 chlorine: therefore 1 at. chlorine to 2 at. carbon.

Iodide of Selenethyl, $\text{C}_2\text{H}_5\text{SeI}^2$, is obtained on adding hydriodic acid to a solution of the chloride or nitrate, as a black liquid, having a semi-metallic lustre, sinking in water. It is inodorous, does not solidify at 0°C .; dissolves only in ammonia.

Nitrate of Selenethyl is formed by dissolving selenethyl in hot, moderately strong nitric acid, the action being attended with evolution of nitric oxide gas.

Oxychloride of Selenethyl. $\text{C}_2\text{H}_5\text{SeCl}^2\text{O} = \frac{\text{C}_2\text{H}_5\text{SeCl}}{\text{C}_2\text{H}_5\text{SeCl}}\text{O}$? Chloride of selenethyl dissolves readily in ammonia, forming chloride of ammonium and oxychloride of selenethyl. The latter may be extracted by absolute alcohol, and crystallises in highly lustrous, colourless cubes, generally grouped in stellate masses. Hydrochloric acid added to the aqueous solution throws down the oily chloride of selenethyl; and sulphurous acid throws down a fetid mixture of selenethyl and the chloride. (Joy.)

ETHYL STANNIDES OF. See STANNETHYLS.

ETHYL SULPHIDES OF. Three sulphides of ethyl are known, viz. the proto-, di-, and tri-sulphide. They are oily liquids having a pungent alliaceous odour.

Protosulphide of Ethyl. $(C^2H^5)^2S$. *Sulphydric or Hydrosulphuric ether.* (Döbereiner, Schw. J. lxi. 377.—Regnault, Ann. Ch. Phys. [2] lxxi. 387.—Loir, Compt. rend. xxvi. 195.—Riche, Ann. Ch. Phys. [3] xliii. 297.)—This compound, the analogue of common ether, is produced by the action of protosulphide of potassium on ethylsulphate of potassium, chloride of ethyl, and other ethyl-compounds; also, according to Döbereiner, by dissolving protosulphide of iron in a mixture of strong hydrochloric acid and alcohol.

Preparation.—An alcoholic solution of potash is divided into two equal parts: one part is saturated with sulphydric acid gas, and then mixed with the other; the liquid is introduced into a tubulated retort; vapour of hydrochloric ether is passed through it to saturation; and heat is then gradually applied, the stream of hydrochloric ether vapour being still kept up. From the distillate, which contains alcohol as well as sulphide of ethyl, the sulphide of ethyl is precipitated by water; it is then purified by washing with water, dehydrated by chloride of calcium, and rectified (Regnault). Faudrimont (Compt. rend. liv. 616) distils sulphide of potassium with iodide of ethyl. Löwig distils sulphide of potassium with ethylsulphate of barium.

Properties.—Sulphide of ethyl is a colourless oily liquid having a very pungent, disagreeable, alliaceous odour. Specific gravity = 0.825 at 20° C. Boiling point 73° C. Vapour-density 3.00 (Regnault); calculated (2 vol.) = 3.12. It is insoluble in water, but soluble in alcohol.

It is very inflammable and burns in the air with a blue flame. When poured into chlorine gas, it takes fire spontaneously. Nitric acid oxidises it readily, converting it partly into ethyl-sulphurous acid $(SO)^2.C^2H^5.H.O^2$. It is not decomposed by boiling with potash-ley, but on distilling it over hydrate of potassium sulphide of potassium is formed, and alcohol passes over, together with undecomposed sulphide of ethyl, $(C^2H^5)^2S + 2KHO = K^2S + 2(C^2H^5.H.O)$. It is not altered by mercuric oxide, but forms a yellow precipitate with acetate of lead. (See ADDENDA, p. 967.)

Compounds of Ethylic Sulphide with Metallic Chlorides.

Mercury-compound. $(C^2H^5)^2S.Hg^2Cl^2$.—By agitating aqueous mercuric chloride with sulphide of ethyl or its alcoholic solution, a crystalline compound is obtained, which may be purified by recrystallisation from boiling alcohol, and obtained in distinct crystals by solution in ether or wood-spirit. It forms monoclinic prisms, in which $\alpha P : \infty P = 103^{\circ} 40'$; $\infty P : oP = 73^{\circ} 10'$. It is heavier than water; has a very unpleasant odour; becomes opaque and gives off sulphide of ethyl on exposure to the air; melts at 90° C. to a colourless liquid, which solidifies to a crystalline mass on cooling; and decomposes at a stronger heat, emitting fetid vapours. (Loir.)

Platinum-compound $2(C^2H^5)^2S.PtCl^4$.—Obtained like the preceding, which it resembles in most of its properties. Melts at 108° C.

Chlorinated Derivatives of Ethylic Sulphide.

Sulphide of ethyl takes fire when poured into chlorine gas; but when dry chlorine is passed into a flask containing sulphide of ethyl, not at first into the liquid, the vessel being kept cool and in the shade, substitution-products are formed, the chlorine quickly disappears, and hydrochloric acid gas is abundantly evolved; towards the end of the operation, the chlorine may be passed directly into the liquid. With about 15 grammes of liquid, the operation is completed in diffused daylight in about four hours. (Riche.)

To separate the products, the liquid is first heated to 70° — 80° C., while a stream of carbonic anhydride is passed through it, whereby chlorine and hydrochloric acid are expelled, and then distilled. It begins to boil at 150° C., the greater portion distils over between 163° and 173° , and the boiling point afterwards rises to 230° ; but the liquid then begins to decompose, giving off hydrochloric acid and leaving a carbonaceous residue (Riche). The only definite compound obtained from it is:

Dichlorethyllic Sulphide. $(C^2H^3Cl^2)^2S$.—This compound forms the greater part of the distillate, passing over between 163° and 173° , and may be purified by rectification. It is a light-yellow liquid of specific gravity 1.547, having a strong unpleasant odour, boiling between 167° — 172° C. It is decomposed by hydrogen and by protosulphide of potassium, with formation of viscid products. (Riche.)

Trichlorethyllic Sulphide. $(C^2H^2Cl^3)^2S$.—If the chlorine is allowed to act on

the sulphide of ethyl in diffused daylight without external cooling, a liquid is obtained blackish at first, becoming deep yellow afterwards, from which, by fractional distillation, this and the following compounds are obtained.

Trichlorethylic sulphide is a dark yellow oil, boiling between 189° and 192° C. (Riché.)

Tetrachlorethylic Sulphide. $(C^2HCl^4)^2S$.—This compound, previously obtained by Regnault, passes over in the distillation between 217° and 222° C. It may be obtained in larger quantity by passing chlorine for a long time, and in large excess, over sulphide of ethyl, heating the liquid ultimately to between 60° and 80° C. It is a yellow liquid of intolerable odour, of specific gravity 1.673 at 24° C., boiling, according to Regnault, at about 160° C. with partial decomposition.

Perchloroethylic Sulphide. $(C^2Cl^3)^2S$ (?)—By the action of chlorine on ethylic sulphide in sunshine. Trichloride of carbon is then formed and a liquid obtained, which is probably $(C^2Cl^3)^2S$; but it has not been analysed. (Riché.)

Disulphide of Ethyl. C^2H^4S , or $C^2H^4S^2$. **Thialol.** (Zeise, Pogg. Ann. xxxi. 371.—Pyr. Morin, *ibid.* xlviii. 483.—Löwig, *ibid.* xxvii. 550.—Löwig and Weidmann, *ibid.* xlix. 326.—Cahours, Ann. Ch. Phys. [3] xviii. 268.—Muspratt, Chem. Soc. Qu. J. iii. 19.)—Produced: 1. By the action of ethyl-sulphate of potassium on disulphide of potassium in concentrated aqueous solution (Zeise). If the solution also contains trisulphide of potassium, a certain quantity of trisulphide of ethyl is formed at the same time; nevertheless the greater part of the trisulphide of potassium likewise yields disulphide of ethyl, part of the sulphur being separated:

2. By distilling oxalate of ethyl with disulphide of potassium.—3. By decomposing

sulphosulphite of ethyl, $\begin{matrix} SO \\ (C^2H^4)^2(S) \end{matrix}$ — a product of the imperfect oxidation of mercaptan by nitric acid (see SULPHUROUS ETHERS)—with potash (Löwig and Weidmann).—4. By the dry distillation of ethyl-sulphocarbonate of potassium. (Zeise.)

Preparation.—1. A mixture of 1 pt. disulphide and 2 pts. ethylsulphate of potassium (or 3 pts. ethylsulphate of potassium and 2 pts. ordinary liver of sulphur) is distilled in a retort with 5 pts. water; more water is added when the residue becomes thick; the distillation is continued; and this treatment is repeated three or four times, as long as oil continues to pass over. The yellow and still impure disulphide of ethyl is separated from the water which has passed over with it, shaken up several times with large quantities of fresh water, and dried for several days over chloride of calcium. Of this oil, which is contaminated with a more fixed oil (hence its boiling point rises from 150° to 200° C.), a quantity is distilled off, sufficient to raise the boiling point to 190° ; the distillate is again distilled till the boiling point rises to 180° ; and this treatment is repeated till a distillate is obtained, which passes over at 161° without leaving any residue. The quantity of the pure product thus obtained is about half that of the impure oil.—2. Muspratt distils together, in a large retort, equal portions of the concentrated solutions of ethylsulphate of calcium and trisulphide of potassium; washes the oily product repeatedly with distilled water; and then rectifies it several times over chloride of calcium.

Properties.—Disulphide of ethyl is a colourless oily liquid, insoluble in water, soluble in alcohol and ether. Its specific gravity is about equal to that of water, so that it first floats upon water, and then, perhaps from absorbing water, sinks to the bottom. It boils at 151° C., passing over undecomposed. It is neutral to vegetable colours; has a very strong and repulsive alliaceous odour (according to Muspratt it has a most disgusting smell when crude, but after rectification the smell is only slightly alliaceous); when inhaled it is very apt to produce headache; tastes first sharp and afterwards sweetish; 10 drops of it given to a rabbit cause convulsive movements, from which, however, the animal slowly recovers. Vapour-density = 4.270 (Cahours). If then its molecule in the state of vapour is condensed to 2 vols., according to the ordinary law, the rational formula must be $C^2H^4S^2$, not C^2H^4S : for $(2.12 + 5.1 + 32) \times 0.0693 = 4.227$.

Decompositions.—1. Disulphide of ethyl is very inflammable, and burns with a blue flame. It is not altered by exposure to the air. Chlorine decomposes it readily, especially in sunshine (Cahours). With bromine it forms a compound, soluble in water, which yields, by distillation, hydrobromic acid and an aromatic liquid. Fuming nitric acid converts it into ethylsulphurous acid, a small quantity of sulphuric acid being also formed. Strong sulphuric acid does not dissolve it in the cold; on applying heat, decomposition takes place, attended with evolution of sulphurous anhydride. With mercuric oxide, disulphide of ethyl slowly forms a yellow mass. The alcoholic solution precipitates mercuric chloride white, acetate of lead yellowish white. (Morin.)

Trisulphide of Ethyl. $(C^2H^5)_3S^3$.—Obtained, together with the disulphide, by distilling a mixture of ethylsulphate and pentasulphide of potassium. On rectifying the product, the disulphide passes over first, and afterwards the trisulphide. It is a heavy, oily liquid, which reacts like the disulphide with nitric acid and with chlorine. (Calours, *loc. cit.*)

Pentasulphide of Ethyl. $(C^2H^5)_5S^5$ (?)—This appears to be the composition of a white, sweet-tasting, fusible sulphuretted compound, precipitated by water from an alcoholic solution of oxalic ether and pentasulphide of potassium. (Löwig, *Chemie der Organischen Verbindungen*, i. 464.)

ETHYL, SULPHYDRATE OF. $C^2H^5S = \begin{matrix} C^2H^5 \\ H \end{matrix} S$. *Hydrosulphate of Ethyl.*

Sulphithylate or Ethylsulphide of Hydrogen. Mercaptan.—This body, which has the composition of alcohol in which the oxygen is replaced by sulphur, was discovered by Zeise in 1833 (Pogg. Ann. **xxi.** 369), and has been further examined by Liebig (Ann. Ch. Pharm. **xi.** 10; **xxiii.** 34), Debus (*ibid.* **lxvii.** 18), Regnault (Ann. Ch. Phys. [2] **lxix.** 390), and others. (See also Gm. viii. 340; Gerh. ii. 284.) The name mercaptan, by which it is generally known, signifies *corpus mercurio aptum*, a body having a strong tendency to unite with mercury.

Mercaptan is produced in numerous cases of the reaction of ethyl-compounds with metallic sulphhydrates, especially with those of the alkali-metals: 1. By the action of sulphhydrate of barium on ethylsulphate of barium or of calcium:

By the action of chloride of ethyl on sulphhydrate of potassium:

3. By the dry distillation of xanthate of potassium.—4. By the action of nitrate of ethyl on sulphhydrate of ammonium. (E. Kopp.)

Preparation.—1. Crystallised ethylsulphate of calcium is distilled with a solution of sulphhydrate of barium; the product is collected in a well cooled receiver; the aqueous portion is decanted; and the mercaptan which remains is purified by distillation with a small quantity of mercury, then dehydrated by chloride of calcium (Zeise).—2. A mixture of alcohol and sulphuric acid, such as is used for preparing the ethylsulphates, is saturated with potash; and the liquid, decanted from the precipitated sulphate of potassium, is mixed with excess of caustic potash, then saturated with sulphuretted hydrogen and distilled (Wöhler).—3. An alcoholic solution of potash is saturated with sulphuretted hydrogen, and then treated with vapour of chloride of ethyl. Baudrimont (Compt. rend. liv. 616) recommends iodide of ethyl for this purpose, instead of the chloride, because it is less volatile.

Properties.—Mercaptan is a colourless, very mobile liquid having a peculiarly offensive alliaceous odour. Specific gravity 0.8325 at 21° C. (Liebig). Boils between 61° and 63° C. Vapour-density = 2.11 (Bunsen); by calculation (2 vol.) = 2.148. It is very inflammable and burns with a blue flame. When a drop of it at the end of a glass rod is briskly agitated, it solidifies by the cold produced by its own evaporation. It is neutral to vegetable colours, very sparingly soluble in water, but dissolves in all proportions in alcohol and ether. It dissolves sulphur, phosphorus, and iodine.

Decompositions.—1. Mercaptan, boiled with moderately strong nitric acid, acquires a red colour, and after a while deposits a peculiar oil. On continuing the ebullition, the oil disappears and ultimately ethylsulphurous acid is obtained.

2. Mercaptan, heated in a sealed tube with triethyllic disulphophosphate, yields sulphide of ethyl and diethyllic disulphophosphate:

3. With pentasulphide of phosphorus, it forms triethyllic and diethyllic tetrasulphophosphates:

(L. Carius, Ann. Ch. Pharm. **cxii.** 190.)

4. Potassium and sodium eliminate hydrogen from mercaptan in the same manner as from alcohol, and form analogous substitution-products, viz. the sulphethylates of potassium and sodium.—5. The alcoholic solution of mercaptan precipitates many metallic salts, forming a yellow precipitate with lead-salts, and white precipitates with cupric acetate, mercuric salts, and trichloride of gold. These precipitates, which are formed from mercaptan by the substitution of a metal for one atom of hydrogen, and

have the general formula $C^2H^4.M.S.$ are called Sulphethyldes, Ethylsulphides, or Mercaptides. This general formula likewise includes certain double sulphur ethers analogous to the double ethylic ethers (p. 542).

Sulphethyldate of Amyl, $C^2H^4S = C^2H^3.C^2H^{11}.S$. — Prepared by heating 1 at. triethyl disulphophosphate with 2 at. amyl alcohol to $150^\circ C.$ till the vitreous mass which is deposited no longer increases in volume:

The ethereal liquid which floats on this mass is decanted and distilled; the liquid which passes over between 120° and $140^\circ C.$ is dissolved in several times its volume of alcohol and precipitated by water; this treatment is repeated several times; and the product is finally washed with water till it is quite free from amyl alcohol.

Sulphethyldate of amyl is a colourless liquid, smelling like sulphide of ethyl, and sulphide of amyl. It boils at 132° — $133.5^\circ C.$ (corrected), under a pressure of 75.8 mm. Vapour-density, obs. = 4.4954 ; calc. = 4.5606 . Its alcoholic solution forms a white precipitate with an alcoholic solution of mercuric chloride. (Carius, Ann. Ch. Pharm. exix. 315; Rép. Chim. pur. 1862, p. 172.)

Sulphethyldate of Copper is obtained as a white gelatinous precipitate on mixing the alcoholic solutions of mercaptan and cupric acetate; also, as a nearly colourless mass, by digesting finely pulverised cupric oxide with mercaptan in a closed vessel. The salt when dry burns in the flame of a candle with a bluish-green light. It is not decomposed by boiling potash; forms a colourless solution with moderately strong hydrochloric acid; and dissolves sparingly in alcohol.

Sulphethyldate of Gold, C^2H^4AuS .—Obtained as a white gelatinous precipitate on mixing the dilute alcoholic solutions of auric chloride and mercaptan (1 pt. mercaptan dissolved in 70 pts. alcohol with 1 pt. chloride of gold in 20 pts. alcohol). Solid trichloride of gold is violently attacked by mercaptan, the mass becoming very hot and giving off large quantities of hydrochloric acid. Oxide of gold is still more violently attacked, the mercaptan sometimes taking fire, and a black instead of a white product being obtained. As the compound produced in these reactions is not $(C^2H^3)^2Au^2S^2$, but C^2H^4AuS , it follows that chlorine or oxygen must be set free, as shown by the equation:

and this, acting on another portion of the mercaptan, doubtless gives rise to the great heat evolved when the materials are used in the undissolved state.

Sulphethyldate of gold remains white when heated to $190^\circ C.$; at 225° it begins to turn brown and gives off a yellowish liquid (probably disulphide of ethyl), unaccompanied by gas, and leaves metallic gold. It is not decomposed by potash, or by sulphuric or hydrochloric acid. Nitric acid decomposes it, with violent evolution of gas.

Sulphethyldate of Lead, obtained by precipitation from alcoholic solutions of mercaptan and acetate of lead, is white, crystalline, soluble in excess of the lead-solution. It blackens by heat; does not appear to be decomposed by potash. Nitrate of lead is not precipitated by mercaptan.

Sulphethyldate of Mercury (mercuricum). C^2H^4HgS , or $(C^2H^3)^2Hg^2S^2$ (according as the atomic weight of mercury is taken at 100 or 200).—This compound is quickly formed on bringing mercuric oxide in contact with mercaptan, either pure or dissolved in alcohol, the action being attended with great evolution of heat. It is a white, crystalline mass, unctuous to the touch, melting at $85^\circ C.$, inodorous even in the melted state. It dissolves in 12 or 15 pts. alcohol of 85 per cent., and separates on cooling in white scales having a silvery lustre. When heated above its melting point, it turns yellow, exhales an intoxicating odour, and gives off metallic mercury. At $130^\circ C.$ it gives off an oil, which appears to be disulphide of ethyl.

Sulphethyldate of mercury is not decomposed by aqueous potash; but aqueous sulphide of potassium separates sulphide of mercury from it, forming a solution which contains the sulphethyldates of potassium and of mercury, probably combined in a double salt. This solution, when boiled and evaporated, yields a white precipitate; on addition of lead-salts, a yellow precipitate; with sulphide of potassium, a grey, insoluble compound. Sulphydric acid decomposes it completely, forming sulphide of mercury and sulphhydrate of ethyl. Dilute hydrochloric acid dissolves it slowly at the boiling heat, and deposits it again on cooling in crystals having a strong lustre. Strong nitric acid decomposes it, with violent evolution of nitrous vapours, forming a solution from which water throws down a colourless oil. Metallic lead immersed in the melted

salt throws down metallic mercury and forms sulphide of ethyl, sulphide of lead, and lead-amalgam.

A compound of *sulphethyrate and chloride of mercury*, $(C^2H^3)^2Hg^{''}S^{''}Hg^{''}Cl^2$, is obtained, on mixing an alcoholic solution of mercaptan with mercuric chloride, as a white bulky precipitate, changing after a while to a mass of crystalline laminae. It is but sparingly soluble in water and in ether; boiling alcohol dissolves it somewhat more freely, and deposits it in thin crystalline laminae on cooling. (Debus.)

Sulphethyrate of Methyl, $C^2H^3S = C^2H^3.CH^3.S$.—This compound, the analogue of Williamson's ethylmethylic ether (p. 542), is obtained by heating a mixture of triethylic disulphophosphate with twice its volume of methylic alcohol in a sealed tube to $150^{\circ}C$., care being taken not to exceed that temperature. The reaction is complete in a few hours, the tube then containing a brownish ethereal liquid, which is nearly pure sulphethyrate of methyl, and a nearly colourless, vitreous mass, consisting of diethylic sulphophosphate:

The reaction is always attended with the formation of secondary products, resulting chiefly from the decomposition of the diethylic sulphophosphate.

Sulphethyrate of methyl, purified by rectification, is a colourless, very mobile liquid, having an odour more like that of methylic than of ethylic sulphide. It boils at 58.8° — $59.5^{\circ}C$. (corrected) under a pressure of 787 mm. Vapour-density, observed = 2.609; calculated = 2.6258. It forms crystalline compounds with metallic chlorides. Its alcoholic solution, mixed with alcoholic mercuric chloride, forms a precipitate consisting of small scales having the composition $C^2H^3S.Hg^{''}Cl^2$. (Carius, *loc. cit.*)

Sulphethyrate of Platinum, $(C^2H^3)^2Pt^{''}S^2$, is a light yellow, muddy precipitate, obtained by mixing the alcoholic solutions of mercaptan and dichloride of platinum, the latter not in excess.

Sulphethyrate of Potassium is produced by the action of potassium on mercaptan (sulphethyrate of hydrogen). It is a dull white granular mass, very soluble in water, less soluble in alcohol. It may be heated considerably above $100^{\circ}C$. without decomposing, but a very strong heat carbonises it. Its aqueous solution likewise decomposes and blackens on exposure to the air. *Hydrochloric* and *dilute sulphuric acids* decompose it, with brisk effervescence. The recently prepared aqueous solution precipitates *lead-salts*, yellow in the cold, white on boiling. The partially decomposed solution forms a brick-red precipitate with *silver-salts*.

Sulphethyrate of Silver is the white precipitate formed on adding nitrate of silver to the aqueous solution of mercaptan; but it appears always to retain a portion of nitrate.

Sulphethyrate of Sodium.—Prepared like the potassium-salt. Dissolves easily in water, forming an alkaline liquid.

Zeise's Indifferent Sulphuretted Oil.

Zeise, in preparing the sulphur-compounds of ethyl, obtained, on several occasions, a peculiar oil, which he sometimes distinguishes by the epithet *indifferent*, and which differs from protosulphide of ethyl, from mercaptan, and from disulphide of ethyl.

This oil is formed in small quantity in the preparation of mercaptan from sulphydrate of barium and an ethylsulphate, and consequently the mercaptan requires to be purified from it. In the preparation of disulphide of ethyl from disulphide of barium and an ethylsulphate, small quantities of this indifferent oil likewise pass over with the disulphide of ethyl. It is however obtained in greatest abundance, mixed with about $\frac{1}{11}$ mercaptan, by distilling 1 at. protosulphide of barium with a concentrated solution of 1 at. ethylsulphate of barium. The mixture becomes turbid at $60^{\circ}C$., then gummy and covered with scum; at the end of the distillation, nothing remains but sulphate of barium. If too much water be added, the whole of the oil remains dissolved in the watery distillate. The oily mixture of this indifferent oil and mercaptan which passes over with the watery distillate (which is free from alcohol) begins to boil at $70^{\circ}C$., but the boiling point gradually rises to 102° ; by repeated fractional distillation, it may be separated into a more volatile portion, the mercaptan, and a less volatile portion, the indifferent oil. The latter may be freed from the last portions of mercaptan by agitation with water and oxide of lead, and from water by rectification over chloride of calcium. It is a transparent, colourless, neutral oil, of specific gravity 0.8449 at $18^{\circ}C$. Its odour resembles that of mercaptan, but is weaker and less ethereal. It burns with a redder flame than mercaptan, producing a larger quantity of sulphurous anhydride. It is more soluble in water than mercaptan. Its alcoholic solution produces no turbidity in lead-

or mercury-salts. It contains 22.3 per cent. carbon, 10.8 hydrogen, and 28.0 sulphur, approximating to the formula $C^2H^{12}SO^2 = \text{mercaptan} + 3 \text{ at. water}$.

ETHYL TELLURIDE OF, or TELLURETHYL. $C^2H^4Te = (C^2H^4)^Te$. *Tellurhydric or Hydrotelluric Ether.* (Wöhler, Ann. Ch. Pharm. xxxv. 111; lxxxix. 69.—Mallet, *ibid.* lxxix. 223; Chem. Soc. Qu. J. v. 71.)—This compound is formed by the action of telluride of potassium on ethylsulphate of potassium:

Preparation.—Telluride of potassium is prepared by mixing 1 pt. of tellurium powder with 10 pts. of burnt tartar; introducing the mixture into a porcelain retort fitted with a glass tube bent downwards at right angles; heating the retort to redness for three or four hours—as long, indeed, as carbonic oxide continues to escape; and then introducing the end of the bent tube into a flask filled with carbonic anhydride, to prevent access of air. As soon as the mixture is quite cold, a concentrated solution of ethylsulphate of potassium (3 or 4 pts. of the solid salt to 1 pt. of tellurium) prepared with water freed from air by boiling, is poured into the retort, which is then tightly corked; and the whole heated for some time, with constant agitation, to 40° or 50° . The resulting purple solution, together with the undissolved portion, is then quickly poured into a flask previously filled with carbonic anhydride; the retort again filled with the same gas; a small quantity of the solution of ethylsulphate poured into it (a portion having been kept back for the purpose); the retort again closed; and the digestion repeated. These precautions are necessary to prevent loss of telluride of potassium by oxidation. The flask is then connected with a condensing tube and receiver, and the mixture kept constantly in a state of gentle ebullition. The flask then becomes filled with the yellow vapour of tellurethyl, and that compound distils over, together with water, in which it sinks in drops. Finally, when about $\frac{2}{3}$ of the monotelluride of ethyl has passed over a small quantity of ditelluride is likewise obtained, differing from the former by its black-red colour.

Properties.—Tellurethyl is a deep yellowish-red liquid, heavier than water, and boiling below $100^\circ C$. It has a strong, very persistent, and extremely disgusting odour like that of sulphide of ethyl, or telluretted hydrogen. It appears to be very poisonous. Its vapour has a deep yellow colour. It is but slightly soluble in water.

Decompositions.—Tellurethyl is very inflammable, and burns with a clear white flame bordered with light blue, giving off thick white fumes of tellurous acid. It remains unaltered under water, but when exposed to the air becomes covered with a yellowish and afterwards with a white film, and is ultimately converted into a white earthy mass. In sunshine this oxidation takes place much more quickly, and is attended with slight fuming; but no fire is produced, even in oxygen gas. Tellurethyl, treated with *nitric acid*, causes violent evolution of nitric oxide, and forms a solution from which aqueous hydrochloric acid throws down a heavy colourless oil. (Wöhler.)

Combinations.—Tellurethyl exhibits the properties of a diatomic radicle, uniting with chlorine, oxygen, and acid radicles in general to form salts. The nitrate is obtained by treating tellurethyl with nitric acid; the other salts by double decomposition.

Bromide. $C^2H^4TeBr^2$.—When a solution of the nitrate or the oxychloride of tellurethyl is mixed with hydrobromic acid, the bromide separates in the form of a pale yellow, very heavy, inodorous oil.

Chloride. $C^2H^4TeCl^2$.—Obtained by mixing a solution of the nitrate, not containing a great excess of nitric acid, with strong hydrochloric acid in a narrow cylindrical vessel. The mixture becomes milky at first, and after a while the chloride sinks to the bottom, in the form of a heavy oil. It may be washed with water, though it is somewhat soluble in that liquid, and also in strong hydrochloric acid. When the latter solution is evaporated at a gentle heat, the chloride separates in oily drops (Wöhler, Mallet). The chloride is also precipitated as an oil on adding hydrochloric or sulphuric acid to a solution of the sulphate or oxychloride. (Wöhler.)

Transparent and colourless oil, heavier than water, and having an unpleasant odour. May be distilled without decomposition, but appears to have a very high boiling-point, for when distilled with water it passes over very slowly. Oxide of silver decomposes this compound, converting it into oxide of tellurethyl. (Mallet.)

Fluoride.—Hydrofluoric acid, added to solutions of the oxychloride, throws down fluoride of tellurethyl, while a soluble fluorine-compound remains in solution and may be crystallised by evaporation. The same compound is obtained by treating oxide of tellurethyl with hydrofluoric acid. (Wöhler.)

Iodide. $C^2H^4TeI^2$.—Formed by mixing a solution of the nitrate, oxychloride, or oxybromide with hydriodic acid, or by supersaturating the chloride with this acid. The iodide separates in the form of a very beautiful orange-coloured precipitate, which

when washed and dried forms an orange-yellow powder. Heated in water, it melts at 60°C . to a heavy, yellowish-red liquid, which, on cooling, solidifies to a yellowish-red, opaque, scaly, crystalline mass, which, like mica, may be very easily broken in the direction of the cleavage-plane. Dissolves sparingly in water, but readily in hot alcohol, from which it crystallises in long, thin, orange-yellow prisms. When heated above its melting point it decomposes, yielding a yellowish-red oil, a black sublimate, and metallic tellurium. If a partially decomposed solution of hydriodic acid be used in the preparation of this body, an almost blood-red precipitate is obtained, most probably containing a higher iodide.

Nitrate. $\text{C}^{\text{H}^{10}}\text{Te}(\text{NO}^2)^2 = (\text{C}^{\text{H}^{10}}\text{Te})^{\text{N}}\text{O}^2$.—Obtained in the form of a white, crystalline mass by dissolving tellurethyl in moderately strong nitric acid, and evaporating to dryness at a gentle heat. This salt burns away like gunpowder when heated. It dissolves readily in water. Alkalis added to the solution form no precipitate, because the oxide of tellurethyl is soluble in water. Sulphurous acid separates tellurethyl in dark red drops. Sulphuretted hydrogen throws down the sulphide (p. 283). Hydrochloric acid precipitates the chloride. (Mallet.)

Oxalate (basic). $(\text{C}^{\text{H}^{10}}\text{Te})^2(\text{C}^{\text{O}}\text{O}^2)^2\text{H}^2 = \text{O}^4$.—Obtained by digesting the oxychloride with water and excess of silver-oxalate. Short, transparent prisms, sparingly soluble in water, with acid reaction. When heated, it melts, boils, gives off tellurethyl, forms a crystalline sublimate, and leaves a residue of tellurium.

Oxide.—Not yet obtained in a state of purity, its isolation being always attended with partial decomposition. It may be obtained: 1. By direct oxidation of the alcoholic solution in the air; the process is however very slow and does not afford a good mode of preparation (Mallet).—2. By treating the chloride immersed in water, with recently precipitated oxide of silver, which immediately acts upon it with spontaneous evolution of heat, and is converted into chloride. The filtered liquid is an aqueous solution of oxide of tellurethyl free from silver and chlorine. By evaporation at a gentle heat, the oxide is obtained as a white mass, having a very distinct crystalline character (Mallet).—3. Wöhler, by digesting a solution of the crystallised oxychloride with recently precipitated oxide of silver, found that chloride of silver was immediately formed; but the liquid did not filter well, the excess of oxide of silver running through. On evaporating it in the water-bath to a syrup, it began to smell of tellurethyl, and the undissolved matter turned black. On dilution with water, it filtered clearly, but the solution, when again evaporated to a syrup, emitted an odour of tellurethyl and began suddenly to give off a gas (carbonic anhydride absorbed from the air) with effervescence.—4. A solution of the sulphate was decomposed with a hot saturated solution of baryta-water, the excess of baryta removed by carbonic acid, the liquid heated some time to expel the carbonic acid, and then filtered. The solution, when evaporated over the water-bath, smelt constantly of tellurethyl, and, as soon as it was brought down to the consistence of a syrup, gave off gas with effervescence. The same evolution of gas was subsequently produced in the cold mass by stirring it. The syrup residue exhibited signs of crystallisation. (Wöhler.)

The crystalline oxide obtained by Mallet decomposed when heated in a tube, yielding metallic tellurium and an oil having a very offensive odour. In the air it burned with the blue flame of tellurium (Mallet).—The solution of the oxide has an alkaline reaction, and when mixed with hydrochloric acid, yields chloride of tellurethyl in colourless oily drops (Wöhler, Mallet).—Yields a crystalline salt with nitric acid. (Wöhler.)

Oxybromide. $(\text{C}^{\text{H}^{10}}\text{Te})^2\left\{\begin{smallmatrix} \text{Br}^2 \\ \text{O} \end{smallmatrix}\right\} = \text{C}^{\text{H}^{10}}\text{TeO}.\text{C}^{\text{H}^{10}}\text{TeBr}^2$.—Obtained by dissolving the bromide in ammonia. Crystallises in shining, colourless prisms, of the same form as the oxychloride.

Oxychloride. $(\text{C}^{\text{H}^{10}}\text{Te})^2\left\{\begin{smallmatrix} \text{Cl}^2 \\ \text{O} \end{smallmatrix}\right\} = \text{C}^{\text{H}^{10}}\text{TeO}.\text{C}^{\text{H}^{10}}\text{TeCl}^2$.—Obtained by dissolving the chloride in caustic ammonia or potash, and evaporating the solution till it crystallises. It is better to add ammonia, because an excess of it does not decompose the product. The salt crystallises easily as the excess of ammonia evaporates. The mother-liquor contains sal-ammoniac or chloride of potassium:

Colourless, highly lustrous, six-sided prisms, soluble in water and alcohol; a solution of the compound in hot alcohol yields very beautiful crystals.

Hydrochloric acid added to solutions of this compound throws down colourless oily chloride of tellurethyl, a small quantity of which remains in solution. Sulphuric acid also precipitates the chloride, while sulphate of tellurethyl remains in solution, and from this the chloride may be precipitated by hydrochloric acid. (Wöhler.)

Oxyiodide. $(C^4H^{10}Te)^2 \left\{ \begin{smallmatrix} I^2 \\ O \end{smallmatrix} \right\} = C^4H^{10}TeO.C^4H^{10}TeI^2$.—Obtained by dissolving the iodide in ammonia and leaving the solution to evaporate spontaneously. Crystallises readily as the ammonia volatilises, in pale-yellow transparent prisms, isomorphous with the corresponding chlorine and bromine compounds. These crystals become orange-yellow on the surface when exposed to the air. They are but sparingly soluble in pure water, but dissolve freely in water containing excess of ammonia. Hydrochloric acid added to the aqueous solution throws down a heavy, yellowish-red mixture of chloride and iodide of tellurethyl. Sulphuric acid throws down the orange-yellow iodide; and hydrochloric acid added to the filtrate separates the colourless chloride. Sulphurous acid precipitates from the solution of the oxyiodide an easily fusible, semi-solid mixture of tellurethyl and the iodide.

Sulphate. $(C^4H^{10}Te)^2 (SO^4)^2.H^2$.—Obtained by adding a hot, neutral, saturated solution of sulphate of silver to a solution of oxychloride of tellurethyl, as long as any chloride of silver is formed.—Crystallises in groups of small, short, colourless prisms, easily soluble in water. Sulphurous acid precipitates from its solution a yellow oily body, of a most disagreeable odour. Chloride of barium throws down sulphate of barium and reproduces the oxychloride.

Sulphide. $C^4H^{10}TeS$.—Sulphuretted hydrogen passed through a solution of the nitrate throws down an orange-coloured precipitate, which on heating the liquid melts into black drops. (Mallet.)

Telluride of Tellurethyl or Ditelluride of Ethyl, $C^4H^{10}Te^2$.—This compound was first obtained by Mallet in endeavouring to prepare telluric mercaptan by saturating an aqueous solution of telluride of potassium and ethylsulphate of barium with telluretted hydrogen, and distilling. At first nothing but tellurethyl passed over; but on applying a stronger heat, another liquid distilled over, having a much greater density and higher boiling point, and so deep a red colour, that, even in small quantity, it appeared black and opaque like bromine. It likewise possesses an extremely offensive odour. (Mallet.)

The same compound is obtained in small quantity in the preparation of tellurethyl by the method given on p. 550. When about $\frac{5}{8}$ of the tellurethyl has passed over, a small quantity of the ditelluride likewise distils over, distinguished by its deep red colour. (Wöhler.)

ETHYLACETAMIDE. $C^4H^9NO = N.H.C^2H^5.C^2H^3O$.—Discovered by Wurtz in 1850 (Ann. Ch. Phys. [3] xxx. 491; Compt. rend. xxxvi. 180). It is obtained: 1. By adding acetate of ethyl to aqueous ethylamine, and evaporating, first over the water-bath, then in vacuo:

2. By the action of cyanate of ethyl on glacial acetic acid:

It is a colourless, syrupy, uncrystallisable liquid, which boils at $200^\circ C$, distilling almost without decomposition. It is decomposed by potash, yielding ethylamine and acetate of potassium, and by phosphoric anhydride, with separation of carbon.

Ethylidiacetamide. $C^4H^{11}NO^2 = N.C^2H^5.(C^2H^3O)^2$. (Wurtz, Ann. Ch. Phys. [3] xlii. 43.)—Produced by heating cyanate of ethyl with acetic anhydride in a sealed tube to 180° — $200^\circ C$:

It is a colourless liquid of specific gravity 1.0092 at $20^\circ C$.

ETHYLAMIDE. Syn. with ETHYLAMINE.

ETHYLAMINES and ETHYLAMMONIUMS. Organic bases formed on the types NH^2 and NH^4 respectively, by the substitution, more or less complete, of ethyl for hydrogen, viz. ethylamine, $N.H^2.C^2H^5$; diethylamine, $N.H.(C^2H^5)^2$; triethylamine, $N.(C^2H^5)^3$; and tetrethylammonium, $N(C^2H^5)^4$. The first three of these com-

pounds, which are formed on the ammonia type, are known in the free state, and, like ammonia, unite directly with acids, forming salts which may be regarded as analogous in composition either to hydrochlorate of ammonia or to chloride of ammonium, *e. g.*:

Tetraphylammonium, on the other hand, like other ammonium-bases (i. 194), is not known in the free state, and its salts cannot be referred to the ammonia type, excepting by regarding them as compounds of triethylamine with chloride, sulphate, &c., of ethyl, *e. g.* iodide of tetraphylammonium $\text{N}(\text{C}^2\text{H}^5)^4.\text{I}$ = iodethylate of triethylamine $\text{N}(\text{C}^2\text{H}^5)^3.\text{C}^2\text{H}^5.\text{I}$. They are, in fact, produced by the direct combination of ethyl-salts with triethylamine; but their chemical reactions are most simply represented by regarding them as ammonium- not as ammonia-salts.

There are likewise ethyl-bases containing methyl, amyl, phenyl, &c., as well as ethyl.

Compt. rend. xxviii. 223 and 323; Ann. Ch. Phys. [3] xxx. 443.)

Formation.—1. By the action of potash on cyanate or cyanurate of ethyl (Wurtz):

In the case of cyanuric ether, however, the transformation into ethylamine does not take place at once, as the preceding equation would indicate; but by three successive steps, each consisting in the assimilation of a molecule of water and the elimination of a molecule of carbonic anhydride, the intermediate products being an indifferent oily body, first observed by Habich and Limpricht (p. 293), and hydrate of triethyl-carbotriamine:

The same products are sometimes obtained by the action of ethylate of sodium on cyanurate of ethyl, and sometimes on the cyanate. (Hofmann, Proc. Roy. Soc. xi. 284.)

2. By the action of potash on ethyl-carbamide (ethyl-urea) (Wurtz):

and similarly according to Tuttle (Ann. Ch. Pharm. ci. 288), by distilling a mixture of urea, ethylsulphate of calcium, and caustic lime, or a mixture of cyanate of potassium, ethylsulphate of calcium, and slaked lime.

3. By the action of ammonia on various ethylic ethers, viz. on the bromide or iodide (Wurtz; Hofmann, Chem. Soc. Qu. J. iii. 300):

on the chloride (Groves, Chem. Soc. Qu. J. xiii. 331), phosphate (De Clermont,

Ann. Ch. Phys. [3] xlv. 335), nitrate (Juncadella, Compt. rend. xlviii. 332), or sulphite (Oarius, Ann. Ch. Pharm. cx. 209).

4. By heating chloride, bromide, or iodide of ammonium with alcohol or ether in sealed tubes (Berthelot, Ann. Ch. Phys. [3] xxxviii. 63):

5. By the decomposition of sulphethamic acid, that compound being resolved by heat into ethylamine, sulphuric acid, and probably alcohol and isethionic acid (Strecker, Ann. Ch. Pharm. lxxv. 50.)

6. Cyanide of ethyl left in contact for some time with hydrochloric or sulphuric acid, yields a salt of ethylamine, just as cyanide of hydrogen treated in the same manner yields a salt of ammonia. (E. Meyer, J. pr. Chem. lxxviii. 279.)

7. White precipitate ($\text{NH}^2\text{Hg}^2\text{Cl}$) heated with iodide of ethyl forms a double chloride of mercury and ethylammonium, a corresponding double iodide, and other compounds (p. 535).

Preparation.—1. By decomposing cyanate of ethyl with potash. The action takes place at ordinary temperatures, and is attended with great evolution of heat; hence it is best to mix the liquids in a bottle having a well ground stopper, which must be tightly secured, and to cool the bottle externally. The decomposition is complete in about five minutes, the vessel then containing nothing but ethylamine and carbonate of potassium. The liquid is then distilled, and the vapour of ethylamine passed into a receiver containing a little water and cooled externally. To obtain the anhydrous base, the aqueous solution thus formed is saturated with hydrochloric acid; and the hydrochlorate of ethylamine crystallised by evaporation, thoroughly dried, and gently heated with twice its weight of quick lime in a long glass tube, closed at one end, the mixture occupying the lower half of the tube, while the upper half is filled with fragments of caustic potash to dry the vapour of ethylamine as it is evolved. The dry vapour then passes through a delivery-tube into a small flask or U-tube surrounded with a freezing mixture, and is there condensed to a liquid. (Wurtz.)

2. By the action of ammonia on bromide of ethyl. Strong ammonia is enclosed, together with excess of bromide of ethyl, in a combustion-tube two feet long, and the sealed tube is immersed in boiling water. Decomposition takes place quickly, with ebullition, and is complete in about a quarter of an hour, its completion being indicated by the volume of the bromide of ethyl remaining constant instead of diminishing. The tube then contains hydrobromate of ethylamine, from which the base may be obtained by distillation with potash or lime. (Hofmann, Chem. Soc. Qu. J. iii. 300.)

3. By heating iodide of ethyl with ammonia in sealed tubes. The action in this case is more complicated than when the bromide is used, the formation of iodide of ethylammonium being accompanied by that of iodide of ammonium, and of the iodides of di-, tri-, and tetraethylammonium, as shown by the following equations:

This mixture of iodides distilled with potash, yields a distillate consisting of ammonia, ethylamine, diethylamine and triethylamine (the hydrate of tetraethylammonium formed at the same time being resolved into triethylamine, water, and ethylene (p. 561), which it is impossible to separate completely by fractional distillation. The separation may however be effected by subjecting the mixture of bases previously dehydrated, to the action of *oxalate of ethyl*, by which the ethylamine is converted into diethylamine.

nide, and the diethylamine into diethyloxamate of ethyl, while the triethylamine remains unaltered:

On distilling the product of this reaction at the heat of the water-bath, the triethylamine, which has not been acted on, passes over pure. The residue consists of a fibrous mass of diethyloxamide saturated with an oily liquid, which is diethyloxamate of ethyl. On submitting this mixture to the action of boiling water, the diethyloxamide dissolves, and the diethyloxamate of ethyl remains as an insoluble oily layer floating on the hot solution, from which it may be separated by a tap-funnel. The diethyloxamide crystallises from the aqueous solution on cooling, and when distilled with potash, yields pure ethylamine:

The oily liquid serves for the preparation of diethylamine, p. 559. (Hofmann, Proc. Roy. Soc. xi. 66, 526.)

4. From nitrate of ethyl. Nitric ether is mixed with twice or three times its weight of absolute alcohol previously saturated with ammoniacal gas; the mixture is heated to 100° C. for two days in a sealed tube half filled with it, then distilled with excess of potash; the vapours which pass over are received in hydrochloric acid; and the chloride of ethyl-ammonium thus formed is separated from chloride of ammonium by solution in alcohol (Juncadella). According to Carey Lea, nitrate of ethyl heated with ammonia yields diethylamine and a small quantity of triethylamine, as well as ethylamine. To separate these bases, he distils the contents of the tube with potash; receives the vapours in dilute sulphuric acid; dissolves out the sulphates of the ethyl-bases with alcohol, which leaves sulphate of ammonium undissolved; then converts them into picrates; and separates the picrates of ethylamine and diethylamine by repeated crystallisation, the ethylamine-salt being the less soluble of the two. The quantity of triethylamine produced is too small to interfere with the process, unless the reaction is conducted in a particular manner to be afterwards described (p. 559). The picrates of ethylamine and diethylamine are decomposed by hydrochloric acid, and the bases are obtained by distillation with potash. (Chemical News, v. 118; Rép. Chim. pure, 1862, p. 239.)

Properties.—Anhydrous ethylamine is a transparent, colourless, very mobile, inflammable liquid, of specific gravity 0.6964 at 8° C. It does not solidify at the temperature of a mixture of solid carbonic acid and ether. Boils at 18.7° C. (Wurtz). Vapour density at 43° and under a pressure of 773.04 mm. = 1.5767 (Izarn). It has a very pungent ammoniacal odour, a strong alkaline reaction, and is highly caustic, a small drop of the concentrated aqueous solution placed upon the tongue producing a burning pain and acute inflammation. It forms very dense white fumes with hydrochloric acid gas, and makes a hissing noise when strong hydrochloric acid is dropt into it. (Wurtz.)

Ethylamine mixes with water in all proportions, the mixture being attended with considerable rise of temperature. The solution is distinguished from aqueous ammonia by a certain degree of viscosity. By continued boiling, the whole of the ethylamine may be expelled.

The solution of ethylamine exhibits, with many metallic salts, reactions similar to those of ammonia. It is however distinguished from ammonia by redissolving the precipitates which it forms with solutions of aluminium (Wurtz), gold, and ruthenium (Carey Lea), and by not redissolving those which it forms with salts of cadmium, nickel, and cobalt. The precipitate formed with cupric salts is less easily soluble in ethylamine than in ammonia (Wurtz). With stannic chloride, ethylamine forms a precipitate very soluble in excess, whereas that formed by ammonia dissolves but slowly in excess of that alkali. The precipitate formed by ethylamine in gold-salts has but little resemblance to fulminating gold: it is decomposed by heat, but without

detonation (Carey Lea). *Dichloride of platinum* is not immediately precipitated ethylamine from a moderately concentrated solution (Wurtz). *Phosphomolybdic acid* forms, with solution of ethylamine, a yellow precipitate like that with ammonia, & more soluble (Meyer).

Decompositions.—1. Ethylamine vapour passed through a red-hot porcelain tube resolved into ammonia, hydrocyanic acid, hydrogen, and a small quantity of a hydrocarbon.—2. On the approach of a burning body, it takes fire and burns with a yellow flame.—3. *Iodine* decomposes the aqueous solution of ethylamine, forming hydriodate ethylamine and diiodoethylamine, which cannot be distilled without decomposition:

Bromine and *chlorine* act in like manner.

4. *Nitrous acid* decomposes ethylamine, with formation of nitrous ether and free nitrogen:

An easy way of exhibiting this reaction is to drop a crystal of nitrite of potassium into a solution of hydrochlorate of ethylamine, mixed with an equal volume of hydrochloric acid. A small quantity of yellow aromatic oil is formed at the same time.

5. With *chloride of cyanogen*, ethylamine acts like ammonia; thus:

6. With *cyanic acid* it forms ethyl-carbamide:

and with *cyanate of ethyl*, diethylearbamide:

7. *Oil of mustard* (sulphocyanate of allyl) converts ethylamine into thioisethylamine, $\text{C}^2\text{H}^5\text{N}^2\text{S}$. (Hinterberger, Ann. Ch. Pharm. lxxxiii. 346.)

8. For the reaction of ethylamine with *dibromide of ethylene*, see ETHYLENE BASES.

Salts of Ethylamine. Ethylamine is a strong base, neutralising acids as completely as ammonia, and expelling ammonia from ammoniacal salts. Most salts of ethylamine are easily soluble in alcohol, a property by which they are distinguished from salts of ammonia. Hence, when the two bases occur together, they may be separated by converting them into chlorides or sulphates, and digesting the dried residue in strong alcohol. According to Meyer (J. pr. Chem. lxvii. 147), the separation is easily effected by treating the mixed bases with excess of tartaric acid, and evaporating; acid tartrate of ammonium then crystallises out, while the ethylamine-salt remains in the form of a syrup, easily soluble in alcohol.

Acetate of Ethylamine.—When ethylamine vapour is passed into a vessel containing glacial acetic acid and surrounded with ice, the salt is obtained in the form of a very deliquescent, crystalline mass of dazzling whiteness. Phosphoric anhydride chars it rapidly, but does not give rise to the formation of any compound analogous to acetonitrile. (Wurtz.)

Bromhydrate or Hydrobromate of Ethylamine, $\text{C}^2\text{H}^5\text{N}.\text{HBr}$, or *Bromide of Ethylammonium*, $\text{C}^2\text{H}^5\text{N}.\text{Br}$.—This salt is produced: 1. By the direct combination of ethylamine and hydrobromic acid.—2. By the action of bromine on aqueous ethylamine (Wurtz).—3. By the action of bromide of ammonium on alcohol or ether (Berthelot, p. 553).—4. By the action of ammonia on bromide of ethyl. It is crystalline, and gives off ammonia when distilled with potash.

Carbonate of Ethylamine.—When hydrochlorate of ethylamine is carefully distilled with carbonate of sodium, both being thoroughly dry, carbonate of ethylamine passes over, and condenses as a crystalline mass saturated with a viscid liquid, whose solution has a strong alkaline reaction. It has an ammoniacal odour, gives off, even at ordinary temperatures, vapours which turn reddened litmus blue; is very deliquescent, and dissolves the basic carbonates of copper and zinc. The analysis of this salt yielded quantities of carbon and hydrogen greater than are required by the formula of acid carbonate of ethylamine, $\text{C}^2\text{H}^5\text{N}.\text{H}.\text{CO}^2$.

Inspecting the so-called *anhydrous carbonate of ethylamine*, obtained by passing carbonic anhydride into anhydrous ethylamine, see below.

Chlorhydrate or Hydrochlorate of Ethylamine, $C^2H^5N.HCl$, or *Chloride of Ethylammonium*, $C^2H^5N.Cl$.—Formation similar to that of the hydrobromate. Prepared by saturating with hydrochloric acid the aqueous solution of ethylamine, which is obtained by distilling cyanic acid with potash. On evaporating to dryness, dissolving the residue in strong boiling alcohol, and cooling the solution, the salt is deposited in large crystalline laminae. From the aqueous solution it crystallises in striated prisms. Fuses between 76° and $80^\circ C.$, and solidifies on cooling in a semi-transparent, crystalline mass. Gives off vapours at a high temperature; boils between 315° and 320° ; and if then left to cool, solidifies in a milk-white, amorphous mass, whose melting point is above 260° . The crystals are very deliquescent. On treating the aqueous solution with amalgam of potassium, hydrogen is given off and a solution of ethylamine is formed. (Wurtz.)

Chloro-aurate, $C^2H^5NCl.AuCl^3$.—Obtained by mixing the aqueous solutions of hydrochlorate of ethylamine and trichloride of gold. Forms very fine, golden-yellow, prismatic crystals, soluble in water, alcohol, and ether. (Wurtz.)

Chloromercurate, $C^2H^5NCl.HgCl$, or $(C^2H^5NCl)^2.Hg^2Cl^2$.—Obtained by mixing the aqueous solutions of corrosive sublimate and hydrochlorate of ethylamine in equivalent quantities. Crystallises more readily than the corresponding salt of methylamine, but forms smaller crystals. From the alcoholic solution it is deposited in small white scales. (Wurtz.)

Chloride of Ethylammonium with Cyanide of Mercury, $C^2H^5NCl.Hg^2Cy^2$.—Obtained by mixing a neutral solution of hydrochlorate of ethylamine with aqueous cyanide of mercury, and evaporating over the water-bath to the crystallising point. Large laminated crystals, which are permanent in the air, and are decomposed by the heat of the water-bath. Soluble in water, sparingly in cold alcohol. Taste disagreeably metallic. (Kohl and Swoboda, Ann. Ch. Pharm. lxxxiii. 342.)

Chloropalladite of Ethylamine, $(C^2H^5NCl)^2.Pd^2Cl^2$.—An aqueous solution of hydrochlorate of ethylamine evaporated over the water-bath with excess of dichloride of palladium, yields large black crystals grouped in feathery tufts; by transmitted light they exhibit a fine red colour. They yield a red-brown powder, and retain their lustre unimpaired at the heat of the water-bath. (Reckenschuss, Ann. Ch. Pharm. lxxxiii. 343.)

Chloroplatinate, $(C^2H^5NCl)^2.Pt^2Cl^4$.—Obtained by mixing the concentrated solutions of tetrachloride of platinum and chloride of ethylammonium, adding alcohol, pressing the resulting yellow precipitate, and dissolving it in boiling water. On cooling, the double salt separates in beautiful tablets of a deep orange-yellow colour. (Wurtz.)

For the compounds of ethylamine with protochloride of platinum and other platinum salts, see PLATINUM-BASES.

Ethylcarbamate of Ethylammonium, $C^2H^5N^2O^2 = \frac{NH(C^2H^5)(CO)^2}{C^2H^5N} \} O = (C^2H^5)^2.CO^2$.—This salt, homologous with the so-called *anhydrous carbonate of ammonia*, is produced by passing carbonic anhydride into anhydrous ethylamine cooled by a freezing mixture (i. 751).

Molybdate of Ethylamine, $(C^2H^5N)^2.H^2Mo^2O^7 = (C^2H^5N)^2.Mo^2O^7$.—Molybdic acid dissolves readily in ethylamine, and the solution left to evaporate over chloride of calcium deposits white scales, which become red-brown when dry, and ultimately assume a regular brown colour. They continually give off ethylamine, and are gradually converted into a more acid salt. (Meyer, J. pr. Chem. lxvii. 161.)

Nitrate of Ethylamine.—Obtained by saturating ethylamine with nitric acid. Very deliquescent; crystallises from the aqueous solution in thin laminae. The syrupy mother-liquor, when heated, gives off gases which burn with a yellow flame, and yields a brown watery distillate with a few drops of oil floating on the surface; the residue is a brown mass which ultimately becomes charred. (Wurtz.)

Oxalate of Ethylamine, $(C^2H^5N)^2.H^2C^2O^4 = \frac{(C^2O^2)^2}{(C^2H^5N)^2} \} O^2$.—Obtained by saturating ethylamine with oxalic acid and evaporating. Crystallises in right rhombic prisms. When heated it gives off 2 at. water, and is converted into ethyloxamide, $N_2(C^2O^2)^2.(C^2H^5)^2.H^2$. Heated with excess of oxalic acid, it yields a small quantity of ethyloxamic acid. (See OXAMIO ACID.)

Phosphate of Ethylammonium and Magnesium, $(C^2H^5N)^2.Mg^2.H^2.(PO^4)^3 + 10H^2O$.—Obtained by adding ordinary phosphate of sodium to a solution of sulphate of magnesium mixed with ethylamine and either of its salts, as a bulky precipitate which becomes crystalline on standing, is much more soluble than the corresponding ammo-

nium-salt, and when left over sulphuric acid, gives off all its water and part of the ethylamine. (Meyer.)

Sulphate of Ethylamine or *Ethylammonium*.—Deliquescent, anhydrous, crystallisable, very soluble in alcohol, dries up in vacuo to a transparent gummy mass. (Wurtz.)

Sulphate of Ethylammonium and Aluminium. *Ethylamine-alum*. $\left\{ \begin{array}{l} (\text{C}^2\text{H}^5\text{N})^2 \\ (\text{Al}^3)^3 \end{array} \right\} 2\text{SO}_4 + 24\text{H}^2\text{O}$.—Obtained by mixing the solutions of the component salts, and evaporating. Crystallises ordinarily in regular octahedrons like common alum, but occasionally in prisms, which, however, yield octahedrons by recrystallisation. (Kenner and Sthamer, Ann. Ch. Pharm. xci. 172; Meyer, *loc. cit.*)

Sulphate of ethylamine also forms crystallisable double salts with the sulphates of magnesium and copper, and with chloride of copper (Meyer); with sulphate of zinc (Carey Lea.) The magnesium-salt appears to contain $2\text{C}^2\text{H}^5\text{N} \cdot \text{Mg}^2 \cdot (\text{SO}_4)^2 + \text{aq}$ (Meyer.)

Sulphydrate of Ethylammonium. Prepared by passing sulphydric acid gas into anhydrous ethylamine cooled with ice. Colourless, easily fusible, volatile crystals which, when exposed to the air, absorb moisture, and change to yellow drops. (Wurtz.)

Tartrate of Ethylammonium and Sodium has been obtained by Carey Lea.

Substitution-products of Ethylamine.

DICHLORETHYLAMINE. $\text{C}^2\text{H}^4\text{Cl}^2\text{N}$. (Wurtz, Ann. Ch. Phys. [3] xxx. 474.)—Chlorine passed into aqueous ethylamine cooled with ice, forms this compound, together with hydrochlorate of ethylamine:

The action is attended with rise of temperature and a slight evolution of nitrogen gas. The dichlorethylamine is deposited in the form of a yellow liquid, which may be purified by washing with water and rectifying over chloride of calcium. It has penetrating odour, and produces coughing and flow of tears. Boils at 91°C . The vapour explodes when heated in a tube, but not with sufficient force to break the tube.

The compound treated with excess of chlorine is converted into a solid body which crystallises in scales. Ammonia decomposes and dissolves it gradually. Caustic potash decomposes it slowly, forming chloride of potassium, acetate of potassium, and ammonia, a gas containing chlorine being also given off in small quantity, and a few drops of an oily liquid, which has a disagreeable odour, like that of impure cyanide of ethyl, sinking to the bottom:

The gas and the oily liquid are secondary products. (Wurtz.)

DIBROMETHYLAMINE. $\text{C}^2\text{H}^4\text{Br}^2\text{N}$. (Wurtz, Ann. Ch. Phys. [3] xxx. 477.)—Bromine acts on ethylamine in the same manner as chlorine, and with considerable violence, so that it is necessary to add the bromine drop by drop, and cool the liquid with ice. The greater part of the resulting dibromethylamine remains dissolved in the watery liquid, only a small portion settling down in the form of an oil as the action approaches its termination. The dissolved portion may, however, be extracted by agitating with ether, and evaporating the ethereal solution. The product is an oily liquid having an orange-red colour arising from a slight excess of bromine, which may, however, be removed by agitation with weak potash. It is heavier than water, and has a pungent odour.

DINIODETHYLAMINE. $\text{C}^2\text{H}^4\text{I}^2\text{N}$. (Wurtz, Ann. Ch. Phys. [3] xxx. 478.)—Iodine introduced into an aqueous solution of ethylamine exerts an immediate action, attended with rise of temperature, producing hydriodate of ethylamine, and a bluish black liquid which is diniodeethylamine. This compound decomposes when distilled, giving off vapours of iodine, and consequently has not yet been obtained in a state of purity. It is soluble in alcohol and ether. Caustic potash decomposes it gradually, forming iodide of potassium, a small quantity of iodate, and a yellow crystalline residuum, the composition of which has not been ascertained.

Diethylamine. $\text{C}^4\text{H}^{11}\text{N} = \text{N} \left\{ \begin{array}{l} (\text{C}^2\text{H}^5)^2 \\ \text{H} \end{array} \right\}$. (A. W. Hofmann, Phil. Trans. 1860, p. 120; Chem. Soc. Qu. J. iii. 300.)—This compound is produced: 1. As hydrobromate by heating an aqueous solution of ethylamine with bromide of ethyl in sealed tubes ($\text{C}^2\text{H}^5\text{N} + \text{C}^2\text{H}^5\text{Br} = \text{C}^4\text{H}^{11}\text{N} \cdot \text{HBr}$), and may be obtained in the free state by dis-

distillation with potash.—2. As a hydriodate, together with the corresponding compounds of the other ethyl-bases, by heating iodide of ethyl with ammonia in sealed tubes, and may be separated by Hofmann's method already described. The liquid diethyloxamate of ethyl is separated from the crystalline diethyloxamide by the method described on page 555, and then distilled. The boiling point quickly rises to 260° C., and the liquid which passes over at that temperature yields diethylamine by distillation with potash:

3. Nitrate of ethyl heated with ammonia yields a mixture of ethylamine and diethylamine, which may be separated in the manner described on pp. 555, 560. (Carey Lea.)

Diethylamine is a volatile, inflammable liquid, boiling at 57° C., very soluble in water, and having a strong alkaline reaction (Hofmann). With *metallic salts*, it acts for the most part like ethylamine, but it is distinguished therefrom by three reactions: 1. It does not precipitate a solution of *protochloride of palladium*.—2. The precipitate which it forms with *zinc-salts* is not soluble in excess of diethylamine.—3. Added in large excess to a solution of *mercuric chloride*, it forms a precipitate which is not soluble in acetic acid, whereas the precipitates formed in like manner by ethylamine and by ammonia, dissolve easily in that acid. (Carey Lea.)

Iodine acts on diethylamine in the same manner as on ethylamine, forming an oily substitution-product. *Nitrous acid* acts upon it in the same manner as on ethylamine. (Riche, Ann. Ch. Pharm. cxi. 91.)

With *cyanate of ethyl* it forms triethylcarbamide (Hofmann, Compt. rend. liv. 252).

For the reaction of diethylamine with *dibromide of ethylene*, see *ETHYLENE-BASES*.

The salts of diethylamine are not much known. The *chloroplatinate*, $2(\text{C}^2\text{H}^5)_2\text{N} \cdot (\text{PtCl}_4)$, is moderately soluble, and crystallises in orange-red granules (Hofmann). Weltzien obtained large orange-yellow shining crystals, which, according to J. Müller, belong to the monoclinic system.

Triethylamine. $\text{C}^2\text{H}^5_3\text{N} = \text{N}(\text{C}^2\text{H}^5)^3$. (Hofmann, *loc. cit.*—Carey Lea, Chemical News, vi. 142; Rép. Chim. pure, 1862, p. 446.)—Produced: 1. By heating diethylamine with bromide of ethyl, and distilling the resulting bromide of triethylammonium with potash.

2. By the action of ethylate of potassium or sodium on cyanate of ethyl, precisely as ethylamine is produced from hydrate of potassium and cyanic ether:

The materials are digested together for several hours at a moderate heat, and then distilled in a sand-bath. The strongly alkaline distillate, saturated with hydrochloric acid and evaporated, yields a residue from which pure triethylamine may be obtained by distillation with potash. The cyanic ether and the sodium-alcohol must be perfectly anhydrous, otherwise the chief product of the reaction will be ethylamine; but even when water is altogether absent, a different reaction sometimes takes place, attended with the formation of triethylcarbotriamine (p. 560).

3. Iodide of triethylammonium is obtained, together with other iodides, by heating iodide of ethyl in a sealed tube with ammonia. The product distilled with potash yields a mixture of ethylamine, diethylamine, and triethylamine, which may be separated by means of oxalic ether as described at p. 555. The triethylamine not being acted upon, passes over by simple distillation. (Hofmann.)

4. Nitrate of ethyl heated in sealed tubes with ammonia always yields a certain quantity of triethylamine, together with ethylamine and diethylamine, and, by proceeding as follows, the proportion of triethylamine may be considerably increased. A mixture of 3 volumes nitrate of ethyl, 3 volumes strong aqueous ammonia, and 2 volumes absolute alcohol, is heated to 100° C. in a sealed tube for four hours. The contents of the tube are then exactly saturated with nitric acid, and evaporated over the water-bath; the pasty mass is dissolved in 4 volumes of absolute alcohol; the solution is distilled with a considerable excess of caustic soda; the distillate is received in a mixture of 3 volumes nitrate of ethyl and 2 volumes absolute alcohol surrounded

by a freezing mixture; and the liquid thus saturated with the alkaline vapour is introduced into sealed tubes and heated in a water-bath. This mode of proceeding yields a product in which the proportion of ethylamine is very small, and of the remainder the diethylamine constitutes three-fourths, the triethylamine one-fourth. To separate these bases, they are converted into picrates, the picrates of ethylamine and triethylamine crystallising out in needles, and the picrate of diethylamine afterwards separating as a heavy oil. The crystalline picrates of the two bases are distilled with an alkali; the vapours condensed in water, and the solution, after moderate concentration, is agitated with ten times its volume of ether, which takes up the triethylamine, leaving the ethylamine dissolved in the water. (Carey Lea.)

6. Triethylamine is given off, together with ethylene and water, in the decomposition of hydrate of tetrethylammonium by heat. (Hofmann.)

Triethylamine is a colourless, strongly alkaline liquid, inflammable, having an agreeable ammoniacal odour; it is but sparingly soluble in water, and, when the quantity of water present is not sufficient to dissolve it, floats on that liquid like an oil. (Hofmann; Lea.)

The aqueous solution forms with salts of *zirconium*, *glucinum*, *cadmium*, and *zinc*, white precipitates insoluble in excess; with *aluminium*-salts, a precipitate easily soluble in excess. It forms a green precipitate with *nickel* salts, greenish-blue with *cobalt* salts, white with *stannous* salts, brown with *nitrate of silver*, reddish-brown with *pentachloride of antimony*, yellow with *uranic* salts, yellowish-white with salts of *mercury*, greyish with salts of *iron*, blue with *copper* salts, white with salts of *magnesium* and *cerium*,—all these precipitates being insoluble in excess of the alkali. With *stannic chloride* it forms a precipitate soluble in excess of the alkali; with *acetate of lead*, a precipitate insoluble in excess of the alkali, but soluble in excess of the lead salt. It does not precipitate the salts of *platinum* or *palladium*. With *trichloride of gold*, it forms a yellow precipitate insoluble in excess, and blackening rapidly, from formation of protoxide of gold, the reduction being attended with evolution of aldehyde. This is the most characteristic reaction of triethylamine. (Carey Lea.)

Hydrobromate of Triethylamine or *Bromide of Triethylammonium* crystallises in beautiful fibrous crystals several inches long. (Hofmann.)

The *hydrochlorate* crystallises in white laminae; it is not deliquescent, very inflammable, volatilises easily without decomposition. (Carey Lea.)

The *chloroplatinate*, $2\text{C}^{\text{H}}_3\text{N}^3\text{Cl.PtCl}_4$, is very soluble in water, and crystallises on cooling from strong solutions in splendid orange-red rhombic crystals. (Hofmann.)

The *nitrate* does not crystallise, but remains in the form of a thick syrup, when its solution is evaporated in vacuo. The *sulphate* is very soluble in water and alcohol; by evaporation in vacuo it is obtained as a confused crystalline mass. It forms a double salt with sulphate of zinc. (Carey Lea.)

Triethylcarbatriamine, $\text{C}^{\text{H}}_3\text{N}^3 = \text{N}^3\{\text{C}^{\text{H}}_2(\text{C}^{\text{H}}_2)^2\text{H}_2\}$; or **Triethylcyanodiamine**, $\text{N}^3\{\text{CN}(\text{C}^{\text{H}}_2)^2\text{H}_2\}$. (Hofmann, Proc. Roy. Soc. xi. 282.)—Not known in the separate state, but obtained as a hydrate, $\text{C}^{\text{H}}_3\text{N}^3\text{O} = \text{C}^{\text{H}}_3\text{N}^3\text{H}_2\text{O}$, by heating ethylate of sodium with cyanurate of ethyl (sometimes also with the cyanate), the ethylate of sodium being then resolved by the heat into ethylene, C^2H^4 , which escapes, and hydrate of sodium, which acts on the cyanuric ether in the manner represented by the equation:

The reaction actually takes place by several stages, as already explained (p. 553).

Hydrate of triethylcarbatriamine is a basic oil, which neutralises acids, forming definite salts. The *gold-salt*, $\text{C}^{\text{H}}_3\text{N}^3\text{HCl.AuCl}_3$, and the *platinum-salt*, $2(\text{C}^{\text{H}}_3\text{N}^3\text{HCl}).\text{PtCl}_4$, have been analysed. The iodide forms splendid crystals.

The hydrated base, which may also be regarded as *triethyl-carbonyl-triamine*, is resolved by distillation into ethylamine and diethylcarbamide:

just as guanidine (carbonyl-triamine) is resolved, under certain circumstances, into ammonia and carbamide (urea):

Diethylamylamine. $\text{C}^{\text{H}}_3\text{N} = \text{N}(\text{C}^{\text{H}}_2)^2\text{C}^{\text{H}}_2$ (Hofmann, Chem. Soc. Qa. J. iv. 315).—Obtained together with water and ethylene-gas by the dry distillation of hydrate of triethylamylammonium (p. 563). It is an oily liquid heavier than water,

bitter, and having a not unpleasant odour. Boils at 154° C. Soluble in water. The sulphate, hydrochlorate, nitrate, and oxalate crystallise easily but are deliquescent. The chloroplatinate crystallises in orange-yellow needles of extraordinary beauty.

Tetretethylammonium. $C^4H^{10}N = N(C^2H^5)^4$. *Tetretethylum*. (Hofmann, Phil. Trans. 1851, p. 367; Chem. Soc. Qu. J. iv. 304.)—This compound, which, like ammonium itself, is not known in the free state, is obtained as an iodide or bromide by the action of iodide or bromide of ethyl on triethylamine:

Iodide of ethyl acts quickly with the aid of heat, the bromide slowly.

The iodide or bromide treated with moist oxide of silver, yields a strongly alkaline solution, containing the hydrate of tetretethylammonium, and this, when treated with acids, yields the other salts. The bromide, chloride, iodide, carbonate, nitrate, phosphate, and sulphate are all crystalline. The orthophosphate $(C^4H^{10}N)^3PO_4$ is strongly alkaline.

Bromide of Tetretethylammonium forms white opaque granular crystals. (Hofmann.)

The *chloride*, obtained by neutralising the solution of the hydrate with hydrochloric acid, forms double salts with the chlorides of gold, mercury, and platinum.

Chloro-aurate. $C^4H^{10}NCl.AuCl^3$.—Lemon-yellow precipitate obtained by mixing the solutions of the two chlorides. Dissolves but sparingly in cold water and in hydrochloric acid.

Chloromercurates.—*a.* $2C^4H^{10}NCl.5Hg^2Cl^2$. White crystalline precipitate, soluble in water and in hydrochloric acid, especially at the boiling heat. From the boiling solution it separates in plates having an unctuous appearance. (Hofmann.)

b. $2C^4H^{10}NCl.Hg^2Cl^2$.—Obtained by decomposing the yellow crystals $C^6H^{18}N^2Hg^2Cl^4$ (pp. 638, 665), with oxide of silver, neutralising the resulting alkaline liquid with hydrochloric acid, and evaporating. It forms white crystals. (Sonnenschein.)

Chloroplatinate. $2C^4H^{10}NCl.PtCl^4$.—Tetrachloride of platinum added to chloride of tetretethylammonium, immediately forms an orange-yellow precipitate, resembling the corresponding potassium and ammonium-salts. Slightly soluble in water; less soluble in alcohol and ether. May be crystallised in beautiful octahedrons. (Hofmann.)

Hydrate. $C^4H^{10}NO = N(C^2H^5)^4 \left\{ \begin{matrix} H \\ O \end{matrix} \right\}$.—Prepared by decomposing the iodide with oxide of silver. The solution of the iodide is gently heated, and recently precipitated oxide of silver added in small portions with agitation, till the resulting iodide of silver assumes a permanent yellow colour. The liquid filtered from the silver-precipitate is a solution of the hydrate of tetretethylammonium. It may likewise be obtained by decomposing the sulphate with baryta; but this process is not so good as the preceding, on account of the difficulty of getting rid of the excess of baryta or of sulphuric acid. The alkaline solution, evaporated in vacuo over sulphuric acid and lime yields, after some time, long hair-like needles which are extremely deliquescent and attract carbonic acid rapidly from the air. By remaining longer in vacuo, the crystals disappear again, and the liquid dries up to a semi-solid mass, which also deliquesces and attracts carbonic acid rapidly.

The solution of this compound is strongly alkaline, and has the pungent bitterness of quinine. In the concentrated state, it burns the tongue and acts on the epidermis like caustic potash or soda; rubbed between the fingers, it excites the well-known sensation produced by the fixed alkalies, and the same peculiar odour. It saponifies fats as readily as potash, converts furfuramide into furfurine, and decomposes oxalic ether into oxalic acid and alcohol. With metallic solutions it behaves like caustic potash, excepting that hydrate of alumina is less soluble in it, and hydrated chromic oxide quite insoluble.

A moderately concentrated solution of hydrate of tetretethylammonium may be boiled without alteration, but at an advanced state of the evaporation, decomposition sets in, even at the temperature of the water-bath, the residue intumescing strongly, and being gradually but completely resolved into water, triethylamine and olefant gas:

The solution of the hydrate boiled for about 24 hours with iodide of ethyl in a flask provided with a condensing tube, so that the volatilised products may be condensed and run back, becomes perfectly neutral, and is converted into alcohol and iodide of tetretethylammonium:

A concentrated solution of the hydrate mixed with an alkaline solution of iodide of potassium, yields a crystalline precipitate of iodide of tetrethylammonium; this effect is due to the insolubility of the latter substance in alkaline liquids.

Iodides of Tetrethylammonium.—*a. Protiodide.* C^4H^9NI . When perfectly anhydrous iodide of ethyl is added to triethylamine, dried over hydrate of potassium, the mixture becomes slightly turbid, heat being evolved at the same time. The action goes on but slowly at ordinary temperatures, the mixture, after several days, being converted into a solid mass; but on exposing the mixture for a minute or two to the temperature of boiling water, a powerful reaction ensues, the liquid remaining for some time in a state of brisk ebullition, even after removal of the heat, and solidifying on cooling, into a hard mass of crystals, which is snow-white or yellowish, according as the triethylamine or the iodide of ethyl is in excess. To avoid loss of triethylamine, it is best to heat the mixture in sealed tubes. On dissolving the crystalline mass in cold water and leaving the solution to evaporate spontaneously, the iodide is obtained in beautiful, well-defined, white crystals, of considerable size, which may be separated by mechanical means from small quantities of a reddish iodine-compound sometimes formed by the action of the air. This latter substance is formed in much larger quantity at higher temperatures, for which reason it is best to avoid the use of hot water in the purification (*vid. infra*).

The crystals are anhydrous, and do not diminish in weight by exposure to the temperature of boiling water. When rapidly heated to a higher temperature, they fuse, and are decomposed into triethylamine and iodide of ethyl, which form two layers in the receiver, but quickly unite and reproduce the original compound.

The aqueous solution mixed with caustic potash solidifies at once to a crystalline mass consisting of the iodide itself, which is less soluble in alkaline liquids than in pure water. With nitrate or sulphate of silver, it yields iodide of silver, and a solution of nitrate or sulphate of tetrethylammonium. With oxide of silver it yields a solution of the hydrated oxide of tetrethylammonium.

b. Teriodide. When iodide of ethyl is heated for some time with alcoholic ammonia in such a manner that the volatilised portions may condense and run back again, a liquid is formed containing iodide of ammonium, and the iodides of the four ethylammoniums; and this liquid, when exposed to the air for about a month (whereby the iodide of ammonium is decomposed and iodine set free), yields teriodide of tetrethylammonium in large, shining, dark-red, prismatic crystals. The same compound is more quickly obtained by heating the liquid with iodine; it then separates in small needle-shaped crystals. (Weltzien, Ann. Ch. Pharm. lxxvi. 292; xli. 33.)

Teriodide of tetrethylammonium boiled with aqueous potash is partially decomposed, giving off a volatile ethyl-base, probably triethylamine, and forming iodide of potassium, iodate of potassium, and iodoform. To account for the formation of these products, however, we must suppose that marsh gas is given off:

Teriodide of tetrethylammonium dissolves slowly in cold water, readily in boiling alcohol; from the latter solution it crystallises in needles arranged in feathery groups. It dissolves in the iodides of potassium, sodium, and the ethyl-ammoniums, and separates from these solutions in large crystals. (Weltzien.)

c. Periodide. The liquid from which the teriodide has crystallised, yielded, on dilution with water, a heavy, red-brown, oily compound, rich in iodine, and probably consisting of a higher iodide of tetrethylammonium. (Weltzien.)

Iodomercurates. *a.* $2C^4H^9NI.5Hg^2I^2$. Obtained by the two following processes: 1. Mercuric iodide boiled with a solution of iodide of tetrethylammonium, is converted into a yellow compound, which melts and collects as a transparent layer at the bottom of the vessel, and, on cooling, solidifies to a brittle mass, having a crystalline fracture. 2. Iodide of tetrethylammonium mixed with a large excess of mercuric chloride forms a whitish crystalline precipitate, which is a mixture of the iodomercurate with a large quantity of the corresponding chlorine-compound:

By boiling with water the latter is removed, while the iodine compound remains. (Hofmann.)

b. $2C^4H^9NI.3Hg^2I^2$. Produced by the action of trimercuramine on iodide of ethyl:

Yellow crystals which dissolve somewhat readily in alcohol, and are not decomposed by water. (R. Müller, Ann. Ch. Pharm. cviii. 6.)

c. $C^2H^3NI.Hg^{II}$. Produced by the action of metallic mercury on teriodide of tetrethylammonium.

The compound dissolves sparingly in water, more easily in hot alcohol, from which it separates on cooling in light yellow, shining, scaly crystals. (H. Risse, Ann. Ch. Pharm. cvii. 224.)

A compound of mercuric iodide with iodide of tetrethylammonium and iodide of mercurio-tetrethylammonium, $C^{12}H^{18}N^4Hg^2I^{10} = 2C^2H^3NI.C^{14}H^{22}Hg^2N^2I^7.Hg^{II}$, is produced, together with several others, by the action of iodide of ethyl on chloride of mercuriammonium (white precipitate), $NH^2Hg^{II}Cl$ (p. 535). It forms yellow crystals which, after being purified by washing with warm absolute alcohol, resemble mosaic gold, and appear under the microscope as cubes with octahedral and dodecahedral faces. They are decomposed by sunlight, with separation of mercury; melt at $150^\circ C.$, and decompose at higher temperatures. They are insoluble in water alcohol, and ether.

Iodide of potassium and iodide of tetrethylammonium dissolve the yellow compound for the most part, with separation of metallic mercury; nitric acid separates mercuric iodide. Its solution in hot hydrochloric acid yields greenish-yellow silky crystals. Chlorine and bromine separate all the iodine after some time, forming crystals with a jetty lustre, resembling naphthalin. When the yellow crystals are heated with recently precipitated oxide of silver, iodide of silver is formed, together with a strongly alkaline liquid, which, after the excess of silver has been removed by sulphuretted hydrogen, contains hydrate of tetrethylammonium. But if the alkaline solution is neutralised with hydrochloric acid, without previous treatment with sulphuretted hydrogen, and evaporated, white crystals are obtained consisting of the compound $2((C^2H^3)^4NCl).Hg^{II}Cl^2$ (p. 561).

Triethylamylammonium. $C^{11}H^{20}N = N(C^2H^3)^3C^3H^{11}$. (Hofmann, Chem. Soc. Qu. J. iv. 313.)—The iodide obtained by the action of iodide of amyl on triethylamine forms fine crystals having a fatty lustre, unctuous to the touch, very soluble in water and alcohol, insoluble in ether. The solutions have the bitter taste of quinine. The hydrate, $N.(C^2H^3)^3(C^3H^{11}) \left\{ \begin{smallmatrix} H \\ O \end{smallmatrix} \right\}$, obtained by heating the iodide with moist oxide of silver, forms an alkaline, very bitter solution, which, when evaporated, yields a non-crystallising syrup. By distillation it is resolved into water, ethylene, and diethylamylamine:

The hydrochlorate forms deliquescent laminae. The chloroplatinate separates from a boiling aqueous solution in splendid orange-yellow needles. The nitrate forms hard needles. The sulphate and oxalate are obtained in gummy masses by evaporation in vacuo.

For bases containing ethyl together with methyl and phenyl, see METHYLAMINES and PHENYLAMINES.

Ammonium-bases produced by the action of Chloracetic Ether on Triethylamine.

Triethyl-oxethylacetylammmonium. $C^{10}H^{20}O^2N = N \left\{ \begin{smallmatrix} (C^2H^3)^3 \\ C^2H^4(C^2H^3)O^2 \end{smallmatrix} \right\}$.—When a mixture of triethylamine and chloracetic ether $[C^2H^3(C^2H^3)ClO^2]$ is heated to $100^\circ C.$ in a sealed tube, a small quantity of gas burning with a green flame is given off; and chloride of tetrethylammonium is formed, together with the chloride of triethyl-oxethylacetylammmonium, that is to say, an ammonium in which three at. H are replaced by 3 at. ethyl and the remaining 1 at. H. by a complex molecule containing the elements of chloracetic ether minus the chlorine.

On adding tetrachloride of platinum to the solution of these chlorides, the chloroplatinate of the complex ammonium-molecule, being slightly soluble, easily separates from the platinum-salt of tetrethylammonium, which is very soluble. Treated with sulphuric acid, it yields the chloride of the complex ammonium, which is very deliquescent. The gold-salt crystallises in needles which melt at $100^\circ C.$

Triethyl-oxacetylammmonium. $C^8H^{16}O^2N = N \left\{ \begin{smallmatrix} (C^2H^3)^3 \\ C^2H^3O^2 \end{smallmatrix} \right\}$.—The preceding chloride, treated with oxide of silver, yields chloride of silver and an alcoholic solution that deposits a crystalline substance, which, though perfectly neutral, unites with nitric and hydriodic acids, forming well defined salts. These salts, however, belong to another

series, differing from the preceding by containing an atom of hydrogen in place of ethyl — a difference which is shown by the elimination of alcohol during the reaction. Hence these salts are not *tetrethylic*, like the preceding, but *triethylic*.

The *chloroplatinate*, $2\{N(C^2H^5)^3(C^2H^3O^2)\}Cl.PtCl_4$, forms splendid rhomboidal prisms. The *chloroaurate* crystallises in needles, moderately soluble in boiling water. The *nitrate* is soluble in alcohol, and is precipitated from the solution by ether in fine needles. The *iodide* forms crystals very soluble in water, and having the composition $[N(C^2H^5)^3(C^2H^3O^2)]I.C^2H^5NO^2$.

The crystalline substance which remains after the treatment of the *tetrethylic chloride* (see above) with oxide of silver, is perhaps the monatomic base, $C^2H^5NO^2$. $N(C^2H^5)^3 \cdot \frac{H}{O}$. It is possible, however, that this compound may split up at the moment of its formation, and that the crystals contain 1 at. water less, having therefore the composition $C^2H^5NO^2$, this being the molecule which enters into the composition of the iodide just mentioned. On this hypothesis, the compound in question would be *triethylic glyceol*:

it is known, indeed, that glyceol itself has a tendency to form compounds similar in composition to the iodide above mentioned, one of them being represented by the formula $(C^2H^5NO^2)Cl.C^2H^5NO^2$.

The *triethylic* compound is not attacked by potash, by boiling nitric acid, or by nitrous acid. When heated, it yields charcoal and a strongly alkaline liquid, which is not triethylamine. (Hofmann, Proc. Roy. Soc. xi. 526; Rép. Chim. pure, 186 p. 196).

ETHYLAMMONIUM. See ETHYLAMINES.

ETHYLAMYL. See ETHYL (p. 526).

ETHYLAMYL-CITRIC ACID. $C^{13}H^{22}O^4 = \left. \begin{matrix} C^6H^8O^4 \\ C^6H^{11} \\ C^2H^5.H \end{matrix} \right\} O^2$.—Obtained by saturating a mixture of amylcitric acid $[(C^6H^8O^4)^{1/3}.C^6H^{11}.H^2.O^2]$ and absolute alcohol with hydrochloric acid gas, then evaporating the alcohol and excess of hydrochloric acid, washing with aqueous carbonate of sodium, dissolving in ether, and decolorising with animal charcoal, as a colourless syrupy liquid, having a very bitter taste and acid reaction. (Breunlin, Ann. Ch. Pharm. xci. 323.)

ETHYL-CARBAMIDES, or *Ethyl-ureas*.—These compounds, derived from carbamide, or urea, $N^2(CO)^2.H^4$, by the substitution of ethyl for the whole or part of the hydrogen, have already been partly described under CARBAMIDE (i. 754). The following additional statements have been recently published by Wurtz (Rép. Chim. pure, 1862, 199) and Hofmann (Proc. Roy. Soc. xi. 273; Compt. rend. liv. 252).

Ethyl-carbamide. $N^2(CO)^2.C^2H^5.H^2$.—Crystallises in oblique rhomboidal prisms having the obtuse edges truncated. Melts at $92^\circ C$. By dry distillation it gives ammonia and a small quantity of ethylamine, and leaves a residue consisting of a mixture of cyanuric ethers, the chief product being diethylic cyanurate $C^4[(C^2H^5)^2.H.N]^2O^2$ (p. 293). (Wurtz).

Diethyl-carbamide. $N^2(CO)^2.(C^2H^5)^2.H^2$.—Colourless, prismatic crystals solid

in water and alcohol; from the alcoholic solution it separates in silky flexible non-deliquescent needles. Melts at 109° — 112.5°C . Boils at 263° (corrected). When boiled with potash, it gives off ethylamine; $\text{N}^2(\text{CO})^2.(\text{C}^2\text{H}^5)^2.\text{H}^2 + \text{H}^2\text{O} = \text{CO}^2 + 2(\text{N}.\text{C}^2\text{H}^5.\text{H}^2)$. It likewise gives off ethylamine when treated with nitrous acid. When chlorine is passed into a solution of diethylcarbamide, a heavy viscid oil is precipitated, partially soluble in water, and having a burning taste and peculiar odour. Nitrate of diethylcarbamide forms rhomboidal prisms, much flattened and extremely deliquescent.

Diethylcarbamide exhibits exactly the same properties, whether prepared by the action of cyanate of ethyl on ethylamine, or of water on cyanate of ethyl. (Wurtz.)

Triethylcarbamide. $\text{C}^3\text{H}^4\text{N}^2\text{O} = \text{N}^2(\text{CO})^2.(\text{C}^2\text{H}^5)^3.\text{H}$.—Produced by the action of cyanate of ethyl on diethylamine. (Hofmann, Wurtz.)

It forms soft crystals, soluble in water, alcohol, and ether, melting at 63°C ., and distilling without decomposition at 223° (Hofmann); boils at about 235° . (Wurtz.) It does not appear to combine with acids, with chloride of gold, or with chloride of platinum. By the action of alkalis it is resolved into ethylamine, diethylamine, and carbonic anhydride. (Hofmann.)

Diethyl-tricarbonyl-tetramide or *-tetramine.* $\text{C}^4\text{H}^4\text{N}^4\text{O}^3 = \text{N}^4(\text{CO})^3.(\text{C}^2\text{H}^5)^2.\text{H}^4$.—This compound, which may be regarded as a carbamide, or urea, of a higher order, is produced by the action of cyanate of ethyl on urea:

It is sparingly soluble in cold water, but dissolves easily in boiling water, and crystallises therefrom in beautiful white scales having a silky lustre. It is easily soluble in alcohol and ether; dissolves also in acids, but not more readily than in water; also in cold potash, and is precipitated unchanged from the solution by acids.

By boiling with potash, however, it is decomposed, yielding ammonia, ethylamine, and carbonic anhydride:

This compound is isomeric with *diethylecyanurate of ammonium*, $\text{C}^2[(\text{C}^2\text{H}^5)^2.\text{NH}^2]\text{N}^2\text{O}^2$; but it does not exhibit the characters of an ammonium-salt. (Hofmann.)

The hydrated base produced by the action of cyanuric ether on ethylate of sodium, viz. triethyl-carbonyl-triamine, $\text{N}^2(\text{CO})^2.(\text{C}^2\text{H}^5)^3.\text{H}^4$ (p. 662), is also related to the ethyl-carbamides.

ETHYLENE. C^2H^4 or C^2H^4 . *Olefiant gas, Bicarburetted Hydrogen, Heavy Carburetted Hydrogen, Elayl, Ethene, Etherin.*—This compound was discovered in 1795 by four Dutch chemists, Deiman, Paets van Troostwyk, Bondt, and Lauwerenburgh (Crell. Ann. 1795, ii. 196, 310, and 430; Gilb. Ann. ii. 201). It is produced by heating alcohol with strong sulphuric acid or boric anhydride; and by the dry distillation of formates, acetates, butyrates, and many other organic bodies, especially fats, resins, caoutchouc, wood, coal, &c.: it is, therefore, a constituent of coal-gas, being in fact the compound to which that gas chiefly owes its illuminating power. It has also been shown by the experiments of Berthelot (Compt. rend. xliii. 236) that ethylene, as well as other hydrocarbons, may be formed directly from inorganic materials, as when a mixture of disulphide of carbon and sulphuretted or phosphoretted hydrogen is passed over red-hot copper, or more abundantly when a mixture of disulphide of carbon, sulphuretted hydrogen, and carbonic oxide is passed over red-hot iron. A mixture of ethylene with tritylene and marsh-gas is also obtained by the dry distillation of formate of barium; and as formic acid may be produced by the action of carbonic oxide on hydrate of potassium, it follows that the ethylene may be considered, in this case also, as produced from inorganic materials.

Preparation.—1. A mixture of 1 vol. strong alcohol and 4 vol. sulphuric acid, is gently heated in a flask or retort, and the evolved gas is passed through two Woulfe's bottles—one containing milk of lime to free it from sulphurous acid, and the other containing strong sulphuric acid to absorb the vapours of ether and alcohol. The mixture soon blackens, and froths considerably towards the end; the frothing may, however, be prevented by adding a sufficient quantity of sand to the mixture to form it into a thick paste. A very good way of conducting the process, given by Mitscherlich (Ann. Ch. Phys. [3] vii. 12), is to boil alcohol of 80 per cent. in a flask, and pass the vapour into a boiling mixture of 10 pts. strong sulphuric acid and 3 pts. water (boiling point 160 — 165°C). In this case, the mixture does not blacken, and the gas obtained is free from sulphurous acid; but it requires to be purified from ether and

alcohol vapour as before. The action consists ultimately in a dehydration of the alcohol; $C^2H^4O - H^2O = C^2H^4$; but it is probable that ethylsulphuric acid is first formed, and yields ethylene by its subsequent decomposition, $C^2H^4.H.SO^4 = C^2H^4 + H^2SO^4$.

2. Absolute alcohol is mixed with four times its weight of fused boric anhydride and the mixture gently heated in a retort. A large quantity of ethylene gas is then evolved, which may be rendered pure by mere washing with water. The residue in the retort serves for a fresh operation. The only inconvenience of this method is, that the delivery-tubes are apt to become stopped up by solid boric anhydride mechanically carried over: hence it is necessary to use very wide tubes. (Ebelmen, Ann. Ch. Phys. [3] xvi. 136.)

Properties.—Ethylene is a colourless gas, having a faint ethereal odour; if quite free from ether-vapour, it would probably be destitute of odour; it is irrespirable. Its specific gravity is 0.9784 (Saussure), answering to a condensation to 2 vol. (h calculation, $\frac{2.12 + 4.1}{2} \times 0.0693 = 0.9702$). When exposed to strong pressure, at temperature of $-110^\circ C.$, it condenses to a limpid liquid, which does not solidify.

Ethylene gas is nearly insoluble in water, and dissolves but sparingly in alcohol (see GASES, ABSORPTION OF); ether dissolves it more freely. It is likewise absorbed by cuprous chloride.

Decompositions.—Ethylene passed through a red-hot tube is resolved into marsh-gas and free carbon, $C^2H^4 = CH^4 + C$. It is very inflammable, and burns in the air with a bright white flame; probably undergoing in the flame the same decomposition as when passed through a red-hot tube, so that the marsh-gas burns, and the separated particles of carbon, being rendered incandescent by the high temperature thus produced, give to the flame its peculiar brightness. Mixed with a quantity of oxygen just sufficient for complete combustion, it explodes violently when brought in contact with flame, or when an electric spark is passed through the mixture. 2 vols. ethylene, containing 2 at. C and 4 at. H, consume 6 at. or 6 vol. O, and produce 4 vol. CO^2 besides water. In chlorine gas, ethylene burns with a very smoky flame, $C^2H^4 + Cl^4 = 4HCl + C^2$. A mixture of 1 vol. ethylene and 2 vol. chlorine burns slowly when set on fire, depositing a very large quantity of charcoal.

Combinations.—Ethylene is a diatomic radicle, uniting with 2 at. chlorine, bromine, cyanogen, and other monatomic radicles, and with 1 at. oxygen, sulphur, and other diatomic radicles. With the elements of 2 at. peroxide of hydrogen, it forms hydrate of ethylene, ethylenic alcohol, or glycol, and with the peroxides of various acid radicles it forms others, which are acid, neutral, or basic, according to the proportions of the combination. With chlorine, bromine, iodine, pernitric oxide, and the chlorides of sulphur, it unites directly. It is quickly absorbed by sulphuric anhydride, and by Nordhausen sulphuric acid, forming ethionic anhydride (p. 524) and isethionic acid. When briskly and continuously agitated with ordinary strong sulphuric acid, H^2SO^4 , it unites therewith, forming ethylsulphuric acid, $C^2H^4SO^4$ (Berthelot, Ann. Ch. Pharm. xciv. 78). When it is heated for some time to $100^\circ C.$ with hydriodic acid, the two combine, forming iodide of ethyl, $(C^2H^4 + HI = C^2H^5I)$. A similar action takes place with hydrobromic acid, but less readily; and with hydrochloric acid it is very slow indeed. (Berthelot, Ann. Ch. Pharm. civ. 184; cxv. 114.)

ETHYLENE, ACETATES OF. (Wurtz, Compt. rend. xliii. 199; Ann. Ch. Pharm. c. 110; Ann. Ch. Phys. [3] lv. 400. Atkinson, Phil. Mag. [4] xvi. 433; Ann. Ch. Pharm. cix. 232.)

Monoacetate. $C^2H^4O^3 = \frac{(C^2H^4)^n}{C^2H^4O.H} O^2 = (C^2H^4)^n.C^2H^4O^2.HO$. *Monoacetic glycol,*

Glycolic monoaceticin.—Obtained: 1. By the action of bromide of ethylene on acetate of potassium:

1 pt. of pure bromide of ethylene and 1 pt. of acetate of potassium, together with 2 pts. of 85 per cent. alcohol, are heated for two days to $100^\circ C.$ in a strong flask (a soda-water bottle answers very well) securely corked. Bromide of potassium is then formed, together with a colourless liquid containing monoacetate of ethylene, acetic acid, and acetic ether (formed by the action of the acetic acid on the alcohol), besides alcohol and water. On distilling it, monoacetate of ethylene mixed with acetic acid passes over between 130° and $180^\circ C.$, and nearly pure monoacetate from 180° to 185° . By repeated rectification of these liquids, the pure monoacetate is obtained, boiling at 182° . In the first distillation, the liquid often jumps violently, in consequence of the separation of a little bromide of potassium; in this case an equal volume of ether must be added to precipitate the bromide of potassium, and the liquid filtered

(Atkinson). Maxwell Simpson recommends, especially for the preparation of large quantities of the monoacetate, to heat the materials, not in a closed vessel, but in a large flask connected with a Liebig's condenser, in such a manner as to cause the condensed vapour to flow back into the vessel. A considerable quantity of diacetate of ethylene is formed at the same time as the monoacetate in this reaction (Lourenço).—2. By the action of acetate of potassium on *chloride of ethylene*. The decomposition does not take place so readily as with the bromide, and requires the mixture to be heated for three or four days (Atkinson).—3. By heating a mixture of 1 at. glycol and 1 at. acetic anhydride in a sealed tube for several hours at a temperature not exceeding 170°C ., and collecting apart the liquid which, in the subsequent distillation, passes over between 180° and 186°C . (Maxwell Simpson, Proc. Roy. Soc. ix. 726.)

4. By heating 1 at. ethylenic alcohol (glycol) with 1 at. acetic acid to 200°C . in a sealed tube. (Lourenço.)

Monoacetate of ethylene is a colourless, oily liquid, boiling at 182°C . It is heavier than water, and miscible with water and with alcohol. The aqueous solution is neutral. It is easily decomposed by potash or baryta, yielding hydrate of ethylene, and an acetate of the base.

Monethylenic Diacetate. $\text{C}^4\text{H}^{10}\text{O}^4 = \left\{ \begin{array}{c} \text{C}^2\text{H}^4 \\ \text{C}^2\text{H}^3\text{O} \end{array} \right\}^2 \text{O}^2 = (\text{C}^2\text{H}^4)'' . (\text{C}^2\text{H}^3\text{O})^2$.—Produced:

1. By the action of iodide or bromide of ethylene on acetate of silver:

Iodide of ethylene is mixed by small portions with well-dried acetate of silver, and the mixture is introduced into a flask. A brisk action soon begins, and the mass assumes a yellow colour, from formation of iodide of silver, and gives off a considerable quantity of gas, principally carbonic anhydride and ethylene (arising from secondary actions). As soon as the mixture is sufficiently cooled, a fresh portion is introduced, and the process continued till between 100 and 160 grammes of iodide of ethylene have been used. At the end of the reaction, there is found in the flask a yellow mass of iodide of silver saturated with a liquid; and on distilling this mixture, which requires a somewhat high temperature, an acid liquid passes over, coloured brown by iodine, and containing acetic acid besides neutral products. When subjected to fractional distillation, it begins to boil at 120°C ., but the temperature soon rises, and the portion which distils over between 160° and 200° must be collected apart. The distillate, which is still acid, is redistilled over oxide of lead, and again subjected to fractional distillation, till it passes over almost entirely between 180° and 190° . If it still contains a trace of iodide, it must be rectified over oxide of silver (Wurtz). Bromide of ethylene is, however, to be preferred to the iodide for this preparation, because it is more easily obtained and has a lower atomic weight. (Wurtz.)

2. By heating monoacetate of ethylene with chloride of acetyl in a sealed tube to 100°C . for a day, the action taking place in two stages, as shown by the following equations:—

Two layers of liquid are thus formed, the lower consisting of water, the upper of diacetate and acetoxychloride of ethylene. (Lourenço, Ann. Ch. Pharm. cxiv. 126.)

It is a colourless neutral liquid, nearly inodorous at common temperatures, but smelling slightly of acetic acid when heated. Specific gravity = 1.128 at 0°C . Boiling point 186° — 187°C . Vapour-density = 4.744.

When poured into a small quantity of water, it sinks to the bottom in the form of an oil. It dissolves in 7 pts. of water at 22° , and is separated from the solution by chloride of calcium. Alcohol and ether dissolve it in all proportions (Wurtz). By bases, in presence of water, it is resolved into acetic acid and hydrate of ethylene. (Wurtz.)

Polylethylenic Diacetates.—These ethers, which may be regarded as compounds of acetic anhydride, $\text{C}^4\text{H}^{10}\text{O}^4$, with 2, 3, 4, &c., molecules of oxide of ethylene, are pro-

668 ETHYLENE: ACETOBUTYRATE—BENZOATE

duced, together with monethylenic diacetate, by heating oxide of ethylene with glacial acetic acid or acetic anhydride, and may be separated by fractional distillation. The first portion of the distillate consists of monethylenic diacetate, after which there pass over successively:

Diethylenic diacetate, $\left\{ \begin{smallmatrix} \text{C}^2\text{H}^4 \\ \text{C}^2\text{H}^2\text{O} \end{smallmatrix} \right\} \text{O}^2 = (\text{C}^2\text{H}^4\text{O})^2 \cdot \text{C}^2\text{H}^2\text{O}^2$, boiling at about 250°C .

Triethylenic diacetate, $\left\{ \begin{smallmatrix} \text{C}^2\text{H}^4 \\ \text{C}^2\text{H}^2\text{O} \end{smallmatrix} \right\}^2 \text{O}^4 = (\text{C}^2\text{H}^4\text{O})^3 \cdot \text{C}^2\text{H}^2\text{O}^2$, boiling at about 290°C .

Tetreethylenic diacetate, $\left\{ \begin{smallmatrix} \text{C}^2\text{H}^4 \\ \text{C}^2\text{H}^2\text{O} \end{smallmatrix} \right\}^3 \text{O}^6 = (\text{C}^2\text{H}^4\text{O})^4 \cdot \text{C}^2\text{H}^2\text{O}^2$, a viscid liquid which boils above 300°C . under the ordinary atmospheric pressure, and requires to be distilled in a rarefied atmosphere.

The same compounds may be produced by the combination of neutral diethylenic acetate with 1, 2, 3, &c., molecules of oxide of ethylene.

Each of them, when distilled with potash, yields the corresponding polyethylenic alcohol, the general equation of the decomposition being:

ETHYLENE, ACETOBUTYRATE OF. $\text{C}^2\text{H}^4\text{O}^4 = \left\{ \begin{smallmatrix} \text{C}^2\text{H}^4 \\ \text{C}^2\text{H}^2\text{O} \end{smallmatrix} \right\} \text{O}^2 = \begin{smallmatrix} \text{C}^2\text{H}^4 \\ \text{C}^2\text{H}^2\text{O} \end{smallmatrix}$

$(\text{C}^2\text{H}^4)^n \cdot \text{C}^2\text{H}^2\text{O}^2 \cdot \text{C}^2\text{H}^2\text{O}^2$. (Maxwell Simpson, Proc. Roy. Soc. x. 116.)—Obtained: 1. By heating equivalent quantities of butyrate of silver and acetoxychloride of ethylene to 100° — 120°C ., or of acetate of silver and butyroxylchloride of ethylene to 150° , then digesting with ether, filtering, and distilling (Simpson):

2. By heating monoacetate of ethylene with butyric acid or chloride of butyryl, or monobutyrate of ethylene with acetic acid or chloride of acetyl (Lourenço). It is a colourless liquid, having a bitter, pungent taste, heavier than water, insoluble in water, soluble in alcohol. It is very stable, being but slowly decomposed by aqueous potash, even at the boiling heat. (Simpson.)

ETHYLENE, ACETOVALERATE OF. $\text{C}^2\text{H}^4\text{O}^4 = (\text{C}^2\text{H}^4)^n \cdot \text{C}^2\text{H}^2\text{O}^2 \cdot \text{C}^2\text{H}^2\text{O}^2$. (Lourenço, Ann. Ch. Pharm. cxiv. 122.)—Obtained by heating monoacetate of ethylene with valeric acid, or *vice versa*. Colourless, oily, neutral liquid, boiling at about 230°C ., insoluble in water, soluble in alcohol and ether.

ETHYLENE, ACETOXYCHLORIDE OF. $\text{C}^2\text{H}^4\text{ClO}^2 = (\text{C}^2\text{H}^4)^n \cdot \text{C}^2\text{H}^2\text{O}^2 \cdot \text{Cl}$. *Glycol chloracetique, Glycolic Chloracetin*. (Maxwell Simpson, x. 114.)—Obtained by passing dry hydrochloric acid gas into monoacetate of ethylene at 100°C ., precipitating with water, washing, drying, and rectifying. It is a colourless liquid, having a specific gravity of 1.1783 at 0°C . Boils at 145° without decomposition. Vapour-density by observation = 4.369; by calculation (2 vol.) = 4.244.

ETHYLENE, ACETOXYIODIDE OF. $\text{C}^2\text{H}^4\text{IO}^2 = (\text{C}^2\text{H}^4)^n \cdot \text{C}^2\text{H}^2\text{O}^2 \cdot \text{I}$. *Glycol iodoacetique, Glycolic Iodacetin*.—Obtained by passing hydriodic acid gas into monoacetate of ethylene, or a mixture of equivalent quantities of glacial acetic acid and glycol, externally cooled, till a portion of the liquid gives a considerable oily precipitate on the addition of water; if the passage of the gas be further continued, iodide of ethylene is likely to be formed. The product is well washed with very dilute potash and dried in vacuo.

Glycolic iodacetin is, at ordinary temperatures, an oily liquid, having a sweetish pungent taste; at low temperatures it crystallises in tables. It sinks in water, and is insoluble in that liquid, but dissolves in alcohol and ether. Heated with potash, it yields iodide of potassium, acetate of potassium, and oxide of ethylene. (Simpson.)

ETHYLENE, BENZOATE OF. $\text{C}^2\text{H}^4\text{O}^4 = \left\{ \begin{smallmatrix} \text{C}^2\text{H}^4 \\ \text{C}^2\text{H}^2\text{O} \end{smallmatrix} \right\} \text{O}^2$. *Glycolic Dibenzate*.—68 grms. of benzoate of silver (rather more than 2 at.) and 29 grms. bromide of ethylene are heated for several days to 100°C . in a long-necked flask; the product is taken up with ether, and the solution treated with a small quantity of slaked lime, then filtered and distilled in the water-bath. The residue on cooling becomes filled with crystals, which are to be separated from the mother-liquor, pressed between paper, and purified by several recrystallisations from ether.

By spontaneous evaporation of the ethereal solution, the compound is deposited in

shining, colourless, right rhomboidal prisms, which melt at $67^{\circ}\text{C}.$, forming a liquid which boils at a temperature above the boiling point of mercury, and distils without alteration. It is easily decomposed by heating with potash, yielding hydrate of ethylene and benzoate of potassium. (Wurtz, *Ann. Ch. Phys.* [3] lv. 437.)

ETHYLENE, BROMIDE OF. $\text{C}^2\text{H}^2\text{Br}^2$.—This compound was discovered by Balard in 1826 (*Ann. Ch. Phys.* [2] xxxii. 375); further examined by Löwig (*Das Bren und sein chemisches Verhalten*, Heid. 1829, p. 47), Serullas (*Ann. Ch. Phys.* [2] xxxix. 228), D'Arcet (*L'Institut*, 1835, No. 105; *J. pr. Chem.* v 28), and Regnault (*Ann. Ch. Phys.* [2] lix. 358). It is produced by the direct combination of bromine with ethylene. Bromine gradually dropped into ethylene-gas quickly loses its colour, absorbs the gas, and is converted into bromide of ethylene, which may be purified by washing it with alkaline water, and then distilling over sulphuric acid and caustic baryta alternately (Balard). As the combination is attended with great evolution of heat, which may occasion loss of bromine, it is usually recommended to pass a stream of ethylene-gas through bromine covered with a layer of water; unless, however, the current of gas is very slow, there is great risk of both ethylene and bromine being carried off uncombined. The following is a good method of preparation:—A strong glass bottle of 2 or 3 litres capacity is provided with a perforated cork, through which is fitted a glass tube open at both ends, and reaching nearly to the bottom of the bottle, while the upper end, slightly projecting over the cork, communicates by means of a flexible caoutchouc-tube, with a gas-holder containing ethylene. To start the operation, the bottle is detached and filled over water with ethylene-gas, into which are then poured from 100 to 130 grms. of commercial bromine and about half that quantity of water, the cork with the glass tube being immediately replaced. On gently agitating the bottle, the ethylene is rapidly absorbed, and on turning the stop-cock of the gas-holder, the gas rushes into the bottle as into a vacuum. If the agitation be continued, a very large volume of ethylene may be thus united with the bromine in a very short time, without the loss of a particle of the constituents or of the compound. (Hofmann, *Chem. Soc. Qu. J.* xiii. 67.)

Bromide of ethylene is a colourless, fragrant liquid, which solidifies to a crystalline mass at about $0^{\circ}\text{C}.$, melts at 9° , and boils at 129° . Specific gravity = 2.16. Vapour-density = 6.485 (Regnault); by calculation (2 vol.) = 6.564. It is insoluble in water, but soluble in alcohol and in ether.

Bromide of ethylene is decomposed by alcoholic potash, which abstracts the elements of a molecule of hydrobromic acid, leaving bromomethylene or bromide of vinyl, $\text{C}^2\text{H}^2\text{Br}$. With *sulphhydrate of potassium* it yields sulphhydrate of ethylene, $\text{C}^2\text{H}^4\text{H}^2\text{S}^2$; with *monosulphide and disulphide of potassium*, it yields mono- and disulphide of ethylene. With *acetate of silver* it yields diacetate of ethylene (p. 567), and acts in like manner on other silver-salts. With *acetate of potassium*, dissolved in aqueous alcohol, it forms monoacetate of ethylene (p. 567). According to Lourenço, the first product of the action is diacetate of ethylene, which is then resolved by the water present into monoacetate of ethylene and acetic acid (or by the alcohol into monoacetate of ethylene and acetic ether). Heated with *cyanide of potassium*, it yields cyanide of ethylene, $\text{C}^2\text{H}^2\text{Cy}^2$ (Simpson, i. 314). With *ammonia* it forms ethylene-diamine, diethylene-diamine, and triethylene-diamine. For the reactions with *ethylamine*, *phenylamine*, *triethylphosphine*, and other organic bases, see AMMONIUM-BASES (i. 196); also ETHYLENE-BASES and PHOSPHORUS-BASES.

Brominated Derivatives of Bromide of Ethylene.

Bromide of ethylene is decomposed by alcoholic potash, which abstracts the elements of one molecule of hydrobromic acid, leaving monobromomethylene, $\text{C}^2\text{H}^2\text{Br}$. This compound, like ethylene itself, unites with 2 at. bromine, forming $\text{C}^2\text{H}^2\text{Br}^2$, which is in like manner attacked by alcoholic potash, yielding dibromomethylene; and by continuing this alternate treatment with alcoholic potash and bromine, the two following series of compounds are obtained:

Bromomethylene . . .	$\text{C}^2\text{H}^2\text{Br}$	Dibromide of Bromomethylene . . .	$\text{C}^2\text{H}^2\text{Br}.\text{Br}^2$
Dibromomethylene . . .	$\text{C}^2\text{H}^2\text{Br}^2$	Dibromide of Dibromomethylene . . .	$\text{C}^2\text{H}^2\text{Br}^2.\text{Br}^2$
Tribromomethylene . . .	C^3HBr^3	Dibromide of Tribromomethylene . . .	$\text{C}^3\text{HBr}^2.\text{Br}^2$
Tetrabromomethylene or	C^2Br	Dibromide of Tetrabromomethylene, or Tribromide of Carbon	$\text{C}^2\text{Br}^4.\text{Br}^2$
Dibromide of Carbon }			

Bromomethylene was discovered by Regnault (*Ann. Ch. Phys.* [2] lix. 358); the rest, with the exception of C^2Br^4 and C^3Br^4 , were first obtained by Cahours (*Compt. rend.* xxxi. 293), who did not particularly describe them; he observed, however, that the bromides of the bromomethylenes are more easily attacked by alcoholic potash, in

proportion as they contain more bromine, the reaction yielding, in addition to bromide of potassium and a brominated ethylene, potassium-salts of peculiar brominated acids which have not been examined.

Bromethylene or Bromide of Vinyl. C^2H^3Br .—A mixture of bromide of ethylene and alcoholic potash heated to 30° or 40° C. gives off a gas which, when purified by passing through water, then over chloride of calcium, and condensed in a receiver surrounded with ice and salt, yields bromethylene as a colourless, very mobile liquid, having an alliaceous, ethereal odour. Specific gravity about 1.62. Boils at ordinary temperatures. Vapour-density = 3.691 (Regnault). When kept in a sealed tube it sometimes solidifies to a white amorphous mass of the same composition, having the appearance of porcelain, insoluble in water, alcohol, and ether; this solid modification when heated becomes carbonised, with violent evolution of hydrobromic acid. (Hofmann, Chem. Soc. Qu. J. xiii. 68.)

Potassium heated with bromethylene decomposes it, with ignition. Chlorine attacks it, forming an oily substance (Regnault). With *ethylate* or *amylate* of sodium, it yields bromide of sodium, ethylic or amylic alcohol, and acetylene (Sawitsch, Bull. Soc. Chim. de Paris, 1861, p. 7):

A similar transformation takes place when bromethylene is passed into an ammoniacal solution of nitrate of silver, the silver-compound of acetylene being then produced. (Miasnikoff, *ibid.* p. 12.)

Bromide of Bromethylene. $C^2H^3Br^2 = C^2H^3Br.Br^2$.—Obtained by adding bromine by small portions to bromethylene contained in a long-necked flask surrounded by a freezing mixture; purified by washing with alkaline, and with pure water, drying with chloride of calcium, and rectification. It is a colourless liquid, having an odour somewhat like that of chloroform. Specific gravity = 2.620 at 23° C. Boils at 186.5° C. (Wurtz, Ann. Ch. Phys [3] li. 84.)

Alcoholic potash converts it, partly into dibromethylene, partly into monobromethylene, and the latter, by the further action of the alcoholic potash, is decomposed in the manner above mentioned, yielding among other products acetylene (Sawitsch), and bromacetylene (Reboul). If the bromide of bromethylene is added by drops to a boiling solution of alcoholic potash contained in a flask from which the air has been expelled by boiling the liquid for a short time, and the evolved vapours are freed from admixed alcohol and dibromethylene by passing them through two or three wash-bottles containing water, and in which the air has been replaced by carbonic anhydride, a considerable quantity of gas is obtained, which, when freed from carbonic anhydride by potash, is spontaneously inflammable, and is found to consist of a mixture of acetylene, C^2H^2 , and bromacetylene, C^2HBr . (Reboul, Ann. Ch. Pharm. cxxiv. 267.)

Dibromethylene. $C^2H^2Br^2$.—Produced from the preceding compound, $C^2H^3Br^2$, by the action of sodium, of solid hydrate of potassium, or of alcoholic potash. When solid potash is used, the action is so violent that the dibromethylene distils over almost instantly. With alcoholic potash the action is more moderate; and by dropping the bromide of bromethylene into boiling alcoholic potash, separating the resulting products as above described, and rectifying the liquid collected in the first wash-bottle, the dibromethylene is obtained pure.

Dibromethylene is a colourless, limpid liquid, which, in contact with the air, becomes turbid and deposits a white substance of isomeric composition; having a specific gravity of 3.053 at 14.5° C.; insoluble in water, alcohol, and ether, nearly insoluble in disulphide of carbon; not attacked by mineral acids at mean temperature; decomposed by aqueous ammonia, slowly in the cold, more quickly and completely at 100° C., with formation of bromide of ammonium and separation of a carbonaceous substance. Aqueous potash acts in like manner but more slowly. (Sawitsch, Jahresber. f. Chem. 1860, p. 430.)

Dibromide of Dibromethylene. $C^2H^2Br^4 = C^2H^2Br^2.Br^2$. (Lennox, Chem. Soc. Qu. J. xiii. 206.—Reboul, *loc. cit.*).—Produced: 1. By the direct combination of bromine with dibromethylene, which takes place with great energy (Lennox).—2. By passing acetylene gas into bromine, the compound C^2H^2 then taking up 4 at. Br. (Reboul). When purified by washing and rectification, it boils at about 200° C., but with partial decomposition, giving off vapours which powerfully attack the eyes. When exposed to a freezing mixture, it solidifies to a white crystalline mass. It is insoluble in water, but easily soluble in alcohol and ether (Lennox). Specific gravity 2.88 at 22° C. (Reboul.)

Tribromethylene. C^2HBr^3 .—Obtained by treating the last compound with alcoholic potash, and precipitating with water. It is an oily liquid boiling at 130° C.,

and apt to change spontaneously into an isomeric solid, easily soluble in alcohol and in ether, from which it crystallises in colourless plates. An alcoholic or ethereal solution of the oily modification likewise yields the crystalline solid by slow evaporation. (Lennox, *loc. cit.*)

Dibromide of Tribromethylene. $C^2HBr^3 = C^2HBr^2.Br^2$.—Obtained: 1. By cautiously distilling tribromethylene into a receiver containing bromine. Combination takes place with considerable energy, and the product, after washing with weak potash and with water, is a yellowish-red oil, soluble in alcohol and ether, and solidifying when exposed to a frigorific mixture. (Lennox, *loc. cit.*)

2. By the action of bromine on bromoacetylene, C^2HBr . When the gaseous mixture of this compound and acetylene (p. 570) is passed into bromine covered with a layer of water (to moderate the action, which is otherwise so violent as to set the gas on fire), each of these bodies takes up 4 at. bromine, forming the compounds $C^2H^2Br^2.Br^2$, and $C^2HBr^2.Br^2$, and a liquid is obtained, which, when freed from excess of bromine by aqueous potash, and sufficiently cooled, deposits the latter compound in crystals, while the former remains liquid. (Reboul.)

Dibromide of tribromethylene is insoluble in water, but soluble in alcohol and ether (Lennox, Reboul), especially at the boiling heats of these liquids, and crystallises from its alcoholic solution in beautiful prisms. It smells like camphor, melts at $42-50^\circ C.$, and is decomposed by distillation. (Reboul.)

Tetrabromethylene or Dibromide of Carbon. C^2Br^4 .—Produced by the action of alcoholic potash on the compound, C^2HBr^3 (Lennox), also by that of bromine on alcohol or ether (Löwig). It is a white crystalline solid. For its properties and reactions see vol. i. page 764.

Dibromide of Tetrabromethylene or Tribromide of Carbon. $C^2Br^4 = C^2Br^2.Br^2$.—Obtained: 1. By heating bromine in a sealed tube with dibromide of carbon.—2. By heating either of the compounds, $C^2H^2Br^4$ or C^2HBr^3 , with bromine and water in sealed tubes to $100^\circ C.$ for 15 to 20 hours, or better to 180° for a few hours. Hydrobromic acid is then formed, and as the tube cools, the compound C^2Br^4 is deposited in crystals; the remaining liquid, which still smells of bromine, deposits, when left to evaporate, a mixture of tribromide of carbon and dibromide of tribromethylene, which may be separated by alcohol. The formation of tribromide of carbon is represented by the equations:

and

Tribromide of carbon is but very slightly soluble in alcohol and ether, even at the boiling heats of these liquids, but dissolves easily in sulphide of carbon, and separates from the solution by spontaneous evaporation in hard, rather thick, transparent crystals, having the form of right rectangular prisms, with truncation of the lateral and two of the basal edges. When heated, it decomposes, before melting, at $200-210^\circ C.$ into bromine and dibromide of carbon. (Reboul, *Ann. Ch. Pharm.* exxiv. 271.)

ETHYLENE, BUTYRATE OF. $C^2H^4O^4 = \frac{(C^2H^4)^n}{(C^2H^4O)^n} O^2 = (C^2H^4)^n$.

$C^2H^4O^4$.—Obtained by heating for several hours, in the water-bath, a paste composed of 90 grms. (2 at.) butyrate of silver, 48 grms. (1 at.) of bromide of ethylene, and a sufficient quantity of butyric acid, exhausting the product with ether, and distilling. After the ether has passed over, the greater part of the remaining liquid distils between 230° and $240^\circ C.$, and by fractional distillation butyrate of ethylene is obtained, boiling between 239° and 241° .

Colourless liquid, having a strong butyric odour, which is rather persistent when the liquid is rubbed on the skin. Specific gravity 1.024 at $0^\circ C.$ Boils at about 240° , and distils without alteration. Perfectly insoluble in water, but dissolves in all proportions in alcohol or ether. (Wurtz.)

ETHYLENE, BUTYROXYCHLORIDE OF. $C^2H^4ClO^2 = (C^2H^4)^n.C^2H^4O^2.Cl$
Glycolic Chlorobutyryl, Glycol Chlorobutyrique. (Simpson, *loc. cit.*)—Prepared like the acetoxychloride (p. 568). Colourless liquid, having a pungent, somewhat bitter taste; insoluble in water, freely soluble in alcohol. Specific gravity 1.0854 at $0^\circ C.$ Boiling point about 190° .

ETHYLENE, CHLORIDE OF. $C^2H^4Cl^2$. *Dutch liquid.*—This compound was discovered in 1795 by the Dutch chemists, Deiman, Paets van Troostwyk, Bondt, and Lauwerenburgh (Croll, *Ann.* ii. 200), and has been further examined by Liebig (*Ann. Ch. Pharm.* i. 213; ix. 20), Dumas (*Ann. Ch. Phys.* [2] xlviii. 185), Laurent (*ibid.* lxiii. 377), Regnault (*ibid.* lviii. 301; lxix. 261; lxxi. 371), Mala-

guti (Ann. Ch. Phys. [3] xvi. 6 and 14), and Pierre (Compt. rend. xxv. 130).—See also Gm. (viii. 162). It is easily produced by bringing ethylene gas in contact with moist chlorine (the gases scarcely act upon each other when dry), or with a metallic perchloride, which easily gives up part of its chlorine, or by the action of pentachloride of phosphorus on hydrate of ethylene.

Preparation.—Ethylene gas, produced by heating a mixture of alcohol and sulphure

Fig. 470.

acid (p. 565), is passed through a wash-bottle containing potash to free it from sulphurous acid; through a second containing alcohol, which removes vapour of ether, and sometimes through a third containing water to free it from alcohol-vapour. It then passes into a large glass globe (fig. 470), having a long neck, which descends into a bottle closed with a cork, and after the stream of gas has been continued long enough to expel the air, moist chlorine from another flask is also admitted into the globe. The two gases then unite, forming an oily liquid, which runs down into the receiver.

2. Ethylene gas is passed through the tubulus of a retort containing a slightly heated mixture for the evolution of chlorine (2 pts. black oxide of manganese, 3 pts. common salt, 4 pts. water, and 5 pts. sulphuric acid), and the chloride of ethylene thus formed is distilled off. This process may be employed for the preparation of chloride of ethylene by means of coal-gas instead of pure ethylene. (Limpricht.)

3. Ethylene gas is passed into pentachloride of antimony (produced by saturating ordinary butter of antimony with chlorine, i. 318), and the product is distilled, till the distillate no longer yields any oil on addition of water. The oily chloride of ethylene is then decanted, shaken up with oil of vitriol till it no longer blackens, then distilled over a water-bath.

The product obtained by either of these methods is purified by washing, first with alkaline, then with pure water, dried by contact with chloride of calcium, and rectified.

Properties.—Dichloride of ethylene is a colourless, neutral, oily liquid, having a fragrant ethereal odour, and a sweetish aromatic taste. Specific gravity = 1.247 at 18° C. (Liebig); 1.256 at 12° (Regnault). It boils at 82.6 under a pressure of 765 mm. (Regnault), at 86° under a pressure of 770 mm. (Dumas). Vapour-density = 3.4434 (Gay-Lussac), by calculation (2 vol.) = 3.4303. It is nearly insoluble in water, to which, however, it imparts its odour, but soluble in alcohol and ether. It dissolves a considerable quantity of phosphorus when heated therewith. It may be mixed, and even distilled, with strong sulphuric acid, without alteration.

Decompositions.—1. Dichloride of ethylene is inflammable, and burns with a green, very smoky flame, giving off vapours of hydrochloric acid.—2. When passed in the liquid state through a red-hot tube, it deposits carbon, and yields a mixture of hydrochloric acid gas and a hydrocarbon which burns with a bluish flame.—3. Passed in the state of vapour through a red-hot tube, it yields chloride of carbon, free carbon, and crystals of naphthalin.—4. When covered with water and exposed to sunshine, it is gradually decomposed, yielding hydrochloric acid and acetate of ethyl:

5. Chlorine, especially under the influence of heat or light, transforms it into mono-, di-, tri-, and per-chlorethylene.—6. Ammonia gas does not act upon liquid dichloride of ethylene, but when mixed with the vapour, it forms sal-ammoniac and unflammable gas (Robiquet and Colin, Ann. Ch. Phys. [2] i. 213, ii. 206).—7. The dichloride

heated in sealed tubes with *alcoholic ammonia*, yields the bases $C^2H^4.H^2.N^2$, $(C^2H^4)^2.H^2.N^2$, and $(C^2H^4)^3.N^2$ (see ETHYLENE-BASES). — 8. *Potassium* attacks it violently, forming a porous mass, and eliminating a mixture of hydrogen and chlor-ethylene:

9. It is scarcely attacked by aqueous potash, but by *alcoholic potash*, or *ethylate of potassium* (or sodium), it is resolved into hydrochloric acid and chloroethylene, $C^2H^4.Cl$. — 10. With *sulphydrate*, *monosulphide*, *disulphide*, and *sulphocyanate of potassium*, it yields the corresponding salts or ethers of ethylene.

Chlorinated Derivatives of Chloride of Ethylene.

Dichloride of ethylene subjected to the continued action of chlorine yields the several chlorinated dichlorides contained in the left-hand column of the following table, and each term of this series (beginning with $C^2H^4.Cl^2$), when treated with alcoholic potash, gives up 1 at. HCl, and yields the compound standing opposite to it in the right-hand column.

Dichloride of Ethylene	$C^2H^4.Cl^2$	Chlorethylene	$C^2H^3.Cl$
Monochlorinated	$C^2H^3.Cl.Cl^2$	Dichlorethylene	$C^2H^2.Cl^2$
Dienechlorinated	$C^2H^2.Cl^2.Cl^2$	Trichlorethylene	$C^2H.Cl^3$
Trichlorinated	$C^2H.Cl^3.Cl^2$	Perchlorethylene	C^2Cl^4
Perchlorinated	$C^2Cl^4.Cl^2$		

These compounds are precisely analogous to the brominated compounds previously described. Each compound in the left-hand column of the table may be produced by the action of chlorine on either of the compounds which precede it.

Chlorethylene or *Chloride of Vinyl*, $C^2H^3.Cl$, is, at low temperatures, a very mobile liquid, boiling even at -18° or -15° C. The gas has an alliaceous odour, takes fire with difficulty, and burns with a red flame, green at the edges. Specific gravity of the gas = 2.166. In the liquid state it is insoluble in water, but dissolves in all proportions in alcohol and ether. Potassium slightly heated decomposes the gas, eliminating carbon and a small quantity of naphthalin. By chlorine in sunshine, and by perchloride of antimony, it is converted into the following compound:—

Chloride of Chlorethylene, $C^2H^3.Cl^2 = C^2H^3.Cl.Cl^2$.—The best mode of preparation is to pass the preceding gaseous compound into an apparatus containing pentachloride of antimony, and kept cool at the beginning of the action. It is an oily liquid, boiling at 115° C., and resembling Dutch liquid in appearance and in odour. Specific gravity = 1.422 at 17° C. Vapour-density, observed = 4.722—4.672; calculated (2 vol.) = 4.591.

Dichlorethylene, $C^2H^2.Cl^2$.—Very volatile liquid boiling between 35° and 40° C. Odour alliaceous, like that of monochlorethylene. Specific gravity = 1.250 at 15° C. Vapour-density, observed = 3.321, calculated (2 vol.) = 3.36. When kept in sealed tubes, it changes spontaneously into a white crystalline isomeric substance. If poured into chlorine gas in sunshine, it takes fire and deposits carbon; but if poured into the chlorine in the shade, left there for 12 hours, and then exposed to the sun, it is completely converted into crystals of perchlorinated chloride of ethylene, or sesquichloride of carbon, $C^2Cl^4.Cl^2$.

Chloride of Dichlorethylene, $C^2H^2.Cl^3 = C^2H^2.Cl^2.Cl^2$.—Produced by the continued action of chlorine on Dutch liquid or on chloride of chlorethylene. It is a liquid smelling like the preceding compounds. Specific gravity = 1.676 at 19° C. Boiling point 135° C. Vapour-density, observed = 5.796, calculated (2 vol.) = 5.821.

Trichlorethylene, $C^2H.Cl^3$.—Produced by the action of alcoholic potash on the preceding. It is an oily liquid which gives off hydrochloric acid when distilled.

Chloride of Trichlorethylene, $C^2H.Cl^4 = C^2H.Cl^3.Cl^2$.—Produced by the action of chlorine on Dutch liquid. It is liquid at 0° C., has a rather fragrant odour and hot sweetish taste. Specific gravity = 1.66267 at 0° C. Boiling point, 163.8° under a pressure of 763.35 mm. Vapour-density, observed = 7.087, calculated (2 vol.) = 7.016. Alcoholic potash decomposes it, with great rise of temperature, yielding chloride of potassium and the following compound:—

Perchlorethylene or *Dichloride of Carbon*, C^2Cl^4 .—Produced also by several other reactions (i. 767).

Chloride of Perchlorethylene or *Trichloride of Carbon*, $C^2Cl^5 = C^2Cl^4.Cl^2$.—Produced by the continued action of chlorine on chloride of ethylene or its chlorinated derivatives, and by several other reactions (i. 766).

ETHYLENE, CHLORIODIDE OF. C^2H^4Cl . (Maxwell Simpson, Proc. Roy. Soc. xi. 690; xii. 278).—Produced by passing ethylene-gas into aqueous chloride of iodine, or by agitating iodide of ethylene with the same solution containing free iodine; the former process is to be preferred. The reddish oil which collects at the bottom of the liquid is washed with dilute potash and distilled.

Chloriodide of ethylene is a colourless oil having a sweet taste and slightly soluble in water. Specific gravity = 2.151 at $0^\circ C$. Boils at 146° — $147^\circ C$. Heated with alcoholic potash, it decomposes, yielding iodide of potassium and a gas which burns with a green flame, and is probably chloride of vinyl, C^2H^3Cl .

ETHYLENE, CYANIDE OF. $C^2H^4N^2 = C^2H^4.Cy^2$.—Obtained by the action of cyanide of potassium on bromide or chloride of ethylene (see p. 212).

ETHYLENE, DIBROMIDE, DICHLORIDE, and DI-IODIDE OF. See ETHYLENE, BROMIDE, CHLORIDE, and IODIDE OF.

ETHYLENE, ETHYLATES OF. (Wurtz, Ann. Ch. Pharm. cviii. 84).—The *monoethylate* or *ethyl-glycol*, $C^4H^{10}O^2 = \left\{ \begin{smallmatrix} C^2H^4 \\ C^2H^5.H \end{smallmatrix} \right\} O^2$, is produced by the action of iodide of ethyl on ethylenate of sodium:

It is an ethereal liquid, boiling somewhere about $130^\circ C$., but it has not been obtained quite free from the following compound.

Diethylate of Ethylene, or *Diethyl-glycol*. $C^4H^{14}O^2 = \left\{ \begin{smallmatrix} C^2H^4 \\ C^2H^5 \end{smallmatrix} \right\} O^2$.—The preceding compound treated with potassium yields the compound $\left\{ \begin{smallmatrix} C^2H^4 \\ C^2H^5.K \end{smallmatrix} \right\} O^2$; and this, when treated with iodide of ethyl, yields diethylate of ethylene:

It is a colourless, very mobile liquid, having a fragrant ethereal odour. Specific gravity = 0.7993 at $0^\circ C$. Boils at 123.6° under a pressure of 758.8 mm. Vapour-density, obs. = 4.095; calc. = 4.089. It is isomeric with acetal, but is distinguished therefrom by its higher boiling-point, acetal boiling at $104^\circ C$.

ETHYLENE, HYDRATES OF.—ETHYLENIC ALCOHOLS. These bodies, which may be regarded as compounds of oxide of ethylene and water, are represented by the general formula:

The first term of the series ($n = 1$) was discovered by Wurtz in 1856; the rest, up to $n = 6$, were obtained by Wurtz and by Lourenço in 1859 and 1860.

Monoethylenic Alcohol, Glycol. $C^2H^4O^2 = \left\{ \begin{smallmatrix} C^2H^4 \\ H^2 \end{smallmatrix} \right\} O^2 = C^2H^4O.H^2O$. (Wurtz, Compt. rend. xliii. 199; Ann. Ch. Pharm. c. 110; further, and in detail, Ann. Ch. Phys. [3] lv. 400; Ann. Ch. Pharm. Suppl. i. 85).—The term *glycol*, formed from the first syllable of *glycerin* and the last of *alcohol*, denotes that the compound, as a diatomic alcohol, is intermediate between alcohol and glycerin, which are respectively mono- and tri-atomic.

Preparation.—This compound, the type of the diatomic alcohols, is obtained by distilling the diacetate or monoacetate of ethylene with potash:

1. Diacetate of ethylene (6.15) grm. is mixed in a flask with hydrate of potassium (4.72 grm.), previously ignited and pulverised. A brisk action immediately takes place, and after the lapse of a day, a mass of acetate of potassium is found in the flask. The mixture is then heated to $180^\circ C$. in an oil-bath, and after a small distillation-tube has been adapted to the flask, the heat is raised to between 260° and 260° . A colourless liquid then passes over, which is to be rectified, and the portion which distils between 190° and 200° collected apart. (Wurtz.)

2. Atkinson (Phil. Mag. [4] xvi. 433) prepares glycol by the action of potash or baryta on monoacetate of ethylene, p. 668. According to Debus (Ann. Ch. Pharm. cx. 316), the quantity of glycol thus obtained is only about half the calculated quantity, the loss apparently arising from the formation of a compound which is but slowly resolved by heat into glycol and acetate of potassium. He therefore recommends the following process:—

3. The monoacetate of ethylene mixed with an equal volume of water is exposed for twelve or sixteen hours in a strong, well-corked flask, to the temperature of boiling water, whereby it is for the most part resolved into acetic acid and glycol. On distilling the contents of the flask, water and acetic acid pass over below 150°C .; glycol mixed with a considerable quantity of the undecomposed acetate between 150° and 190° ; and above 190° , glycol containing a comparatively small portion (about 15 per cent.) of the acetate. The portion boiling between 150° and 190° is again heated with water in a close vessel; the portion of the product which distills above 190° is mixed with the former portion boiling at that temperature; the whole is distilled with a quantity of solid potash, just sufficient to neutralise the acetic acid; and the liquid which passes over at 245° is rectified. Glycol is thus obtained boiling at 196° .

In all processes for obtaining glycol from the acetates or other compounds of ethylene, excess of alkali is to be avoided, as it greatly diminishes the quantity of the product: in general, also, hydrate of barium is preferable to potash. The following method gives good results when rather large quantities of glycol are to be prepared. The mixture of mono- and diacetate of ethylene, boiling between 180° and 190° , which is obtained by the action of bromide of ethylene on acetate of potassium (pp. 566, 567), is mixed with as much hydrate of barium as would be sufficient to decompose it were it all pure mono-acetate of ethylene, and the mixture is heated in a water-bath till the alkaline reaction disappears; a further quantity of hydrate of barium is then added in small portions at once, the mixture being heated for an hour or more after each addition, until the alkaline reaction becomes permanent. The greater part of the acetate of barium thus formed crystallises out on cooling; the crystals are separated and washed with alcohol, the alcoholic washings being added to the liquid drained from the crystals, whereby more acetate of barium is precipitated; this is separated by filtration; and the filtrate then yields pure glycol by fractional distillation.

4. Glycol is also produced, together with diethylenic and a small quantity of triethylenic alcohol, by the direct combination of water with oxide of ethylene. When oxide of ethylene is heated with water for several days in a strong sealed flask, a sweetish liquid is obtained, from which glycol may be separated by fractional distillation. (Wurtz, Ann. Ch. Pharm. cxiii. 255.)

Properties.—Glycol is a colourless, inodorous, somewhat viscid liquid, of specific gravity 1.125, boiling at 197.5°C . It mixes with water and with alcohol, but is only slightly soluble in ether. It dissolves hydrate of potassium, chloride of calcium, chloride of sodium, chloride of zinc, trichloride of antimony, and mercuric chloride; carbonate of potassium in small quantity, the sulphate scarcely at all.

Decompositions.—1. Glycol is easily oxidisable. When it is dropt on platinum-black, the metal becomes incandescent, and carbonic anhydride is given off. If the action be moderated by diluting the glycol with water, and the oxygen of the air with carbonic anhydride, glycolic acid, $\text{C}^2\text{H}^4\text{O}^3$, is produced by the oxidation.—2. Dilute nitric acid at mean temperatures converts glycol into glycolic acid, at higher temperatures into oxalic acid (Wurtz). When glycol, diluted with four times its volume of water, is placed in a tall vessel, strong nitric acid poured in through a long tube-funnel, so as to form a layer at the bottom, and the whole heated to about 30°C ., glycolic acid, glyoxylic acid, $\text{C}^2\text{H}^4\text{O}^3$, and perhaps also glyoxal, $\text{C}^2\text{H}^2\text{O}^2$, are formed (Debus, Ann. Ch. Pharm. cx. 316).—3. Glycol heated to 250°C . with hydrate of potassium, is converted into oxalic acid, with evolution of hydrogen:

4. Glycol heated with chloride of zinc is dehydrated, and yields aldehyde, $\text{C}^2\text{H}^4\text{O}$ (isomeric with oxide of ethylene), and acetaldehyde, $\text{C}^2\text{H}^4\text{O}^2$, a polymeric modification of aldehyde, boiling at 110°C . (Wurtz, Bauer, Rép. Chim. pure, 1860, p. 244.)—

5. Glycol heated with oxygen-acids yields ethylenic ethers containing 1 or 2 at. of the acid radicle, according to the proportions used (Lourengo, Bull. Soc. Chim. Nov. 1859; Ann. Ch. Pharm. cxiv. 122), e. g.:

6. Heated with *hydrochloric acid*, it yields hydroxychloride of ethylene (glycolic chlorhydrin). (Wurtz.)

Similar reactions with *hydrobromic* and *hydriodic acids* (Wurtz).—7. *Pentachloride of phosphorus* acts violently on glycol, forming dichloride of ethylene (Wurtz):

8. Glycol is likewise strongly attacked by the *chlorides of acetyl, butyryl*, and other monatomic acid radicles, yielding acetoxychloride of ethylene, &c. (Lourenço p. 670); thus:

The same, and analogous compounds, are obtained by heating glycol with a fatty acid and hydrochloric or hydriodic acid: *e. g.*

9. Glycol heated with *iodide of ethyl* is partially decomposed, yielding monoethylate of ethylene (p. 676).

Ethylenates of Sodium.—Sodium acts rapidly on glycol, eliminating hydrogen and forming monosodic ethylenate or monosodic glycol, $\begin{array}{c} \text{C}^2\text{H}^4 \\ \text{Na}.\text{H} \end{array} \left\{ \begin{array}{c} \text{O}^2 \\ \text{O}^2 \end{array} \right\}$, a white crystalline substance, which, when treated with iodide of ethyl, yields iodide of sodium and monoethylate of ethylene (p. 574). Heated in a sealed tube with bromethylene (bromide of vinyl), $\text{C}^2\text{H}^3\text{Br}$, it yields ethylene gas and glycol, together with bromide of sodium and a small quantity of a sodium-salt which is soluble in alcohol, and when decomposed by sulphuric acid, yields an acid having the odour of acetic acid, but exerting a reducing action on silver-salts. (Wurtz.)

Monosodic ethylenate fused with excess of sodium is slowly converted into disodic ethylenate or disodic glycol, $\text{C}^2\text{H}^4.\text{Na}^2.\text{O}^2$. This compound heated with dibromide of ethylene in a flask connected with a well cooled receiver, yields bromethylene, together with glycol and bromide of sodium (Wurtz):

Polyethylenic Alcohols.

These compounds, whose composition is represented by the general formula given on p. 574, when $n = 2$ or upwards, are produced in the following ways:

1. By heating oxide of ethylene with water in sealed tubes. In this manner Wurtz obtained diethylenic alcohol, together with monethylenic and a small quantity of triethylenic alcohol.

2. By heating oxide of ethylene with glycol in sealed tubes: this reaction yields diethylenic and triethylenic alcohols. (Wurtz.)

3. By distilling the corresponding polyethylenic diacetates (p. 568) with an alkali, the general equation of the decomposition being:

By this process, Wurtz obtained the di-, tri-, and tetr-ethylenic alcohols.

4. By heating glycol with dibromide of ethylene to 110° — 120° C. in sealed tubes. The first products of the reaction are diethylenic alcohol, glycolic bromhydrin (hydroxybromide of ethylene), and water, as shown by the equation:

and the other polyethylenic alcohols are formed, each from the one next below it in the series, by the action of the glycolic bromhydrin, according to the general equation:

The hydrobromic acid thus formed then acts on the excess of glycol present, reproducing glycolic bromhydrin, and thus the action is continued. By this process, the 2-, 3-, 4-, 5-, and 6-ethylenic alcohols have been obtained, and separated by fractional distillation; and when a sufficient excess of glycol is present, the temperature being still kept between 110° and 120° C., still higher members of the series are obtained, becoming continually more viscid, and each differing from the preceding in boiling-point by about 45° C. If the temperature of the mixture is allowed to rise above 130° , the liquid turns brown and yields the hydrobromic ethers of the polyethylenic alcohols instead of the alcohols themselves, the hydrobromic acid produced by the reaction then acting, not only on the glycol, but likewise on the polyethylenic alcohols. (Lourenço, *Compt. rend.* li. 365; *Rép. Chim. pure*, ii. 467; *Ann. Ch. Pharm.* cxvii. 269.)

The polyethylenic alcohols may be supposed to be formed by the union of two or more molecules of glycol, with elimination of a number of molecules of water, less by one than the number of molecules of glycol which enter into the combination generally:

Diethylenic Alcohol. $\text{C}^4\text{H}^{10}\text{O}^3 = \left\{ \begin{smallmatrix} \text{C}^2\text{H}^4 \\ \text{H}^2 \end{smallmatrix} \right\} \text{O}^3 = (\text{C}^2\text{H}^4\text{O})^2.\text{H}^2\text{O}$. (Lourenço, *Bull. Soc. Chim.* 1859, p. 77.)—This compound, the first discovered of the polyethylenic alcohols, contains the elements of 1 at. oxide of ethylene and 1 at. glycol, ($\text{C}^2\text{H}^4\text{O} + \text{C}^2\text{H}^4\text{O}^2$), and hence was originally called "intermediate glycol-ether." It is prepared by heating 3 at. glycol with 1 at. dibromide of ethylene (equal weights of the two) to 120° C. in a sealed flask for four days. Other modes of formation have already been mentioned.

It is a sweetish syrupy liquid, boiling at about 245° C., soluble in water, alcohol, and ether. Vapour-density, observed = 3.78 at 311° C.; calculated = 3.67 (Lourenço). It is easily oxidised by contact with platinum-black, or by treatment with nitric acid; the latter converts it into diglycolic acid, $\text{C}^4\text{H}^8\text{O}^3 =$

$\left\{ \begin{smallmatrix} \text{C}^2\text{H}^4\text{O} \\ \text{H}^2 \end{smallmatrix} \right\} \text{O}^3$, in the same manner as glycolic acid, $\left\{ \begin{smallmatrix} \text{C}^2\text{H}^2\text{O}^2 \\ \text{H} \end{smallmatrix} \right\} \text{O}^2$, to glycol, $\left\{ \begin{smallmatrix} \text{C}^2\text{H}^4 \\ \text{H}^2 \end{smallmatrix} \right\} \text{O}^2$, both these acids containing the diatomic radicle glycolyl, $\text{C}^2\text{H}^2\text{O}$, derived from ethylene, C^2H^4 , in the same manner as acetyl, $\text{C}^2\text{H}^3\text{O}$, from ethyl, C^2H^5 ; viz. by the substitution of O for H^2 . (Wurtz.)

Triethylenic Alcohol. $\text{C}^6\text{H}^{14}\text{O}^4 = \left\{ \begin{smallmatrix} \text{C}^2\text{H}^4 \\ \text{H}^2 \end{smallmatrix} \right\} \text{O}^4 = (\text{C}^2\text{H}^4\text{O})^3.\text{H}^2\text{O}$.—This compound is best prepared by heating oxide of ethylene with glycol in a sealed tube ($2\text{C}^2\text{H}^4\text{O} + \text{C}^2\text{H}^4\text{O}^2 = \text{C}^6\text{H}^{14}\text{O}^4$). The chief product of this reaction is, however, diethylenic alcohol; but after this has been removed by fractional distillation, the residue yields at about 290° C. a very thick liquid, which is triethylenic alcohol. (Wurtz.)

This alcohol is likewise easily oxidised by platinum-black and by nitric acid, the latter converting it into diglycolethylenic acid, $\text{C}^6\text{H}^{12}\text{O}^4 = \left\{ \begin{smallmatrix} \text{C}^2\text{H}^4 \\ \text{H}^2 \end{smallmatrix} \right\} \text{O}^4$. (Wurtz.)

Tetreethylenic Alcohol. $\text{C}^8\text{H}^{18}\text{O}^5 = \left\{ \begin{smallmatrix} \text{C}^2\text{H}^4 \\ \text{H}^2 \end{smallmatrix} \right\} \text{O}^5 = (\text{C}^2\text{H}^4\text{O})^4.\text{H}^2\text{O}$.—Boils under the ordinary pressure, above 300° C.; in a highly rarefied atmosphere (under a pressure of 0.025 mm.) at 230° C. (Lourenço.)

Pentethylenic Alcohol. $\text{C}^{10}\text{H}^{22}\text{O}^6 = \left\{ \begin{smallmatrix} \text{C}^2\text{H}^4 \\ \text{H}^2 \end{smallmatrix} \right\} \text{O}^6 = (\text{C}^2\text{H}^4\text{O})^5.\text{H}^2\text{O}$.—Boils at 230° under a pressure of 0.025 mm. (Lourenço.)

Hexethylenic Alcohol. $\text{C}^{12}\text{H}^{26}\text{O}^7 = \left\{ \begin{smallmatrix} \text{C}^2\text{H}^4 \\ \text{H}^2 \end{smallmatrix} \right\} \text{O}^7 = (\text{C}^2\text{H}^4\text{O})^6.\text{H}^2\text{O}$.—Boils at 225° under the same pressure. (Lourenço.)

ETHYLENE, HYDROXYBROMIDE OF. $\text{C}^2\text{H}^3\text{BrO} = (\text{C}^2\text{H}^4)^{\cdot}\text{HO.Br}$.
Glycolic Bromhydrin, Glycol bromhydrique. (Lourenço, *Bull. Soc. Chim. de Paris*, i. 77.)—Produced, together with diethylenic alcohol, by heating 3 at. monethylenic

alcohol (glycol), with 1 at. bromide of ethylene (equal weights of the two), to 120° C. in a sealed flask:

ETHYLENE, HYDROXYCHLORIDE OF. $\text{C}^2\text{H}^4\text{ClO} = (\text{C}^2\text{H}^4)^2.\text{HO}.\text{Cl}$
Glycolic Chlorhydrin, Glycol chlorhydrique. (Wurtz, Ann. Ch. Pharm. cx. 125.)
 —Obtained: 1. By saturating glycol with hydrochloric acid gas, heating the liquid to 100° C., repeating these operations till the liquid, on being removed from the tube, no longer gives off fumes of hydrochloric acid, and rectifying (Wurtz).—2. By heating glycol to 100° C. with disulphide of chlorine in a flask provided with an upright condensing tube:

The sulphide of chlorine must be added at once in slight excess, otherwise an insoluble compound (perhaps a sulphurous ether) is produced at the same time. The heating is continued as long as any gas is evolved; the product is dissolved in ether; decanted from the sulphur which separates; then shaken up with moist carbonate of potassium, and distilled after the ether has been evaporated off over the water-bath. The product amounts to nearly the theoretical quantity. (Carius, Ann. Ch. Pharm. cxxiv. 257.)

Hydroxychloride of ethylene is a colourless neutral liquid, boiling at 128° C., soluble in water, burning with green colour in the flame of a lamp (Wurtz). Diluted with half its volume of water, and treated with *sodium-amalgam*, it is converted into common alcohol, $\text{C}^2\text{H}^4\text{O}$, the change consisting in the replacement of an atom of chlorine by an atom of hydrogen (Lourenço, Compt. rend. lii. 1043). Treated with an alcoholic solution of *sulphhydrate of potassium*, it yields oxysulphhydrate of ethylene, $\text{C}^2\text{H}^4.\text{H}^2.\text{SO}$. (Carius.)

ETHYLENE, HYDROXYIODIDE OF. $\text{C}^2\text{H}^4\text{IO} = (\text{C}^2\text{H}^4)^2.\text{HO}.\text{I}$. *Glycolic Iodhydrin, Glycol iodhydrique.* (Maxwell Simpson, Proc. Roy. Soc. x. 1191.)
 —Hydriodic acid is rapidly absorbed by glycol, great heat being evolved, and the liquid becoming black and thick from separation of iodine; and on removing the iodine by dilute potash, a mass of white crystals is obtained, consisting of iodide of ethylene:

But if the temperature be prevented from rising by surrounding the vessel with cold water during the passage of the gas, a liquid product is obtained, which, after being treated with metallic silver to remove free iodine, exhibits approximately the composition of glycolic iodhydrin, viz. 11.1 per cent. carbon and 3.5 hydrogen, the formula $\text{C}^2\text{H}^4\text{IO}$ requiring 13.9 C. and 3.0 H.

It is soluble in water and alcohol, but insoluble in ether. It has no taste at first, but almost burns the tongue after a time. It is decomposed by heat, yielding iodide of ethylene, and probably glycol:

It acts with great energy on silver-salts. Potash decomposes it, yielding iodide of potassium and oxide of ethylene.

ETHYLENE, IODIDE OF. $\text{C}^2\text{H}^4\text{I}^2$.—Discovered in 1821 by Faraday (Ann. Phil. xviii. 118); examined also by Regnault (Ann. Ch. Phys. lix. 367), D'Arcet (l'Institut. 1835, No. 105), and E. Kopp (J. Pharm. [3] vi. 110). It is produced: 1. By the direct combination of iodine and ethylene in sunshine (Faraday), or under the influence of a heat of 50°–60° C. (Regnault).—2. When vapour of iodide of ethyl is passed through a red-hot porcelain tube (E. Kopp):

3. By the action of hydriodic acid on glycol when the liquid is not kept cool (Simpson). It is easily prepared on the small scale by passing ethylene gas over gently heated iodine, part of the product then subliming in colourless needles. To obtain larger quantities, the iodine is heated in a long-necked flask, and a stream of ethylene gas directed on to its surface. The heat is raised very gradually, and as soon as the mass has become liquid, the gas is passed into it. By this means a brown liquid is at length obtained, which crystallises on cooling. It is purified from excess of iodine by washing with dilute potash, and finally recrystallised from alcohol. (Regnault.)

Iodide of ethylene crystallises in colourless needles or prisms, melts at 75° C., and sublimes easily, but with partial decomposition; it is only in an atmosphere of hydrogen or ethylene gas that it can be sublimed in perfectly colourless crystals. It is

insoluble in water, but dissolves easily in ether and in boiling alcohol, from which it crystallises for the most part on cooling.

Iodide of ethylene is easily resolved into ethylene and iodine, this decomposition taking place slowly, even at ordinary temperatures, especially under the influence of light. At 85° C. it takes place rapidly, either in the air or in vacuo. It burns when held in the flame of a spirit-lamp, giving off vapours of iodine and hydriodic acid. Chlorine or bromine converts the compound into chloride or bromide of ethylene, the iodine being partly set free, partly uniting with the chlorine or the bromine. Aqueous potash acts but slowly upon it, even at the boiling heat; but when boiled with alcoholic potash, it is completely decomposed, partly into ethylene and iodine, partly into hydriodic acid and iodethylenes, C^2H^4I .

ETHYLENE, IODATED. C^2H^4I . *Iodethylene, Iodide of Vinyl*.—Prepared by distilling iodide of ethylene with a strong alcoholic solution of potash, the receiver being kept at a low temperature. On adding water to the distillate, iodethylenes separates as a colourless liquid, having an alliaceous odour. It is insoluble in water, but very soluble in alcohol and ether. Nitric acid decomposes it, separating iodine and red vapours. (Regnault, *loc. cit.*—E. Kopp, *Compt. rend.* xviii. 871.)

ETHYLENE, IODOCHLORIDE OF. C^2H^4ClI .—Obtained by agitating an aqueous solution of chloride of iodine containing a trace of free iodine with iodide of ethylene, till the latter is converted into a black oily liquid, washing this liquid with dilute potash, and distilling:

It is a colourless liquid having a sweet taste, slightly soluble in water, boiling at about 147° C. (Maxwell Simpson, *Proc. Roy. Soc.* xi. 390; *Rép. Chim. pure*, 1862, p. 350.—See ADDENDA, p. 968.)

ETHYLENE, OXIDE OF. C^2H^4O . *Ethylene ether, Glycolic ether*. (Wurtz [1859], *Compt. rend.* xlviii. 101; *Ann. Ch. Pharm.* cx. 125; *Rép. Chim. pure*, i. 222; in detail; *Ann. Ch. Phys.* [3] lv. 418, 427; *Compt. rend.* xlix. 398; *Ann. Ch. Pharm.* cxiv. 51; *Compt. rend.* l. 1195; *Ann. Ch. Pharm.* cxvi. 249; *Rép. Chim. pure*, ii. 340; *Compt. rend.* liii. 378; liv. 277; *Rép. Chim. pure*, 1862, p. 16, 176; *Chem. Soc. J.* xv. 387.)

This compound is produced by the action of potash on glycolic chlorhydrin. Chloride of potassium then separates, and oxide of ethylene is given off in vapour, which may be condensed in a receiver surrounded with a frigorific mixture and containing a few lumps of chloride of calcium, over which the product may be afterwards rectified.

Oxide of ethylene is a transparent colourless liquid, boiling at 13.5° C., under a pressure of 746.5 mm. Vapour-density, obs. = 1.422; calc. = $\frac{2.12 + 4.1 + 16}{2} \times 0.0693$. It is isomeric with aldehyde, but is distinguished from that compound by its boiling-point (aldehyde boiling at 21° C.), and by its strong basic properties. It does not unite with the acid sulphites of alkali-metals, and does not form with ammonia a compound analogous to aldehyde-ammonia (i. 107).

Oxide of ethylene mixes in all proportions with water and with alcohol. The aqueous solution treated with sodium-amalgam in a vessel cooled by a freezing mixture yields ethylic alcohol:

The liquid remaining after the alcohol has been distilled off contains glycol and the polyethylenic alcohols. (Wurtz, *Rép. Chim. pure*, 1862, p. 177.)

Oxide of ethylene is a strong base, uniting directly with acids, *e. g.* with hydrochloric acid to form hydroxychloride of ethylene or glycolic chlorhydrin (p. 577), $C^2H^4O.HCl$; with acetic acid to form monoacetate of ethylene, $C^2H^4O.C^2H^3O^2$; with acetic anhydride in various proportions, forming diacetate of ethylene, $C^2H^4O.C^2H^3O^2$, and the several polyethylenic diacetates included in the general formula, $(C^2H^4O)^n.C^2H^3O^2 =$

$\left\{ \begin{matrix} C^2H^4O \\ C^2H^3O^2 \end{matrix} \right\} O^{n+1}$ (p. 568). In like manner it unites with water, forming glycol,

$C^2H^4O.H^2O$, and the polyethylenic alcohols, $(C^2H^4O)^n.H^2O = \left\{ \begin{matrix} C^2H^4O \\ H^2 \end{matrix} \right\} O^{n+1}$ (p. 574), which may also be regarded as compounds of oxide of ethylene with glycol, $= \left\{ \begin{matrix} C^2H^4O \\ H^2 \end{matrix} \right\} O^2.(C^2H^4O)^{n-1}$.

Oxide of ethylene precipitates magnesia, alumina, ferric oxide, and cupric oxide, as

hydrates, from the solutions of their salts, and is itself precipitated by *potash* or *lime* from its combination with hydrochloric acid. When it is sealed up in a flask with strong solution of *chloride of magnesium* for several hours, hydrate of magnesium deposited, and glycolic chlorhydrin remains in solution:

Oxide of ethylene unites directly with *water*, forming glycol and the polyethylene alcohols (Wurtz); with *sulphydic acid*, forming (probably) sulphydic glycol and polyethylene oxysulphydrates (Foster, p. 582); with *bromine*, forming the compound $(\text{C}^2\text{H}^4\text{O})^2.\text{Br}^2$; with *ammonia*, to form the ethylene-hydoramines, $(\text{C}^2\text{H}^4\text{O})^2.\text{NH}^2$ (p. 59); with *aldehyde*, forming the polymeric compound, $\text{C}^2\text{H}^4\text{O}^2$.—Oxide of ethylene vapour is absorbed by *chloride of calcium* at common temperatures. (Foster.)

Compounds polymeric with Oxide of Ethylene.

Dioxethylene. $\text{C}^2\text{H}^4\text{O}^2 = \left. \begin{smallmatrix} \text{C}^2\text{H}^4 \\ \text{C}^2\text{H}^4 \end{smallmatrix} \right\} \text{O}^2$.—Bromide of ethylenic oxide subjected the action of reducing agents, such as sulphydic acid or metals, gives up its bromine and is converted into this compound. The reduction is best effected with mercury. On leaving this metal in contact with the bromine-compound in a tube for twenty-four hours, a colourless mass is obtained, consisting of bromide of mercury impregnated with a volatile liquid, which may be distilled off.

This liquid has a faint but pleasant odour, crystallises at 90°C ., boils at 102°C . Specific gravity 1.0482. Vapour-density, obs. = 3.10; calc. (2 vol.) = 3.0 ($= \frac{4.12 + 8.1 + 2.16}{2} \times 0.0693$). It is soluble in alcohol and ether; is not attacked by ammonia; unites slowly with acetic anhydride at 120°C .

Dioxyethylene is probably the ether of diethylenic alcohol, $(\text{C}^2\text{H}^4\text{O})^2.\text{H}^2\text{O} - \text{H}^2\text{O}$ $\text{C}^2\text{H}^4\text{O}^2$; it is perhaps also a homologue of Buttlorow's dioxymethylene, produced by the action of oxide of lead or oxide of silver on iodide of methylene.

Compound of Ethylenic Oxide with Aldehyde. $\text{C}^2\text{H}^4\text{O}^2 = \text{C}^2\text{H}^4\text{O}.\text{C}^2\text{H}^4\text{O}$ (Wurtz, Rép. Chim. pure, 1862, p. 16).—Obtained by heating aldehyde to 100°C . for a week with excess of glycol, and submitting the liquid product to fractional distillation. The compound $\text{C}^2\text{H}^4\text{O}^2$ then passes over below 100° , afterwards water at glycol.

The compound of ethylenic oxide and aldehyde is a colourless liquid, having a agreeable, but rather pungent odour, somewhat like that of aldehyde. Specific gravity = 1.0002 at 0°C . Boils at 82.5° . Vapour-density, obs. = 3.192; calc. (2 vol.) = 3.047. If aldehyde is the oxide of ethylidene, this body may be regarded as an oxide of ethylene and ethylidene.

It is soluble in $1\frac{1}{2}$ volumes of water, but is separated from the solution by potash and by chloride of calcium. Nitric acid attacks it strongly, forming glycollic and oxalic acids, together with other products. It is not altered by caustic potash. It reduces an ammoniacal solution of nitrate of silver at 100°C ., but not completely. Heated at 140° with acetic acid, it yields diacetate of ethylene, together with a much more volatile product, having an odour like that of Bauer's acetaldehyde.

Oxide of ethylene and aldehyde do not unite directly when heated together at 100°C .; but the aldehyde is resinified as when heated with potash.

ETHYLENE, OXYBROMIDE OF, or Bromide of Ethylenic Oxide. $\left. \begin{smallmatrix} \text{C}^2\text{H}^4\text{O} \\ \text{C}^2\text{H}^4\text{O} \end{smallmatrix} \right\} \text{Br}^2$.—When equivalent quantities of cooled bromine and oxide of ethylene are mixed and enclosed in a sealed tube immersed in a freezing mixture, the two bodies unite into a red crystalline compound, which melts at 65°C . to a dark red liquid, boiling at 95° , and emitting an orange-coloured vapour, which condenses on cooling to the red liquid and crystals. The compound has a pungent odour, and gives off a perceptible vapour at ordinary temperatures. It is insoluble in water, but soluble in alcohol and ether. Reducing agents, such as metals and sulphydic acid, remove the bromine and convert the compound into dioxethylene.

ETHYLENE, OXYSULPHIDE OF. $\text{C}^2\text{H}^4\text{SO}$ (Crafts, Ann. Ch. Pharm. cxiv. 113; cxv. 123).—Produced: 1. By the action of water on sulphobromide of ethylene.—2. By the action of nitric acid on protosulphide of ethylene (p. 583). To obtain it pure, the sulphide of ethylene is added by small portions to fuming nitric acid; the excess of acid is then evaporated, and the crystalline residue is washed, first with water, then with alcohol, till it no longer exhibits any acid reaction. It is soluble in water, and crystallises from the solution in acute rhombohedrons of 73° . It does not unite with acids, is not attacked by ammonia, but potash decomposes it, separating sulphide of ethylene and a brown resinous body.

This body might be represented by the formula $\begin{matrix} \text{C}^2\text{H}^4\text{S} \\ \text{H} \end{matrix} \left\{ \text{O}, \text{ or } \begin{matrix} \text{C}^2\text{H}^4\text{O} \\ \text{H} \end{matrix} \right\} \text{S}$; but its reactions are not such as to lead to the supposition that it is thus constituted.

Dioxysulphide of Ethylene. $\text{C}^2\text{H}^4\text{SO}^2$. (Crafts, *loc. cit.*)—This compound, which has the composition of hydrate of sulphethylene, $\begin{matrix} \text{C}^2\text{H}^4\text{S} \\ \text{H}^2 \end{matrix} \left\{ \text{O}^2, \text{ or glycol in which 2 at. H are replaced by 1 at. S, or of glycolic acid in which O is replaced by S, is obtained by heating protosulphide of ethylene with fuming nitric acid in sealed tubes to } 150^\circ \text{C., care being taken not to exceed this temperature, and to stop the operation before the oxidation is quite complete. As soon as the liquid in the tubes becomes well saturated with pernitric oxide, the dioxysulphide separates in small crystals. The tubes are then to be opened, and the liquid poured into water, which separates a small quantity of the dioxysulphide; and this, together with the crystals, is washed with boiling water, which removes the oxysulphide, } \text{C}^2\text{H}^4\text{SO}, \text{ that may adhere to them. Further purification may be effected by dissolving the crystals in strong nitric acid, and again separating with water.}$

Dioxysulphide of ethylene separates from its solution in strong nitric acid in small crystals, which under the microscope exhibit the form of prisms with obtuse summits. It is very slightly soluble in ordinary *nitric acid*, quite insoluble in water. *Caustic potash* dissolves it without blackening, but converts it into a body which appears to possess slight acid properties and is not precipitated from its solution by acids.

Guthrie (Chem. Soc. Qu. J. xiv. 132) obtained a *hydrate of oxydisulphide of ethylene*, $\text{C}^2\text{H}^4\text{S}^2\text{O} \cdot \text{H}^2\text{O}$, by treating sulphochloride of ethylene (p. 584) with caustic potash. It is a yellowish liquid, insoluble in water, soluble in alcohol and ether.

ETHYLENE, OXYSULPHYDRATE OF. $\text{C}^2\text{H}^4\text{SO} = \begin{matrix} (\text{C}^2\text{H}^4)^{\text{H}} \\ \text{H}^2 \end{matrix} \left\{ \text{S} \right\} \text{O}^{\text{H}^2}$. *Mono-sulphhydrate of Ethylene. Sulphydic Glycol.* (Carius, Ann. Ch. Pharm. cxxiv. 257.)—This body, intermediate in composition between glycol and sulphhydrate of ethylene (p. 585), is obtained as a potassium-salt by treating glycolic chlorhydrin with excess of sulphhydrate of potassium in alcoholic solution:

The alcoholic liquid is boiled for a quarter of an hour in a vessel provided with an upright condensing tube; the liquid filtered from the chloride of potassium is super-saturated with dilute hydrochloric acid and evaporated in a shallow dish at 30° — 40°C. till an oily liquid begins to separate; and the residue is treated with cold water, which dissolves chloride of potassium, and separates oxysulphhydrate of ethylene, as an oily liquid, which is to be washed with a little cold water, dissolved in a small quantity of dilute alcohol; and the solution filtered, if necessary, and evaporated in a rarefied atmosphere, taking care to avoid over-heating.

Oxysulphhydrate of ethylene is a colourless liquid of the consistence of glycol, heavier than water, and having a faint odour like that of mercaptan. It dissolves sparingly in pure water, easily in water containing a small quantity of alcohol, very slightly in pure ether.

Nitric acid converts it almost wholly into isethionic acid, $\text{C}^2\text{H}^4\text{SO}^4$, with only traces of sulphuric and oxalic acids.

With the salts of the heavy metals, oxysulphhydrate of ethylene yields precipitates whose composition is expressed by the general formula $\begin{matrix} (\text{C}^2\text{H}^4)^{\text{H}} \\ \text{HM} \end{matrix} \left\{ \text{S} \right\} \text{O}^{\text{H}^2}$. These precipitates are flocculent, but quickly become granular, especially the lead-, mercury-, and silver-compounds. At 100°C. they soften to glutinous masses; the mercury-salt, however, melts to a viscid liquid. The *mercury-salt* is white, moderately soluble in strong alcohol, whence it separates by slow evaporation in long thread-like curved needles. The *zinc-salt* is white; the *copper-salt* dirty blue-green; the *lead-salt* light yellow; the *silver-salt* yellowish. They are all insoluble in water and in acids, moderately soluble in strong alcohol, and are decomposed by sulphhydrate of potassium.

Diethylenic Oxysulphhydrate. $\text{C}^4\text{H}^8\text{SO} = \begin{matrix} (\text{C}^4\text{H}^8)^{\text{H}^2} \\ \text{H}^2 \end{matrix} \left\{ \text{S} \right\} \text{O}^{\text{H}^2}$. (Carius, *loc. cit.*)

—This compound, analogous to diethylenic alcohol, is produced, with evolution of sulphydric acid, by boiling the alcoholic solution of the preceding compound:

To prepare it, the alcoholic solution obtained in the preparation of the monoethylenic compound, after filtration from chloride of potassium and neutralisation with hydro-

chloric acid, is evaporated, with gentle ebullition, till the excess of the latter is expelled; the oily liquid which then separates solidifies on cooling to a white crystalline mass, generally enclosing a certain quantity of the monoethylenic oxysulphhydrate; it may be purified by washing with cold, very dilute alcohol, and recrystallisation from alcohol.

Diethylenic oxysulphhydrate crystallises from alcohol in groups of very slender microscopic needles; melts at 60°C .; is insoluble in water, but easily soluble in alcohol. The solution is precipitated by metallic salts, the precipitates resembling those formed by the monoethylenic compound in colour and other properties.

Diethylenic oxysulphhydrate is easily oxidised by dilute nitric acid, taking up 3 at.

oxygen, and forming an acid, $\left\{ \begin{smallmatrix} (\text{C}^2\text{H}^4)^{\prime\prime} \\ (\text{SO})^{\prime\prime} \\ \text{H}^2 \end{smallmatrix} \right\} \text{O}^4$, which is dibasic, and easily forms salts in which both atoms of typic hydrogen are replaced by metals. The barium- and lead-salts are easily soluble, and crystallise indistinctly in microscopic laminae.

When oxide of ethylene is heated to 100°C . in a close vessel filled with sulphydric acid gas, the gas is rapidly absorbed, and a somewhat oily liquid is formed, which cannot be distilled under the ordinary atmospheric pressure: it boils without distilling to any perceptible extent, the thermometer gradually rising to 300° and the liquid turning brown. The first product of this reaction is in all probability oxysulphhydrate of ethylene, and the gradual rise of the boiling point seems to show that a number of polyethylenic sulphhydrates of continually increasing complexity are subsequently formed. (G. C. Foster, *Epistolary communication*.)

ETHYLENE, STEARATE OF. $\text{C}^{28}\text{H}^{54}\text{O}^4 = \left\{ \begin{smallmatrix} (\text{C}^2\text{H}^4)^{\prime\prime} \\ (\text{C}^{18}\text{H}^{32}\text{O})^{\prime\prime} \end{smallmatrix} \right\} \text{O}^2$.—Obtained by decomposing stearate of silver with bromide of ethylene and treating the product with ether, &c., as in the preparation of the benzoate (p. 568). It forms small, light, shining scales, resembling stearin, which melt at 76°C . (Wurtz.)

ETHYLENE, SUCCINATES OF. (Lourenço, *Rép. Chim.* pure, 1860, p. 179; *Ann. Ch. Pharm.* cxv. 358.)—Two of these ethers have been obtained, viz.—

1. *Succinethylenic acid.* $\text{C}^6\text{H}^{10}\text{O}^3 = \left\{ \begin{smallmatrix} (\text{C}^2\text{H}^4)^{\prime\prime} \\ (\text{C}^4\text{H}^4\text{O}^2)^{\prime\prime} \\ \text{H}^2 \end{smallmatrix} \right\} \text{O}^3$.—This compound, which may be regarded as derived from diethylenic alcohol by the substitution of 1 at. succinyl for 1 at. ethylene, is produced when glycol and succinic acid in equivalent proportions are heated together in a sealed tube to 190° — 200°C . for about ten hours. An oily acid liquid is then obtained, which on standing solidifies to a mass of small crystals of succinethylenic acid. This compound melts below 100°C ., is soluble in water and alcohol, sparingly in ether, and when neutralised with ammonia, forms with nitrate of silver a curdy precipitate insoluble in acids, and exhibiting a composition intermediate between $\text{C}^6\text{H}^8\text{Ag}^2\text{O}^3$ and $\text{C}^6\text{H}^8\text{AgO}^4$, but nearer to the former.

2. *Neutral Succinate of Ethylene.* $\text{C}^6\text{H}^8\text{O}^4 = \left\{ \begin{smallmatrix} (\text{C}^2\text{H}^4)^{\prime\prime} \\ (\text{C}^4\text{H}^4\text{O}^2)^{\prime\prime} \end{smallmatrix} \right\} \text{O}^2$.—Obtained by heating succinethylenic acid to nearly 300°C . Water is then given off, and the residue solidifies on cooling to a crystalline mass of the neutral succinate. It melts below 90°C ., is insoluble in water and in ether, but moderately soluble in boiling alcohol, whence it separates on cooling in very small crystals. It is decomposed by distillation.

ETHYLENE, SULPHATE (ACID) OF. $\text{C}^2\text{H}^4\text{SO}^3 = \left\{ \begin{smallmatrix} (\text{C}^2\text{H}^4)^{\prime\prime} \\ (\text{SO}^2)^{\prime\prime} \\ \text{H}^2 \end{smallmatrix} \right\} \text{O}^2$. *Sulphoglycolic acid* (Simpson, *Proc. Roy. Soc.* ix. 725).—Produced by heating a mixture of glycol and monohydrated sulphuric acid to 150°C .

It is not known in the free state. The barium-salt is obtained by diluting the above-mentioned mixture with water, saturating with carbonate of barium, filtering, and evaporating to a syrup over the water-bath, whereupon it separates as a white solid mass, which may be purified by pressure between paper, and evaporation in vacuo over oil of vitriol. It is somewhat deliquescent, and does not readily crystallise. Decomposes slightly at 100°C . Easily soluble, in water, nearly insoluble in absolute alcohol and in ether. From the aqueous solution sulphuric acid throws down sulphate of barium. Baryta-water occasions no precipitate in the cold, but on heating the liquid for some time, it becomes turbid, from separation of the same salt.

ETHYLENE, SULPHIDES OF. These compounds are obtained by treating

chloride or bromide of ethylene with alcoholic solutions of the corresponding sulphides of potassium.

Protosulphide of Ethylene. C^2H^4S . Löwig and Weidmann in 1840 (Pogg. Ann. xlix. 123) obtained this compound in an impure state as an amorphous precipitate, decomposing when distilled, by the action of chloride of ethylene on protosulphide of potassium; and Crafts (Ann. Ch. Pharm. cxxiv. 110) has recently obtained it pure and in well-defined crystals, by the action of protosulphide of potassium on bromide of ethylene, which is much more easily attacked than the chloride. The action is attended with considerable rise of temperature, and the resulting sulphide of ethylene distilled off at $200^{\circ}C$. condenses in white crystals, which must be washed with ether to free them from an oily substance.

Protosulphide of ethylene is somewhat volatile at common temperatures, and distils undecomposed at 199° or $200^{\circ}C$., solidifying at 112° in the crystalline form. It dissolves in alcohol, in ether, and more abundantly in sulphide of carbon, from which it separates in well-developed oblique rhombic prisms of $69^{\circ}44'$, generally most developed in the direction of the base.

Chlorine decomposes it, with evolution of hydrochloric acid. With bromine it unites directly, forming a sulpho-bromide, $C^2H^4SBr^2$. It is oxidised by fuming nitric acid, the product consisting of C^2H^4SO , if the temperature is kept below $100^{\circ}C$., but of $C^2H^4SO^2$ (pp 580, 581), either pure or mixed with the preceding, if it is allowed to rise to 150° (Carius, Ann. Ch. Pharm. cxxv. 123). It does not unite with ammonia.

Protosulphide of ethylene is isomeric with the compound obtained by passing sulphydric acid into aldehyde. The latter compound is perhaps sulphide of ethylidene, and is distinguished by its higher boiling point, not beginning to distil below $205^{\circ}C$., and the boiling point then quickly rising to 260° , at which temperature partial decomposition takes place. (Carius.)

Disulphide of Ethylene. $C^2H^4S^2$ is a soft yellowish powder, which melts below $100^{\circ}C$., and is decomposed by distillation. (Löwig and Weidmann, Pogg. Ann. xvi. 84; xlix. 128; Gm. viii. 355.)

Pentasulphide of Ethylene. $C^2H^4S^5$ (?).—Produced by the action of alcoholic tri-, or penta-sulphide of potassium on chloride of ethylene. It is a yellowish precipitate, melting below $100^{\circ}C$., and decomposing at a somewhat higher temperature. (Löwig and Weidmann.)

ETHYLENE, SULPHITES OF. Isethionic acid, $C^2H^4SO^4$, may be regarded as *ethylene-monosulphurous acid*, $C^2H^4O^2.SO^2$, that is, glycol with 1 at. sulphurous anhydride, or $(C^2H^4)^n \begin{smallmatrix} (SO)^n \\ H^2 \end{smallmatrix} O^2$, diethylenic alcohol in which 1 at. C^2H^4 is replaced by SO ; and disulphetholic acid, $C^2H^4S^2O^4$, may be regarded as *ethylene-disulphurous*

acid, $C^2H^4O^2.2SO^2$, i. e. glycol with 2 at. sulphurous anhydride, or as $(C^2H^4)^n \begin{smallmatrix} (SO)^2 \\ H^2 \end{smallmatrix} O^4$, i. e. triethylenic alcohol in which 2 at. C^2H^4 are replaced by 2 at. SO (Carius, Ann. Ch. Pharm. cxxiv. 262). See ISETHIONIC ACID, and SULPHUROUS ETHERS.

ETHYLENE, SULPHOBROMIDE OF. $C^2H^4SBr^2$. (Carius, Ann. Ch. Pharm. cxxiv. 113).—This compound, which may be regarded as a dibromide of ethylenic sulphide, $C^2H^4S.Br^2$, or as a sulphydrate of dibromethyl, $(C^2H^4Br^2)_2S$, is produced by the direct combination of bromine with protosulphide of ethylene. It is a yellow solid substance, nearly insoluble in rectified ether and in sulphide of carbon. When exposed to moist air, or treated with a small quantity of water, it is converted into white crystals containing less bromine than the original compound. These crystals dissolve in a larger quantity of water; and by treating the solution with oxide of silver to remove hydrobromic acid, then filtering and evaporating, small rhombic tables are obtained, consisting of oxysulphide of ethylene, C^2H^4SO .

ETHYLENE, SULPHOCHLORIDES OF. (Guthrie, Chem. Soc. Qu. J. xii. 109; xiii. 36 and 134; xiv. 128.—Jahresber. f. Chem. 1849, p. 479; 1860, p. 433).—The following compounds of this group have been obtained:

Dichlorosulphide of Ethylene	or	Sulphydrate of Dichlorethyl
$C^2H^4.Cl^2S$	—	$C^2H^4.Cl^2 \begin{smallmatrix} \{ \\ H \end{smallmatrix} S$
Disulphochloride of Ethylene	or	Disulphide of Chlorethyl
$C^2H^4.Cl^2S^2$	—	$C^2H^4.Cl^2 \begin{smallmatrix} \{ \\ C^2H^4.Cl^2 \end{smallmatrix} S^2$

Disulphochloride of Chloroethylene	or	Disulphide of Dichlorethyl
$C^2H^4Cl^2.Cl^2S^2$	=	$\begin{matrix} C^2H^4Cl^2 \\ C^2H^4Cl^2 \end{matrix} \} S^2$
Disulphochloride of Dichlorethylene	or	Disulphide of Trichlorethyl
$C^2H^4Cl^1.Cl^2S^2$	=	$\begin{matrix} C^2H^4Cl^1 \\ C^2H^4Cl^2 \end{matrix} \} S^2$

The first two of these compounds are produced by the direct combination of the chlorides of sulphur, Cl^2S and ClS , with ethylene; the third is also a product of the action of ClS on ethylene; and the fourth is produced by the action of chlorine on the third, or on disulphide of ethyl.

They are all decomposed by distillation, and therefore the weights of their molecules cannot be determined by experiment. The last compound may, however, be produced by the direct substitution of chlorine in disulphide of ethyl, which, as shown by its vapour-density (p. 547), is $(C^2H^4)^2.S^2$, not C^2H^4S ; the product formed from it by the action of chlorine is therefore $(C^2H^4Cl^2)^2.S^2$, not $C^2H^4Cl^2S$; and hence also it is probable that the two preceding compounds are correctly represented by the formulæ above given, rather than by the halves of those formulæ.

Dichlorosulphide of Ethylene, $C^2H^4Cl^2S$, is obtained by passing ethylene gas very slowly through dichloride of sulphur (Cl^2S) contained in a bulb-apparatus, and when the saturation is nearly finished, heating the liquid to $100^\circ C.$, and passing a rapid stream of ethylene through it, partly to complete the action, partly to get rid of chlorinated compounds of ethylene formed at the same time; or the liquid, before complete saturation, is dropped into water at $80^\circ C.$ to decompose the still remaining chloride of sulphur; repeatedly shaken up with fresh quantities of water at the same temperature; then left in contact for some time with dilute soda-ley; agitated with anhydrous ether to free it from suspended sulphur; the residue left on evaporating the ether is again dissolved in the smallest possible quantity of ether; and the residue left on evaporating this solution is dried in vacuo over oil of vitriol. (Ann. Ch. Pharm. cxiii. 2.)*

It is a straw-yellow liquid, having a pungent odour like that of oil of mustard, an astringent taste like that of horse-radish, and raising blisters on the skin; even the vapour destroys the epidermis on the more tender parts. Specific gravity 1.408 at $13^\circ C.$ It is insoluble in water, nearly insoluble in cold, slightly soluble in hot alcohol, soluble in about 60 times its volume of boiling ether. It is decomposed by heat, giving off chlorine, sulphydric acid, and volatile products containing sulphur and carbon.

Disulphochloride of Ethylene, $C^2H^4Cl^2S^2$, or *Disulphide of Monochlorethyl*, $\begin{matrix} C^2H^4Cl^1 \\ C^2H^4Cl^1 \end{matrix} \} S^2$.—This compound was first obtained by Niemann (Ann. Ch. Pharm. cxiii. 288), afterwards in a state of greater purity by Guthrie. It is produced when disulphide of chlorine, Cl^2S^2 , is brought in contact with ethylene gas, either in sunshine or at a temperature of $100^\circ C.$ It is purified by agitation with warm water, drying, digestion in ether, and evaporation of the ethereal solution in vacuo. It is a pale yellow liquid, having a not unpleasant odour, a sweet astringent taste, and acting strongly on the mucous membranes. Specific gravity = 1.346 at $19^\circ C.$ Caustic potash converts it into hydrate of ethylenic oxysulphide, $\begin{matrix} C^2H^4 \\ C^2H^4 \end{matrix} \} \begin{matrix} S \\ O \end{matrix} .H^2O$. Not volatile without decomposition.

Disulphochloride of Monochlorethylene, $C^2H^4Cl^1S^2 = C^2H^4Cl^1.Cl^2S^2$, or *Disulphide of Dichlorethyl*, $\begin{matrix} C^2H^4Cl^2 \\ C^2H^4Cl^2 \end{matrix} \} S^2$.—This body is also a product of the action of ethylene on sulphide of chlorine:

It is prepared by passing a rapid current of dry ethylene gas for some time through sulphide of chlorine contained in a capacious retort provided with a vertical condensing tube, afterwards heating the liquid in a smaller retort till the boiling point rises to $180^\circ C.$ (whereupon hydrochloric acid escapes and scarcely anything but unaltered sulphide of chlorine distils over); decanting the liquid residue from the sulphur which separates on cooling; digesting it for some hours with water at $80^\circ C.$, then with dilute soda-ley; and dissolving it in ether, &c., as in the preparation of the compound $C^2H^4Cl^2S$. It is a clear pale yellow liquid of specific gravity 1.599 at $11^\circ C.$, having a sweet, astringent taste, and when recently prepared, an agreeable odour, resembling oil of peppermint and oil of lemon; three or four drops of it produce head-ache. It is

* The dichloride of sulphur is prepared by saturating disulphide of chlorine (S^2Cl^2) with dry chlorine at $10^\circ C.$ and collecting the distillate from this product, which passes over between 70° and $90^\circ C.$

ETHYLENE: SULPHYDRATE—ETHYLENE-BASES. 585

soluble in alcohol and ether, insoluble in water. Not volatile without decomposition. When treated with chlorine, it is converted into the following compound:—

Sulphochloride of Dichlorethylene, $C^2H^2Cl^2S^2 = C^2H^2Cl^2.Cl^2S^2$, or *Disulphide of Trichlorethyl*, $\left. \begin{matrix} C^2H^2Cl^3 \\ C^2H^2Cl^2 \end{matrix} \right\} S^2$.—Produced by passing chlorine-gas through the preceding compound in the dark, first at mean temperature, afterwards at $100^\circ C.$, or by the action of chlorine on disulphide of ethyl. Purified by passing a stream of carbonic anhydride through it to remove hydrochloric acid and small quantities of sulphide of chlorine, then digesting in ether, &c. It is a clear, pale yellow liquid, of specific gravity 1.219—1.225 at $13.5^\circ C.$ It has a pungent, suffocating odour, is insoluble in water, soluble in alcohol and ether; decomposes when distilled in the air, but volatilises completely without decomposition in an atmosphere of carbonic anhydride. (Guthrie.)

ETHYLENE, SULPHYDRATE OF. $C^2H^2S^2 = \left(\begin{matrix} C^2H^4 \\ H^2 \end{matrix} \right) S^2$. *Ethylenic or Glycolic Mercaptan*.—Obtained in alcoholic solution by mixing chloride of ethylene with alcoholic sulphhydrate of potassium, and separating the liquid from the resulting chloride of potassium by distillation. The solution has a pungent odour like that of mercaptan, and forms with acetate of lead a yellow precipitate consisting of $C^2H^2Pb^2S^2$. (Löwig and Weidmann, Pogg. Ann. xlix. 132.)

When bromide of ethylene is poured into a concentrated alcoholic solution of sulphhydrate of potassium, the liquid becomes warm, and deposits a large quantity of bromide of potassium; and on adding water to the filtered alcoholic solution, ethylenic mercaptan separates as a colourless oil, which is partially decomposed by distillation. (Kekulé, *Lehrbuch*, i. 665.)

ETHYLENE-BASES. Cloez in 1853 (*l'Institut*, 1853, p. 213), by heating alcoholic ammonia in sealed-tubes with chloride or bromide of ethylene, obtained three volatile bases, which he supposed to be monamines, containing the radicles CH , C^2H^2 , and C^3H^3 , viz.:

The second of these bases, or a substance isomeric therewith, was likewise obtained by Natanson (*Ann. Ch. Pharm.* xcii. 48; xcvi. 20), who took the same view of its constitution.

But the more complete investigation to which these bases have been subjected by Hofmann (*Proc. Roy. Soc.* ix. 154; x. 224), has shown that they are diamines, formed from a double molecule of ammonia, N^2H^4 , by the substitution of 1, 2, and 3 molecules of ethylene for 2, 4, and 6 at. of hydrogen respectively. The mode of formation of their hydrobromates, or the dibromides of the corresponding diammoniums, is shown by the following equations:—

The formation of these three diatomic bromides is precisely analogous to that of the monobromides of the ethylammoniums (p. 564), the first being produced by the simple combination of the ammonia with the ethylenic bromide, whereas the formation of the second and third is accompanied by that of bromide of ammonium.

Chloride of ethylene appears to act on ammonia in a similar manner, but not so readily. The reaction presents, moreover, several phenomena which still require further investigation. The bromide acts upon alcoholic ammonia at ordinary temperatures, but on aqueous ammonia only when assisted by heat.

The dibromides of the ethylene-diammoniums distilled with potash yield the corresponding bases in the form of hydrates, which retain their water with such obstinacy that they can scarcely be dehydrated by caustic lime or baryta; the remark applies more especially to ethylene-diamine, which requires prolonged treatment with sodium

* It deserves to be noticed that the experimental data which have reference to the formation and properties of the third base are still very scanty.—A. W. H.

to yield up the last portions of water. By this means the anhydrous bases or diamines are obtained, viz.:

The second of these formulæ is exactly double that of the acetenamine of Cloez; the first and third differ from the double formulæ of formenamine and propylenamine (p. 585) by 2 at. hydrogen.

The inadmissibility of the monatomic formulæ is shown: *Firstly*, by the results of analysis, as may be seen by the following comparison of the calculated and experimental numbers of the hydrate of the first base ($\text{C}^2\text{H}^4\text{N}^2.\text{H}^2\text{O}$, or $\text{C}^2\text{H}^6\text{N}^2.\text{H}^2\text{O}$, according to Cloez; $\text{C}^2\text{H}^4\text{N}^2.\text{H}^2\text{O}$ according to Hofmann), and of the corresponding hydrochlorate:

	Calculation.		Analyses.	
	$\text{C}^2\text{H}^6\text{N}^2.\text{H}^2\text{O}$	$\text{C}^2\text{H}^4\text{N}^2.\text{H}^2\text{O}$	Cloez.	Hofmann.
Carbon . . .	31.58	30.76	31.12	30.67
Hydrogen . . .	10.52	12.82	12.78	12.97
Nitrogen . . .	36.84	35.90	35.80	36.32
Oxygen . . .	21.06	20.52		
	100.00	100.00		

	Calculation.		Analyses.	
	$\text{CH}^3\text{N}.\text{HCl}$	$\text{C}^2\text{H}^4\text{N}^2.\text{H}^2\text{Cl}^2$	Cloez.	Hofmann.
Carbon . . .	18.32	18.04	17.56	17.87
Hydrogen . . .	6.11	7.52	7.39	7.55
Nitrogen . . .	21.37	21.06	20.47	
Chlorine . . .	54.20	53.38	53.62	53.17
	100.00	100.00		

Secondly, by the boiling points. The three anhydrous bases boil at 117° , about 170° , and about 210° C. respectively, the difference of the first two being 53° , and of the second and third 40° . Now homologous substances related to one another in the manner indicated by the monatomic formulæ, CH^3N , $\text{C}^2\text{H}^4\text{N}$, $\text{C}^3\text{H}^5\text{N}$, that is to say, differing by CH^2 , do not generally differ in boiling point by more than 20° . Moreover, methylamine, which contains 2 at. H more than the supposed formenamine of Cloez, is a gas at ordinary temperatures, and does not liquefy till cooled considerably below the freezing point of water.

Thirdly, and chiefly, by the vapour-densities. The vapour-density of the first base in the anhydrous state, as determined by experiment, is 2.00 (Hofmann): now the formula of ethylene-diamine, $\text{C}^2\text{H}^4\text{N}^2$, calculated for a condensation to 2 volumes, gives

$$\frac{2 \cdot 12 + 8 \cdot 1 + 2 \cdot 14}{2} \times 0.0693 = 2.08, \text{ whereas that of formenamine, } \text{CH}^3\text{N}, \text{ calculated for a like condensation, give } 1.014.$$

In like manner the vapour-density of the second anhydrous base is by experiment 2.7; and by calculation from the diatomic formula, $\text{C}^2\text{H}^4\text{N}^2$, representing a condensation to 2 volumes, it is 2.9, the monatomic formula, $\text{C}^2\text{H}^4\text{N}$, requiring 1.45.

The vapour-densities of the hydrated bases appear at first sight, to furnish an argument in favour of the monatomic formulæ. That of the first hydrated base was found by Cloez to be 1.47. Now the formula, $\text{C}^2\text{H}^4\text{N}^2\text{O}$ or $\text{C}^2\text{H}^6\text{N}^2\text{O}$, calculated for 2 vol. gives

$$\frac{2 \cdot 6 + 4 \cdot 1 + 14 + 8}{2} \times 0.0693 = 1.32; \text{ whereas the diatomic formula, } \text{C}^2\text{H}^6\text{N}^2\text{O} \text{ or } \text{C}^2\text{H}^4\text{N}^2\text{O}, \text{ requires } 2.70.$$

This, however, is a case of *dis-association* (see AROMATIC WEIGHTS, i. 467), the hydrate splitting up, at the high temperature at which the vapour-density was taken, into water and the anhydrous base, each of which occupies 2 vols., and therefore the whole 4 vols. That these hydrated bases do actually split up in this manner at high temperatures, has been experimentally demonstrated with regard to another base of similar constitution, which will be afterwards mentioned (see p. 588).

The ethylene-diamines obtained as above are volatile, strongly alkaline bodies, which neutralise acids completely. Ethylene-diamine is a liquid; diethylene-diamine is a solid substance, crystallising in transparent, well-developed crystals, which, in winter are apt to attain considerable magnitude. Monoethylene-diamine heated with nitrous acid yields oxide of ethylene and free nitrogen:

Assuming that the diatomic ethylene-bases imitate the deportment of the monatomic ethyl-bases, each of the ethylene-diamines, when treated with dibromide of ethylene, might be expected to be converted into the dibromide of the next higher base; tri-bromethylene thus treated would yield the dibromide of tetrethylene-diammonium

$[\text{N}^2(\text{C}^2\text{H}^4)]^2\text{Br}^2$, which, subjected to the action of moist oxide of silver, should be converted into the fixed base $[\text{N}^2(\text{C}^2\text{H}^4)]^2\text{O}^2$. These reactions do, in some measure, actually occur, but they assume a much more complicated character, in consequence of the tendency belonging to dibromide of ethylene of exerting upon the diamines already formed, an action similar to that which it exerted, in the formation of these diamines, upon ammonia itself, thereby giving rise to the formation of triamines, tetramines, and, in general, bases of higher atomicity.

Ethylene-diamines containing both Monatomic and Diatomic Alcohol-radicles.—The typic hydrogen of the ethylene-diamines may be replaced by the monatomic alcohol-radicles, methyl, ethyl, &c. Each of these bases, when subjected to the action of iodide of ethyl, takes up a quantity of that compound, forming the iodide of a diammonium containing both ethyl and ethylene, and this iodide treated with oxide of silver, yields a diamine in which 2 at. of the original base are replaced by ethyl. Thus, by subjecting monoethylene-diamine to the alternate action of iodide of ethyl and oxide of silver, the following series of iodides is obtained:

The first two iodides treated with oxide of silver yield volatile bases; the third and fourth yield the fixed bases $\text{N}^2\text{H}(\text{C}^2\text{H}^5)^6(\text{C}^2\text{H}^4)]^2\text{O}^2$, and $[\text{N}^2(\text{C}^2\text{H}^5)^8(\text{C}^2\text{H}^4)]^2\text{O}^2$, bearing a close resemblance to hydrate of tetrethylammonium, the base with 6 at. of ethyl being incapable of taking up any more ethyl.

Diethylene-diamine subjected to the same alternate treatment with iodide of ethyl and oxide of silver, yields only three bases, one volatile and two fixed. The corresponding iodides are:

Iodide of Methyl acts on the ethylenamines in a similar manner, except that, as in its action on ammonia and the monamines, the final products of substitution are obtained at once, with little or none of the intermediate compounds; thus, with ethylene-diamine, it gives:

Di-iodide of Hexmethyl-ethylene-diammonium, $[\text{N}^2(\text{CH}^3)^8(\text{C}^2\text{H}^4)]\text{I}^2$,
and with diethylene-diamine:

The dibromides of diethyl-ethylene-diammonium and diethyl-diethylene-diammonium are obtained, together with other products, by the action of dibromide of ethylene on ethylamine:

The former of these bromides yields, by distillation with anhydrous baryta, a liquid, which has a strong ammoniacal odour, and solidifies to a crystalline mass, somewhat like fused stearic acid. It may be regarded as

Oxide of Diethyl-ethylene-diammonium . . . $[N^2H^2(C^2H^5)^2(C^2H^4)]^2O$;

or, Hydrate of Diethyl-ethylene-diamine . . . $[N^2H^2(C^2H^5)^2(C^2H^4)] \cdot H^2O$.

The anhydrous base $N^2H^2(C^2H^5)^2(C^2H^4) = C^2H^{16}N^2$, is obtained by repeatedly distilling the hydrate with excess of anhydrous baryta. Its vapour-density, determined by experiment, is 57.61 (referred to hydrogen as unity), which agrees very nearly with the number calculated from the formula $C^2H^{16}N^2$ for a condensation to 2 vol., viz. $\frac{8.12 + 16.1 + 2.14}{2} = 58$. But the hydrated base, $C^2H^{16}N^2 \cdot H^2O$, is found by experi-

ment to have a vapour-density of 33.2, whereas, for a condensation to 2 volumes, it should be $\frac{116 + 18}{2} = 67$. This hydrate exhibits, therefore, the same anomaly as the

hydrate of ethylene-diamine, that is to say, its vapour, when heated 16° or 20° above its boiling point, splits up into the anhydrous base and water, each of which occupies 2 volumes, and the whole, therefore, 4 volumes. That such is the case may be experimentally demonstrated by confining a quantity of the vapour in a tube standing over mercury, heating it, by means of a glass paraffin-bath, to about 170° C., observing its volume, and then passing up a few pellets of anhydrous baryta: the mercury immediately begins to rise, and the volume of the vapour is soon reduced one-half. (Proc. Roy. Soc. x. 597.)

The second of the above-mentioned bromides, the dibromide of diethyl-diethylene-diammonium, yields, by distillation with baryta, a base, which is liquid at ordinary temperatures, and boils at 185° C. This base is diethyl-diethylene-diamine; it is likewise produced by the action of dibromide of ethylene on diethyl-ethylene-diamine, according to the equation:

Ethylene-triamines, tetramines, &c. The action of dibromide (chloride or iodide) of ethylene on ammonia, gives rise, not only to ethylene-diamines, but likewise to ethylene-bases of higher order, that is to say, bases in which a greater number of ammonia-molecules are joined together by the substitution of ethylene for an equivalent quantity of hydrogen. It is obvious that two molecules of ammonia can be joined together into a stable compound by one molecule of a diatomic radicle, three ammonia-molecules by two molecules of diatomic radicles, four by three, &c., thus:

And generally, to unite n ammonia-molecules into a stable compound, the number of diatomic radicles which is necessary and sufficient, is $n-1$; but the number of such radicles which enter into the combination, may, of course, be increased by further substitution, so long as there is any hydrogen left to be replaced.

The number of stable compounds which can be formed by the action of n molecules of dibromide of ethylene, or other diatomic alcohol-radicle on $2n$ molecules of ammonia, is represented by the following equations:

the last term being $[N^{\frac{n}{2}}R^{\frac{n}{2}}]Br^{\frac{n}{2}} + \frac{3n}{2}NH^{\cdot}Br$, if n is even,

or $[N^{\frac{n+1}{2}}R^{\frac{n+1}{2}}]Br^{\frac{n+1}{2}} + \frac{3n-1}{2}NH^{\cdot}Br$, if n is odd.

Thus for $n=4$, the series of equations representing the possible number of stable polyatomic bases produced is,

and for $n=5$,

The first equation of each series :

represents the formation of the first or simplest term of each polyatomic group, or that in which the replacement of the hydrogen by the diatomic alcohol-radicle is the least that is consistent with stability.

The action of an alcoholic dibromide on primary, secondary, and tertiary monamines, *e.g.* on ethylamine, diethylamine, and triethylamine, is subject to precisely similar laws; but it evidently becomes less complicated, and the number of possible products less numerous, as the number of atoms of replaceable hydrogen in the monamine is diminished.

To return to the general equation just cited. If $n=1$, it assumes the simple form :

which, if $R = C^2H^4$, represents the formation of dibromide of ethylene-diammonium, the diamine of which, undergoing further substitution under the influence of dibromide of ethylene, yields the higher terms of the series of diatomic ethylene-bases, *viz.* $N^2(C^2H^4)^2H^2$ and $N^2(C^2H^4)^3$.

When $n=2$, the general equation becomes

representing the formation of the first term of a series of tri-ammonium compounds;

the following terms of which are $N^2R^3H^8$, $N^2R^3H^7$, $N^2R^3H^6$ and N^2R^3 .

In the ethylene-series, this last equation represents the formation of tribromide of diethylene-triammonium, $[N^2(C^2H^4)^2H^8]Br^3$; which, under the influence of

an alkali, yields diethylene-triamine, $N^2(C^2H^4)^2H^2$, capable, when subjected to the alternate action of dibromide of ethylene and oxide of silver, or an alkali, of yielding tri-

ethylene-triamine, $N^2(C^2H^4)^3H^2$, and other triamines of higher degrees of substitution:

The portion of the mixture of volatile bases, obtained by the action of ammonia on dibromide of ethylene, which, after several rectifications, boils between 200° and 220° C., consists almost wholly of di- and tri-ethylene-triamine. These bases cannot be separated by distillation, in consequence of the proximity of their boiling points; but their separation is effected by transforming them into platinum-salts, which crystallise with remarkable facility.

Both diethylene-triamine and triethylene-triamine are powerfully alkaline liquids; soluble in every proportion in water and alcohol, almost insoluble in ether. They boil respectively at about 208° and 216° C. They neutralise acids completely, giving rise to the formation of well-defined and in most cases beautifully crystallised salts, which are generally very soluble in water, sparingly soluble in alcohol, insoluble in ether. The aqueous solutions of the salts are not precipitated by solutions of caustic alkalis, but solid hydrate of potassium separates their bases in the form of nearly colourless oily liquids, which rapidly attract carbonic acid from the air.

Both these bases, and indeed the triamines generally, are capable of forming three classes of salts, containing respectively 3, 2 and 1 molecule of acid; thus, diethylene-

triampo appears to form three hydrochlorates, containing $N^2(C^2H^4)^2H^2.3HCl$, $N^2(C^2H^4)^2H^2.2HCl$, and $N^2(C^2H^4)^2H^2.HCl$, the latter being still doubtful, but the two former being established by numerous experiments. The platinum-salts appear to exhibit a still greater diversity of composition, being capable, not only of forming salts corresponding to the three hydrochlorates just mentioned; viz.

but likewise compounds in which the number of tetrachloride-of-platinum molecules diminishes, whilst the amount of hydrochloric acid remains constant; such as

not to speak of water of crystallisation, which many of these salts retain with great pertinacity.

This great diversity of salts introduces considerable difficulty into the process of separating the two bases by converting them into saline compounds; most of the salts, however, and especially the platinum-salts, crystallise very readily, a circumstance which greatly facilitates the determination of the conditions under which the more important salts are produced.

The triplatinic salt of diethylene-triamine, $2(C^2H^4)^2N^2.3HCl.3PtCl^4$, crystallises in magnificent golden-yellow needles. It cannot be recrystallised without decomposition; a peculiarity which likewise belongs to the platinum-salts of several other triatomic ammonias. New platinum compounds are thus produced, in some of which the chloride is united with a smaller number of molecules of platinic chloride; whilst others, almost insoluble in water, and containing a very large amount of platinum, appear to be produced by platinic substitution.

Triethylene-triamine, $C^3H^3N^3 = N^2(C^2H^4)^2H^2$, forms salts of greater solubility than those of diethylene-triamine, and exhibits a greater tendency to form imperfectly saturated salts; indeed, the normal or triacid salts of this base are obtained only in presence of a large excess of acid, feebly acid solutions always depositing salts containing 2 at. acid to 1 at. of the base; and these diacid salts, when mixed with the free base, yield salts approaching in composition to the mono-acid salts, e.g. $C^3H^3N^3.HBr$ though these last have not been obtained quite pure.

The normal platinum-salt, $2(C^3H^3N^3.3HCl).3PtCl^4$, crystallises in long gold-coloured needles, much more soluble in water than the platinum-salts of the ethylene-diamines as well as of diethylene-triamine, with which the triethylene-triamine is likely to be contaminated. It cannot be recrystallised without suffering decomposition like the diethylenic platinum-salt above mentioned. Left in contact with an excess of the triacid hydrochlorate of triethylene-triamine, it changes, after a day or two, into well-formed prisms of considerable size, containing about 8 per cent. of platinum less than the original salt, and apparently consisting of a platinum-compound the constitution of which is not yet perfectly established.

The normal gold-salt $C^3H^3N^3.3HCl.3AuCl^3$ crystallises in yellow plates soluble in water, alcohol, and ether: they may be recrystallised from water, but on protracted ebullition they are decomposed, with separation of metallic gold.

Ethylated Triamines.—The ethylene-triamines just described are powerfully acted on by the iodides of methyl and ethyl, doubtless producing ethylated or methylated ethylene-triamines. The products thus formed have not however been examined in detail, but some of the ethylated derivatives of the ethylene-triamines have been obtained by the action of dibromide of ethylene on ethylamine. This reaction, as already observed (p. 587), yields a mixture of bases, which may be partly separated by fractional distillation. The portion which, after several rectifications, passes over below $200^\circ C$. consists mainly of two ethylated diamines, $N^2(C^2H^4)(C^2H^5)H^2$, and $N^2(C^2H^4)(C^2H^5)^2$.

The portion of the mixture boiling above 200° contains the ethylated triamines. Dissolved in hydrochloric acid and mixed with tetrachloride of platinum, it yields a splendidly crystallised platinum-salt, which, by numerous crystallisations, may be separated into two salts, one sparingly soluble, the other more soluble in water. They consist of the platinum-salts of the two bases:

Diethylene-triethyl-triamine

Triethylene-triethyl-triamine

Both these bases are oily liquids, powerfully caustic, extremely soluble in water, boiling between 220° and 250° C. Both form neutral crystalline salts very soluble in water, likewise, though less so, in alcohol. The gold and platinum salts of diethylene-triethyl-triamine, which have the normal composition, crystallise well.

The salts of the second bases are even more soluble than those of the first: the platinum-salt crystallises only when the solution is evaporated nearly to dryness.

Diethylene-diethyl-triamine, $C^2H^2N^3 = N^3 \begin{matrix} (C^2H^5)^3 \\ (C^2H^5)^3 \\ H^2 \end{matrix}$; is another base sometimes

found among the bases of higher boiling-point produced by the action of dibromide of ethylene on ethylamine. Its formation is due to the presence of small quantities of ammonia in the ethylamine employed:

This base forms remarkably beautiful crystalline salts, among which the *hydrochlorate*, $C^2H^2N^3 \cdot 3HCl$, is distinguished by its insolubility in alcohol, a property which renders it easy to separate this base from the other bases accompanying it. The *hydrochlorate* crystallises in leaves having a nacreous lustre: it is very soluble in water insoluble in ether. The corresponding *hydriodate*, $C^2H^2N^3 \cdot 3HI$, is much more soluble and is formed only when a great excess of acid is present. In fact, the ethylated ethylene-triamines exhibit the same tendency to form diatomic salts as the ethylene-triamines themselves. A solution of diethylene-diethyl-triamine just neutralised with hydriodic acid, deposits the salt $C^2H^2N^3 \cdot 2HI$. The *nitrate*, $C^2H^2N^3 \cdot 3HNO^3$, dissolves readily in hot, moderately in cold water, and is deposited from a hot saturated solution on cooling in large rectangular tables having the aspect of nitrate of silver.

TETRAMINES.—The general equation a (p. 589), when $n = 3$, becomes:

showing that the simplest tetramine of the ethylene series is:

The separation of this base among the products of the action of dibromide of ethylene on ammonia is attended with very great difficulty, on account of its high boiling point; but it may be obtained pure by submitting ethylene-diamine to the action of dibromide of ethylene:

The hydrobromic acid which appears in this equation arises from another phase of the reaction not yet completely studied.

Triethylene-tetramine, separated from the bromide by oxide of silver, is a powerfully alkaline liquid, which dries up to a syrup, showing no tendency to crystallise. The platinum-salt, $C^2H^{10}N^4 \cdot 4HCl \cdot 2PtCl^4$, is pale yellow, amorphous, almost insoluble.

Ethylated Tetrammoniums.—These compounds, obtained by the action of dibromide of ethylene on ethylamine and diethylamine, are more easily prepared in a state of purity than the ethylene-tetrammoniums themselves.

Dibromide of ethylene heated with *diethylamine* to 100° C. in sealed tubes for some hours, forms three bromides, viz. bromide of diethylammonium, dibromide of ethylene-tetreehyl-diammonium, and tetrabromide of triethylene-octethyl-tetrammonium:

some difficulty be converted, by the action of iodide of ethyl, first into the pentethylene-pentethylated, and lastly into the pentethylene-hexethylated tetrammonium.

Hexethylene-tetrethyl-tetrammonium, which, as already mentioned, is occasionally produced by the action of dibromide of ethylene on ethylamine, may be obtained in a state of purity by the action of dibromide of ethylene on ethylene-diethyl-diamine, or on diethylene-diethyl-diamine; thus:

and:

Monatomic Bases produced by the action of Dibromide of Ethylene on Ammonia and the Monamines.

The action of ammonia on the bromides of diatomic alcohol-radicles likewise gives rise to the formation of monatomic ammonium-bases, containing monatomic radicles in which 1 atom of hydrogen is replaced by bromine. Thus *ammonia and dibromide of ethylene* acting upon one another in equal numbers of molecules may produce the following compounds containing the monatomic radicle bromethylammonium, C^2H^4Br :

These monatomic bromides differ from the diatomic bromides in this respect, that only half the bromine which they contain is removable by oxide of silver, whereas in the diatomic bromides, both atoms of bromine may be thus removed. (See AMMONIUM-BASES, i. 196.)

Further, if the reaction takes place in presence of water, the bromine within the radicle may be removed in the form of hydrobromic acid, and its place supplied by the molecular residue of the water, HO, producing monatomic bromides containing the radicle oxethyl, $C^2H^4(HO)$ or C^2H^4O ; viz. $[N(C^2H^4O) H^3] Br$, &c. (the oxethylenamines).

Lastly, a third class of monatomic bromides may be produced in consequence of the tendency of dibromide of ethylene to split up into hydrobromic acid and bromide of vinyl, C^2H^3Br (p. 569). In this manner the bromides of vinyl-ammonium, $[N(C^2H^3) H^3] Br$, and of di-, tri-, and tetra-vinyl-ammonium may be produced.

These reactions are complicated, a very large number of bases being produced at once, so that the separation of them becomes a matter of considerable difficulty. Simpler results are obtained by acting on dibromide of ethylene with ethylamine, diethylamine and triethylamine, the reaction becoming less complicated as the number of atoms of replaceable hydrogen in the amine becomes less; it is especially in the action of dibromide of ethylene on the tertiary amines, that the monatomic bromides are produced: the results suggested by theory for this case are simple, but experiment has failed to produce some of the most interesting terms which are possible. But all the possible compounds are obtained when a tertiary monophosphine is substituted for the tertiary monamine; with *triethylphosphine*, for instance, the following salts are generated.

(See PHOSPHORUS-BASES.)

Oxethylenamines or Ethylene-hydoramines. (A. Wurtz, Compt. rend. dlix. 898; liii. 838; Rép. Chim. pure, 1860, p. 67 and 1861, p. 41.)—Oxide of ethylene unites directly with ammonia in various proportions, forming a series of bases which Wurtz, who discovered them, represents by the general formula $(C^2H^4O)^n.NH^4$,

When oxide of ethylene is placed in contact with a concentrated aqueous solution of ammonia, a powerful action takes place in a few minutes; on evaporating the product over the water-bath, and saturating the syrupy residue with hydrochloric acid, a mixture of the hydrochlorates of three oxethylenic bases is obtained, viz. of mono-, di-, and tri-oxethylenamine, which may be separated by means of absolute alcohol.

VOL. II.

Q Q

1. The hydrochlorate of trioxethylenamine, $(C^2H^4O)^3 \left\{ \begin{smallmatrix} H \\ NH^2 \end{smallmatrix} \right\} HCl$, is insoluble in absolute alcohol, and is precipitated on adding that liquid to the mixture.

2. On adding tetrachloride of platinum to the alcoholic solution, the dioxethylenamine is precipitated in the form of a platinum salt containing $2 \left[(C^2H^4O)^2 \left\{ \begin{smallmatrix} H \\ NH^2 \end{smallmatrix} \right\} HCl \right]. PtCl^4$. If the alcoholic solution contains a little water, as when a strong aqueous solution of chloride of platinum is used, this salt is not entirely precipitated, but the precipitation may then be completed by the addition of ether.

3. If the ether be added in successive small portions, the character of the precipitate gradually changes, and in place of the preceding platinum-salt, which crystallises in splendid rhomboidal prisms, light, golden-yellow, nacreous scales are at length obtained, consisting of the platinum-salt of monoxethylenamine, $2 \left[(C^2H^4O) \left\{ \begin{smallmatrix} H \\ NH^2 \end{smallmatrix} \right\} HCl \right]. PtCl^4$.

The hydrochlorate of monoxethylenamine, $(C^2H^4O) \left\{ \begin{smallmatrix} H \\ NH^2 \end{smallmatrix} \right\} HCl$, separates spontaneously after a long time from the alcoholic mixture of the hydrochlorates of this and the dioxethylenic base, obtained as above, in small crystals, which may be freed from the thick mother-liquor by rapid washing with absolute alcohol.

The hydrochlorates of these two bases are likewise formed by heating a mixture of hydroxychloride of ethylene (glycolic chlorhydrin) and aqueous ammonia to $100^\circ C$, in a strong flask for several hours:

The product of the reaction is evaporated to dryness, and the residue digested with absolute alcohol, which dissolves the two oxethylenic hydrochlorates, and leaves the sal-ammoniac. Hydrochlorate of trioxethylenamine does not appear to be formed in this reaction.

The bases separated from the hydrochlorates by the action of oxide of silver, and evaporated in vacuo, are thick syrupy liquids, having a strong alkaline reaction, and remaining in the form of thick syrups when their solutions are evaporated in vacuo.

Tetroxethylenamine or *Tetrethylene-hydoramine*, $(C^2H^4O)^4 \cdot NH^3$.—When trioxethylenamine is heated in a sealed tube with hydroxychloride of ethylene, a mass of crystals is formed, consisting of the hydrochlorates of tri- and tetra-oxethylenamine, together with a syrupy liquid containing the free tetrethyleneated base. The hydrochlorate of this base is formed by the direct union of the elements of the acting substances:

The hydrochlorate of trioxethylenamine is formed, together with oxide of ethylene, in the manner shown by the equation:

and the oxide of ethylene thus set free unites with another portion of trioxethylenamine, producing the free tetrethyleneated base.

The *chloroplatinate* of this base, $2[(C^2H^4O)^4 \cdot NH^3] \cdot 2HCl \cdot PtCl^4$; crystallises in fine golden-yellow scales, easily soluble in water, insoluble in alcohol and ether.

The mono-, di-, and tri-ethylenated bases, in the free state, may be referred to the type ammonia, NH^3 , by supposing them to contain the monatomic radicle *oxethylenic*, $C^2H^4(HO)$ or C^2H^4O ; their formulæ then become

Their salts may, of course, be represented as ammonium-salts,—a mode of representation which may also be extended to those of the fourth base; the hydrochlorates, for example, may be formulated thus:

But the fourth base $(C^2H^4O)^4 \cdot NH^3$, in the anhydrous state cannot be represented as an ammonia. Moreover it is found that trioxethylenamine, $(C^2H^4O)^3 \cdot NH^3$, can take up, not only 1 at. C^2H^4O to form the tetrethyleneated base, but likewise 2, 3, 4, &c., molecules of oxide of ethylene, forming bases of greater and greater complexity, and continually diminishing in basic power, but, nevertheless all possessing the same general

characters, being capable of turning reddened litmus blue, saturating hydrochloric acid, and forming hydrochlorates which unite with dichloride of platinum. The platinum-salts thus obtained are very difficult to separate one from the other, being non-crystalline gummy masses. Two of them have, however, been obtained in a sufficiently definite state for analysis, and have yielded numbers agreeing approximately with the formulæ $2[(C^2H^4O)^2NH^2] \cdot 2HCl.PtCl^4$ and $2[(C^2H^4O)^2NH^2] \cdot 2HCl.PtCl^4$. Now, it is impossible to refer these more complex bases, containing more than four molecules of oxide of ethylene, to the ammonium type; hence it is better to regard the whole series of bases as formed on the mixed type, $\frac{nH^2O}{H^2N}$, or $\frac{nH^2}{H^2}O^n$, their general

formula being $\frac{(C^2H^4O)^n}{H^2N}$ or $\frac{(C^2H^4)^n}{H^2}O^n$; hence the name hydoramines, proposed by Kekulé. (See foot-note, vol. i. p. 197.)

This mode of representation may also be extended to those bases produced by the action of dibromide of ethylene on triethylamine and triethylphosphine, which on p. 593 are spoken of as monatomic, and containing the radicles bromethyl and oxethyl, &c.

Bromide of Triethyl-bromethylammonium $\frac{(C^2H^4Br)^n}{(C^2H^4)^2}N.Br = \frac{(C^2H^4)^n}{(C^2H^4)^2}Br^2$

See the article AMMONIUM-BASES (i. 196); also Kekulé's *Lehrbuch* (p. 558).

For ethylene-bases containing Arsenic, see vol. i. p. 400; for those containing Phosphorus, see PHOSPHORUS-BASES.

A. W. H.

ETHYLENE-CARBAMIDES. *Ethylene-urcas.* (Volhard, Proc. Roy. Soc. xi. 268.)—Compounds produced by the action of cyanic acid and the cyanic ethers on the ethylene-diamines.

Ethylene-dicarbamide. $C^2H^4N^4O^2 = N^4(\dot{C}O)^2(C^2H^4)^2H^4$.—This compound, which contains the elements of 1 at. ethylene-diamine ($C^2H^4N^2$), and 2 at. cyanic acid ($CHNO$), is produced by the action of cyanate of silver on dichloride of ethylene-diammonium. It crystallises in prisms soluble in water and in alcohol; melts at $192^\circ C$; dissolves easily in hydrochloric or nitric acid, and separates out unaltered on evaporation. Boiled with very strong potash-solution, it splits up into ethylene-diamine, carbonic acid, and ammonia:

Ethylene-dicarbamide is a *mono-acid tetramine*, forming with dichloride of platinum the salt $2(C^2H^4N^4O^2.HCl).PtCl^4$, and with trichloride of gold the salt $C^2H^4N^4O^2.HCl.AuCl^3$. The platinum-salt crystallises in orange-red prisms; the gold-salt in golden-yellow scales.

Ethylene-diethyl-dicarbamide. $C^4H^{12}N^4O^2 = N^4(\dot{C}O)^2(C^2H^4)^2(C^2H^5)^2H^4$.—Of this compound there are two modifications: α obtained by the action of cyanate of silver on chloride of ethylene-diethyl-diammonium; β , by the direct union of 1 at. ethylene-diamine ($C^2H^4N^2$) with 2 at. cyanate of ethyl (C^2H^5NO). Both these bodies crystallise in needles; but α dissolves very easily in water and in alcohol; melts with partial decomposition at $124^\circ C$, forms a platinum-salt containing $C^4H^{12}N^4O^2.HCl.PtCl^4$, and an unstable gold-salt; whereas β , though easily soluble in boiling water, dissolves with difficulty in cold water, and is even less soluble in alcohol: it melts without decomposition at $201^\circ C$, solidifying again at 186° , and does not unite with the chlorides of gold and platinum. Moreover, α heated with potash is resolved into ethylene-diethyl-diamine and the products of decomposition of cyanic acid, viz. carbonic acid and ammonia:

whereas β splits up into ethylene-diamine and the derivatives of cyanic ether, viz. carbonic acid and ethylamine:

The two modifications of diethylcarbamide produced, the one by treating cyanate of ethyl with ethylamine or with water (i. 754), the other by the action of cyanic acid on diethylamine, exhibit similar differences, the former splitting up into carbonic acid and ethylamine; the latter into carbonic acid, ammonia, and diethylamine.

ETHYLENE-DICHLORIDE OF PLATINUM. $C^2H^4PtCl^2 = (C^2H^4PtCl).Cl$. *Inflammable or Detonating chloride of platinum, Ethyl-chloroplatinic acid.* (Zeiss, [1830] Pogg. Ann. xxi. 497 and 542; xl. 234.—Grüss and Martius, Proc. Roy. Soc. xi. 509.—Gm. viii. 388.—Gerh. ii. 315.)—Obtained by distilling alcohol with tetrachloride of platinum. Aldehyde is then given off, together with hydrochloric acid and chloride of ethyl, and there remains a dark brown liquid, which deposits a large

quantity of a black explosive powder containing ethylene-dichloride of platinum together with hydrochloric acid and other substances :

Preparation.—1. One pt. of tetrachloride of platinum, as free as possible from dichloride, is dissolved in 10 pts. alcohol of specific gravity 0.823; the solution distilled till the residue is brought down to one-fifth (a very gentle heat only being applied towards the end of the operation, because the mixture is very apt to jump and splash over); the liquid residue filtered to separate it from the black inflammable platinum deposit; the filtrate (the *crude liquid*) cautiously evaporated to dryness; the brown residue, mixed with black and yellow particles, exhausted with cold water; and the yellowish brown solution separated from the undissolved brown gummy substance, and evaporated,—most advantageously in vacuo, because in that case there is not so much insoluble brown matter reproduced. The yellow or yellowish brown residue is then redissolved in water, a few brown particles again remaining undissolved, and the filtrate evaporated in vacuo over solid potash: ethylene-dichloride of platinum then remains in a state of tolerable purity. (Zeise.)

2. A concentrated aqueous solution of tetrachloride of platinum is added to a concentrated aqueous solution of the compound of ethylene-dichloride of platinum and sal-ammoniac, as long as a precipitate of chloroplatinate of ammonium continues to fall; the liquid quickly filtered, and evaporated quickly in vacuo, first over oil of vitriol, and then over oil of vitriol and hydrate of potash; the gummy and friable residue washed with a small quantity of water to remove any excess of tetrachloride of platinum, or of the compound of ethylene-dichloride of platinum with sal-ammoniac, that may be present; then dissolved in a larger quantity of lukewarm water, filtered from the chloroplatinate of ammonium, and evaporated in vacuo. This method yields the purest product. (Zeise.)

Properties.—Ethylene-dichloride of platinum is a very pale lemon-coloured substance, which becomes brown and black by exposure to light, but does not absorb moisture from the air. It dissolves slowly in water and in alcohol. The solutions have an acid reaction, and are very liable to alteration.

Decompositions.—1. The compound subjected to dry distillation froths up moderately, gives off a large quantity of hydrochloric acid gas and carburetted hydrogen, and leaves a black residue, which, when heated in the air, burns without flame like charcoal, and leaves metallic platinum.—2. If set on fire in the air before it has been ignited, it burns with flame and leaves metallic platinum having a silvery lustre.—3. The aqueous solution heated to the boiling point quickly becomes turbid, and deposits nearly all the platinum in the metallic state, at the same time giving off hydrochloric acid and a large quantity of combustible gas, but neither alcohol nor ether. The solution likewise becomes decolorised and deposits a brown mucus, even at ordinary or slightly elevated temperatures, especially if exposed to light. The aqueous solution of the pure compound obtained by the second mode of preparation may be evaporated in vacuo without decomposition; but the solution of the compound prepared by the first method suffers some degree of decomposition when thus evaporated. If, however, a large quantity of hydrochloric acid be added to the aqueous solution, it is not decomposed even by boiling.—4. If *nitrate of silver* be added to the aqueous solution just so long as a precipitate of chloride of silver continues to form — and the liquid be then filtered, the filtrate becomes turbid in a few minutes and soon yields a large quantity of black pulverulent platinum-deposit, which increases considerably on the application of heat; after which the filtrate will again throw down chloride of silver from a solution of the nitrate. Part of the chlorine is therefore more intimately combined than the rest.—5. The aqueous solution mixed with excess of *potash*, yields, after a few days, a brown-grey gummy deposit, retaining, however, a considerable quantity of platinum, which is not precipitated till the liquid is heated. If the aqueous solution be immediately heated with excess of potash, it gives off a gas and a distillate which smells like tallow, and deposits a black powder mixed with metallic scales, which, when dried and then strongly heated, detonates with violence; it also sets fire to alcohol.—6. The aqueous solution acts with *magnesia* in the same manner as with cold potash, forming a powder, which when freed from magnesia by dilute nitric acid, and well washed and dried in vacuo, likewise explodes violently when heated.—7. *Copper* and *mercury* throw down from the aqueous solution a black precipitate which detonates when heated.—8. *Sulphydric acid* gas passed through the aqueous solution eliminates a gas, decolorises the liquid completely, and forms a yellow precipitate, which soon turns black. The filtered liquid contains nothing but hydrochloric acid. (Zeise.)

Combinations.—Ethylene-dichloride of platinum unites with ammonia, with the chlorides of ammonium, potassium, and sodium, and with the chlorides of several organic bases.

PtCl₂.Cl.—Obtained by precipitating a concentrated aqueous solution of ethylene-dichloride of platinum, or its compound with sal-ammoniac or chloride of potassium, with a slight excess of caustic ammonia or carbonate of ammonia. If the compound with chloride of potassium be used, that salt is found in the filtrate. With the sal-ammoniac compound, potash may be used for the preparation instead of ammonia. Caustic ammonia in large excess exerts a decomposing action on the compound: hence it is better to use carbonate of ammonia. (Zeise.)

The bulky, and at first light-yellow precipitate blackens by exposure to air and light; its colour is also gradually changed by the action of water or alcohol. When subjected to dry distillation, it gives off a combustible gas, hydrochloric acid gas, and sal-ammoniac, and leaves a mixture of platinum and charcoal. As it burns in the air, the mass finally takes fire from end to end. The compound dissolves in water somewhat more readily than gypsum; the solution treated with potash gives off ammonia, and when heated with an acid deposits metallic platinum. Alcohol appears to dissolve the compound more readily than water. Dilute hydrochloric acid colours it a darker yellow, and then dissolves it, producing the following compound. (Zeise.)

Ethylene-dichloride of Platinum with Sal-ammoniac. Inflammable Chloroplatinate of ammonium.—The crude liquid (p. 596), which should not be rendered turbid by a concentrated solution of chloride of potassium, is diluted with a four-fold quantity of water, and decanted from the detonating platinum-deposit; a quantity of sal-ammoniac, amounting to 18 per cent. of the tetrachloride of platinum used to form the crude liquid is then dissolved in it; the solution evaporated down to one-third; the brown crystalline mass which forms on cooling, broken up and dissolved in a small quantity of warm water, after the very acid mother-liquid has run off; the solution evaporated at a gentle heat and cooled to the crystallising point; the crystals washed with a small quantity of water, then dissolved in a larger quantity; and the solution is left to crystallise by evaporation in vacuo.

Lemon-yellow, transparent, shining, oblique rhombic prisms, often half an inch long, which become covered with a black film on exposure to air and light. (Zeise.)

The crystals contain 6.18 per cent. ($1\frac{1}{2}$, or perhaps more correctly 1 at.) water of crystallisation, which they give off at 100° C. or in vacuo, without further decomposition; heated to redness in the air, they leave platinum. Their aqueous solution, when heated alone, or mixed either hot or cold with excess of potash, exhibits the same decompositions as the solution of ethylene-dichloride of platinum heated alone. Mixed with caustic potash and evaporated, it yields a white precipitate. The crystals dissolve in less than 5 pts. of cold water, more sparingly in alcohol. (Zeise.)

Ethylene-dichloride of Platinum with Chloride of Potassium. C²H²PtCl².KCl. Inflammable Platinopotassic Salt.—Obtained by diluting the crude liquid in the retort (p. 596) with about four times its bulk of water; decanting it from the detonating platinum-deposit; dissolving in it a quantity of chloride of potassium equal to $\frac{1}{2}$ of the dichloride of platinum used for the preparation of the crude liquid; and otherwise proceeding as in the preparation of the sal-ammoniac compound.

Large lemon-yellow, transparent, shining, oblique rhombic prisms. $\infty P : \infty P = 103^{\circ} 58'$; $\infty P : \infty P = 112^{\circ} 5'$. (Förchhammer.) Reddens litmus. Has a persistently astringent and metallic taste. Dissolves in 5 pts. warm water, less easily in alcohol.

The crystallised salt exposed to light and air becomes covered with a black crust. It contains 4.72 per cent. (1 at.) water of crystallisation, which it gives off completely between 100° and 160° C. in a current of dry air; it likewise effloresces at ordinary temperatures in very dry air, and quickly in vacuo. The dry salt blackens at about 200° ; gives off without any tumefaction a mixture of 2 vols. hydrochloric acid gas and 1 vol. combustible gas; and leaves a grey mass containing chloroplatinate of potassium (Zeise). According to Griess and Martius, the gas evolved consists of ethylene, the decomposition taking place as shown by the equation: $C^2H^2PtCl^2.KCl = PtCl + KCl + C^2H^4$.

Chlorine gas acts on the dry salt only when aided by heat; it then forms hydrochloric acid and trichloride of carbon. Chlorine, bromine, and iodine, added to the aqueous solution of the salt, emit an odour of ether. The dry pulverised salt heated in a stream of hydrogen gas, blackens and exhibits traces of moisture, but does not undergo complete decomposition till it is heated in the current of gas. A stream of hydrogen passed through the aqueous solution throws down metallic platinum. The aqueous solution exhibits, with nitrate of silver, the same reaction as ethylene-dichloride of platinum alone. At 90° C. it decomposes rapidly, but a certain quantity of platinum always remains in solution. In this case also hydrochloric acid, as well as sulphuric and nitric acid, prevents the decomposition, even at the boiling heat; an excess of chloride of potassium appears also to exert a protecting action.

Ethylene-dichloride of Platinum with Chloride of Sodium.—Difficult to crystallise; dissolves somewhat slowly in alcohol, forming a yellow solution, unless an acid is present.

Compounds of Ethylene-dichloride of Platinum with the Chlorides of Organic bases.—A number of these compounds have been obtained by Griess and Martius, but no detailed description of them has yet been published. These compounds, most of which form very fine crystals, may be arranged in two series, comparable in many respects with certain classes of compounds which dichloride of platinum forms with organic bases. Regarding ethylene-dichloride of platinum as the chloride of a monatomic radicle, $C^2H^4PtCl_2$, a very simple relation between the compounds of this body and those of dichloride of platinum becomes perceptible; thus—

Compounds of Dichloride of Platinum.		Compounds of Ethylene-dichloride of Platinum.	
		<i>First Series.</i>	
$PtCl_2$.	.	$(C^2H^4PtCl)_2Cl_2$
$2H^4NCl.PtCl_2$.	.	$2H^4NCl.(C^2H^4PtCl)_2Cl_2$
$2C^2H^3H^3\} NCl.PtCl_2$.	.	$2C^2H^3H^3\} NCl.(C^2H^4PtCl)_2Cl_2$
$(C^2H^4)''H^4\} N^2Cl_2.PtCl_2$.	.	$(C^2H^4)''H^4\} N^2Cl_2.[(C^2H^4PtCl)_2Cl_2]$
		<i>Second Series.</i>	
$H^4Pt''\} N^2Cl_2$.	.	$H^4Pt''\} N^2Cl_2$
$(C^2H^4)^2H^4Pt''\} N^2Cl_2$.	.	$(C^2H^4)^2H^4Pt''\} N^2Cl_2$
$(C^2H^4)^4H^2Pt''\} N^2Cl_2$.	.	$(C^2H^4)^4H^2Pt''\} N^2Cl_2$
$(C^2H^4)''H^4Pt''\} N^2Cl_2$.	.	$(C^2H^4)''H^4Pt''\} N^2Cl_2$
$H^4Pt''\} N^2Cl_2$.	.	$H^4Pt''\} N^2Cl_2$

When the aqueous solution of the last compound in the first of the above series, viz. $(C^2H^4)''H^4\} N^2Cl_2.[(C^2H^4PtCl)_2Cl_2]$, is boiled, a considerable quantity of gas is evolved;

and beautiful yellow sparingly soluble needles are deposited, containing $(C^2H^4)''H^4Pt''\} N^2Cl_2$.

The reaction is represented by the equation,

ETHYLENE-UREAS. See ETHYLENE-CARBAMIDES (p. 595).

ETHYLIDENE. C^2H^4 .—A radicle not known in the separate state, but supposed to exist in certain compounds derived from aldehyde and isomeric with the corresponding compounds of ethylene; e.g.:

Ethylidene-compounds.		Isomeric with	
Aldehyde	C^2H^4O	Oxide of Ethylene	C^2H^4O
Chloride of Ethylidene	$C^2H^4Cl_2$	Chloride of Ethylene	$C^2H^4Cl_2$
Compound of Aldehyde and Acetic Anhydride	$C^2H^4O.C^2H^3O^2$	Diacetate of Ethylene	$C^2H^4.(C^2H^3O^2)$
Compound of Aldehyde and Chloride of Acetyl	$C^2H^4O.C^2H^3OCl$	Acetoxychloride of Ethylene	$C^2H^4.C^2H^3O^2Cl$
Acetal	$C^2H^4O^2$	Diethylate of Ethylene	$C^2H^4.(C^2H^3O^2)$

These two series of compounds are intimately related to each other, and *chloride of vinyl*, C^2H^3Cl , which may be produced from either of them, may be regarded as the link between the two.

Bromide of Ethylidene. $C^2H^3Br^2$. (Wurtz and Frapolli, Ann. Ch. Pharm. cviii. 225.)—This compound is obtained by passing vapour of aldehyde over pentabromide of phosphorus in a vessel externally cooled. The products are bromide of ethylidene and oxybromide of phosphorus ($C^2H^3O + PBr^5 = C^2H^3Br^2 + PBr^3O$), which cannot be separated by fractional distillation, because the bromide of ethylidene is decomposed by heat. The oxybromide of phosphorus may, however, be removed by agitating the mixture with lumps of ice, replacing them as they melt. A dense yellow liquid is thus obtained, which is insoluble in water and is readily decomposed by water, with evolution of hydrobromic acid: hence it is impossible to obtain the compound in a state of sufficient purity for analysis.

Bromide of ethylidene treated with ethylate of sodium yields acetal:

Chloride of Ethylidene. $C^2H^3Cl^2$. (Geuther, Ann. Ch. Pharm. cv. 321.—Wurtz and Frapolli, Compt. rend. xlvii. 418; Ann. Ch. Pharm. cviii. 223.)—Produced by the action of pentachloride of phosphorus upon aldehyde:

Glycol treated with pentachloride of phosphorus yields the isomeric compound, chloride of ethylene.

The vessel containing the chloride of phosphorus must be kept cool, while the aldehyde is added by small portions; afterwards the mixture is warmed, whereupon the whole dissolves to a homogeneous liquid, which gradually blackens when distilled, and gives off below $100^\circ C$. a liquid, from which water separates an oily body, and above 100° oxychloride of phosphorus. The oily liquid, dried by chloride of calcium and rectified, yields chloride of ethylidene.

Chloride of ethylidene is a transparent, colourless, oily liquid, resembling chloroform in taste and odour. Specific gravity 1.189 at $4.3^\circ C$. (Geuther). Boils at 58° (Wurtz and Frapolli), at 60° (Geuther).

It is isomeric with chloride of ethylene, but differs from it in specific gravity and in boiling point, the specific gravity of chloride of ethylene being 1.266 at $12^\circ C$. according to Regnault, and the boiling point 86° according to Dumas. The two bodies differ also in their behaviour with alcoholic potash, chloride of ethylene being easily decomposed thereby into chloride of potassium and the compound C^2H^3Cl ; whereas chloride of ethylidene is not at all affected by alcoholic potash in the cold, and with difficulty even when heated. It appears also to be identical with monochlorinated chloride of ethyl, C^2H^3ClCl (p. 531), that compound having a specific gravity of 1.174 at $17^\circ C$., and boiling at 64° . (Beilstein, Bull. Soc. Chim. de Paris, i. 60.)

Chloride of ethylidene, treated with ethylate of sodium, does not act like the bromide and produce acetal, but yields a gas identical in composition and properties with chloride of vinyl (C^2H^3Cl).

Oxychloride of Ethylidene. $C^2H^3Cl^2O = (C^2H^3)^2 \begin{Bmatrix} Cl^2 \\ O \end{Bmatrix}$. (A. Lieben, Compt. rend. xlii. 662; Ann. Ch. Pharm. cvi. 336.)—This compound, which is isomeric with monochlorethylic ether (p. 540), and may be regarded as a double molecule of aldehyde, in which 1 at. O is replaced by 2 at. Cl, is produced by the action of hydrochloric acid on aldehyde:

When aldehyde cooled by a freezing mixture is saturated with dry hydrochloric acid gas, the liquid increases in volume and separates into two colourless layers, which must be immediately separated, as they act upon each other. The lower layer is aqueous hydrochloric acid; the upper is oxychloride of ethylidene, which may be purified by repeated distillation over chloride of calcium.

Transparent, colourless liquid, smelling of aldehyde and hydrochloric acid. Specific gravity 1.1376 at $12^\circ C$. Boiling point 116° — 117° . Vapour-density 5.08 (taken at 173°); calc. (2 vol.) = 4.95.

Oxychloride of ethylidene is not decomposed by water in the cold, but on heating it is converted thereby into hydrochloric acid and aldehyde. Pentachloride of phosphorus does not act upon it at ordinary temperatures, but when heated with it in a sealed tube to $100^\circ C$. for several hours, it dissolves completely: the organic product cannot, however, be separated from the oxychloride of phosphorus formed at the same time. (Wurtz and Frapolli.)

600 ETHYL-FORMAMIDE — ETHYL-SULPHYDRIC ACID.

Geuther and Cartmell, by treating aldehyde with hydrochloric acid, have obtained, besides the oxychloride just described, another which has the composition $C^2H^3Cl^2O^2$, and may be regarded as a triple molecule of aldehyde, $C^2H^3O^2$, in which 1 at. O is replaced by 2 at. Cl. (Proc. Roy. Soc. x. 110.)

Chlorethylate of Ethylidene. $C^4H^5ClO = C^2H^4.C^2H^3O.Cl$. (Wurtz and Fapoli, Ann. Ch. Pharm. cviii. 226.)—Produced by passing hydrochloric acid to saturation into a mixture of 1 vol. aldehyde and 2 vol. absolute alcohol, surrounded with a freezing mixture. Two layers of liquid are then formed, the lower consisting of aqueous hydrochloric acid and the upper ethereal layer of chlorethylate of ethylidene:

This compound, treated with ethylate of sodium, yields chloride of sodium and acetal:

EUKAIRITE. Syn. with EUKAIRITE.

EUCALYN. $C^6H^{12}O^6$.—A saccharine substance, produced in the fermentation of melitose (the sugar of the eucalyptus), under the influence of yeast:

It is syrupy, dextro-rotatory ($[\alpha] = +50^\circ$ nearly), non-fermentable, and does not acquire that property by the action of sulphuric acid. It becomes coloured at $100^\circ C.$, and at 200° is converted into a black insoluble substance. Strong sulphuric acid and fuming hydrochloric acid destroy it at 100° . Baryta colours it strongly at the same temperature. It reduces tartrate of copper and potassium. These properties are very similar to those of sorbin.

EUCALYPTUS. A genus of Australian plants, one species of which yields, by distillation with water, a volatile oil resembling cajepout oil. Several species of eucalyptus yield the so-called Australian manna, a white, loose, granular mass, in which Johnston found a crystallisable sugar (melitose), containing in the air-dried state, according to his analysis, $C^{12}H^{22}O^{11}.H^2O$, and identical with grape-sugar (Mem. Chem. Soc. i. 159). Berthelot (Compt. rend. xli. 392) also finds it to be identical in composition with grape-sugar, and very similar in its reactions; he regards it as a compound of grape-sugar with the isomeric substance eucalyn. (See MELITOSE.)

EUCAMPITE. See EUKAMPITE.

EUCHEMA SPINOSUM, the so-called Agar-agar (i. 61) contains, according to Oudemans (Arch. Pharm. [2] lxxxvii. 283), nothing but the ordinary constituents of plants.

EUCHLORINE. A gaseous mixture of chlorine and oxide of chlorine, obtained by the action of hydrochloric acid on chlorate of potassium. (See CHLORINE, OXYGEN-COMPOUNDS OF, i. 912.)

EUCHROIC ACID. $C^6H^4N^2O^8$. (Wöhler [1841], Pogg. Ann. lii. 610.—R. Schwarz, Ann. Ch. Pharm. lxi. 49).—Regarded by Laurent and Gerhardt as mellamic acid, $C^6H^4NO^8 = NH^2(C^6O^2)^2$.

The ammonium-salt of this acid is obtained, together with paramide, by heating pulverised mellate of ammonium to 150° — 160° for several hours, stirring it all the while, and continuing the heating as long as any odour of ammonia is given off. A pale yellow powder then remains, consisting of a mixture of paramide and euchroate of ammonium, the latter of which may be washed out by water, and obtained in crystalline crusts by evaporating the filtered solution. On dissolving this salt in a very small quantity of boiling water, adding hydrochloric or nitric acid to the hot solution, and leaving it to cool, euchroic acid separates in the form of a white crystalline powder, which may be purified by recrystallisation.

Euchroic acid crystallises in very small rhomboïdal prisms, usually grouped in pairs; it is sparingly soluble in cold water, and has a strong acid reaction. At $200^\circ C.$ it gives off 10.54 per cent., or 2 at. water (Wöhler). The dried acid is found by analysis to contain:

	Dried at $200^\circ C.$		Wöhler.	Schwarz (mean).
C^{12}	144	47.37	48.66	47.55
H^4	4	1.31	1.66	1.60
N^2	28	9.21	10.98	9.18
O^8	128	42.11		
	304	100.00		

The analytical numbers agree tolerably well with the formula $C^{12}H^4N^2O^8$ proposed by Wöhler, according to which euchroic acid is formed from acid mellate of ammonium by the abstraction of 4 at. water:

The relations of euchroic acid to the other amides of mellitic acid are as follows: Mellitamide $C^{12}H^{12}N^2O^8$ by giving up ammonia is converted into paramide $C^{12}H^4N^2O^8$; this compound dissolved in ammonia and treated with hydrochloric acid yields paramic acid $C^{12}H^2N^2O^8$; and the latter, by addition of water and elimination of ammonia, is converted into euchroic acid.

The acid remains unaltered at $280^\circ C.$, but at a higher temperature melts, boils, and decomposes, yielding hydrocyanate of ammonia, and a dark green, bitter sublimate. (Wöhler).—Zinc, protoxide of iron, or the electric current, throws down from an aqueous solution of euchroic acid a dark blue substance, called euchrone, of unknown composition, insoluble in water, but dissolving with purple colour in alkalis, and quickly oxidising again in the air to euchroic acid (Wöhler).—The deep blue, closely adhering deposit with which zinc becomes covered in the aqueous acid, detaches itself on immersion for a short time in very dilute hydrochloric acid, and may then be collected on a filter, washed, and dried. The black mass thus obtained, which is free from zinc, is instantly oxidised, by the slightest heating, to euchroic acid; it dissolves in aqueous ammonia or potash, with a more splendid colour than that of permanganate of potassium; but the solution becomes decolorised from above downwards, on exposure to the air, and very quickly if agitated. In the boiling acid, zinc acquires a similar coating, but a trace of gas is evolved at the same time, and the liquid deposits a white powder, probably mellate of zinc. A mixture of aqueous euchroic acid and protochloride of iron forms, with alkalis, a thick deep violet-coloured precipitate, which immediately becomes rust-brown on exposure to the air, and dissolves without colour in hydrochloric acid, because the resulting sesquioxide of iron is reduced to the state of protoxide by the euchrone, which is thereby reconverted into euchroic acid. These phenomena are not produced by stannous or manganous chloride. Platinum in galvanic combination with zinc, does not act upon the aqueous acid, but decomposes its ammonia-salt (Wöhler). The aqueous acid is likewise decomposed by the electric current, and covers the negative platinum with a deep blue deposit, which, however, soon ceases to increase. Euchrone is not produced by the action of sulphuretted hydrogen, sulphurous acid, hyposulphites, or arsenites (Schwarz). Euchroic acid mixed with a quantity of water not sufficient to dissolve it in its unaltered state, and heated to $200^\circ C.$ in a sealed glass tube, dissolves completely in the form of acid mellate of ammonium (Wöhler).

Euchroic acid dissolved in water does not decompose when boiled in contact with the air. Hydrochloric acid and nitric acid exert no decomposing action upon it. (Wöhler).

Euchroic acid is dibasic, its neutral salts having the composition $C^{12}(H^2M)^2N^2O^8$.

Euchroates of Ammonium.—The neutral salt, $C^{12}H^4(NH^4)^2N^2O^8$, obtained by evaporating the wash-water of paramide, as above described, forms white, scarcely crystalline crusts, which are decomposed by hydrochloric or nitric, but not by acetic acid. (Wöhler.)

An acid salt is sometimes precipitated from the aqueous solution of the neutral salt instead of the pure acid, and separates from solution in hot water, in yellowish crystals larger than those of the pure acid. (Wöhler.)

Euchroate of Barium. $C^{12}H^4Ba^2N^2O^8 + H^2O$, is precipitated in the form of a pale yellow powder, when baryta-water is dropt into an excess of warm aqueous euchroic acid. (Schwarz.)

An acid barium-salt is obtained, as a pale yellow pulverulent precipitate, on slowly adding baryta-water to a warm solution of euchroic acid in excess. (Schwarz.)

Euchroate of Lead. $C^{12}H^4Pb^2N^2O^8 + H^2O$.—The boiling aqueous solution of euchroic acid, mixed with a dilute solution of neutral acetate of lead, yields, on cooling, a yellow powder, which appears crystalline under the microscope. (The filtrate separated from this precipitate deposits mellate of lead as a white powder when boiled.) The air-dried salt gives off 11.36 per cent. (3 at.) water at $160^\circ C.$, but nothing more at a stronger heat till it begins to decompose. (Wöhler.)

Euchroate of Silver. $C^{12}H^4Ag^2N^2O^8$, is a sulphur-yellow powder, obtained by mixing a boiling aqueous solution of the acid with a dilute solution of nitrate of silver; when treated with ammonia it becomes so gelatinous that it passes through the filter.

EUCHROITE. A native arsenate of copper found at Libethen in Hungary. It contains 33.02 per cent. arsenic anhydride, 47.85 cupric oxide, and 18.8 water

(Turner, Ed. Phil. J. iv. 301), whence the formula $4\text{CuO} \cdot \text{As}_2\text{O}_3 + 7\text{H}_2\text{O}$, or $\text{Cu}_4\text{O} \cdot \text{Cu}_2\text{As}_2\text{O}_3 + 7\text{H}_2\text{O}$. The crystals belong to the trimetric system. Hardness = 3.5 to 4. Specific gravity 3.35 to 3.45. Colour emerald-green. Streak light apple-green. Lustre vitreous. More or less transparent. (Handw. d. Chem. ii. [3] 943.)

EUCHRONE. A product of the decomposition of euchroic acid by zinc and certain other reducing agents (p. 602).

EUCHYSIDERITE. A variety of augite.

EUCLEASE. *Prismatic emerald.*—A silicate of aluminium and glucinum, allied to beryl; found in Peru, Brazil, in the Urals, but rare. Crystallises in monoclinic prisms, often modified by numerous faces. $\alpha\text{P} : \alpha\text{P} = 115^\circ 0'$; $\alpha\text{P}\infty : \alpha\text{P} = 107^\circ 37' 30''$. Ratio of principal axis, clinodiagonal and orthodiagonal = 1 : 0.9713 : 3.0008. Cleavage very distinct, parallel to $\alpha\text{P}\infty$; much less distinct parallel to αP and $[\alpha\text{P}\infty]$. Hardness = 7.5. Specific gravity = 3.0 to 3.1. Colour light yellowish-green to yellow, bluish-green to blue, also white. Lustre vitreous. Transparent to translucent. Fracture conchoidal. Very brittle. When strongly heated before the blowpipe, it swells up and melts in thin splinters to a white enamel. Not attacked by borax or phosphorus-salt. Insoluble in acids.

Euclease was formerly regarded as an anhydrous silicate; but Damour (Compt. rend. xv. 942) has shown that it contains water, his analysis giving:

SiO_2	Al_2O_3	GfO	CaO	FeO	SnO	H_2O	F
41.63	34.07	16.97	0.14	1.03	0.34	6.04	0.38 = 100.60

whence the formula $2\text{GfO} \cdot \text{SiO}_2 + \text{Al}_2\text{O}_3 \cdot \text{SiO}_2 + \text{aq.}$ or $\left(\frac{\text{Gf}}{\text{Al}}\right)^2 \text{SiO}_2 + \text{Al}^2 \text{H}_2\text{O}_2$. (Jahresber. f. Chem. 1852, p. 855; 1853, p. 800; 1855, p. 941. — Dana, ii. 267. — Rammelsberg, p. 571.)

EUCLASITE. A name formerly applied to a green apatite from Lake Baikal.

EUDIALYTE. A mineral from Kandgerdluarsuk in Greenland, crystallised in hemihedral forms of the hexagonal system, the primary form being an acute rhombohedron of $73^\circ 40'$, with the faces αR , ∞R_2 , and other forms subordinate. Cleavage very distinct parallel to αR ; less distinct parallel to R . Occurs also crystallo-granular, massive, and imbedded. Hardness = 5.0 to 5.5. Specific gravity = 2.9. Colour bluish to brownish-red; streak uncoloured. Lustre vitreous. Opaque to slightly translucent. Before the blowpipe it melts easily to a greyish-green enamel; dissolves with moderate facility in borax, yielding a glass slightly coloured by iron; easily decomposed by phosphorus-salt, with separation of a tumefied skeleton of silica. Easily decomposed by hydrochloric acid, with formation of a jelly.

Eudialyte is essentially a zircon-silicate of sodium and calcium, that is to say, a silicate in which the silicon is partly replaced by zirconium; but it likewise contains tantalum, or rather perhaps niobic acid, and several other constituents.

Analyses.—*a.* by Rammelsberg (Pogg. Ann. lxxiii. 142), *b.* by Damour (Compt. rend. xliii. 1197):

	SiO ²	ZrO ²	Ta ² O ₅	FeO	MnO	CaO	Na ₂ O	K ₂ O	Cl	Loss by ignition
a. 49.92	16.88	. .	6.97	1.15	11.11	12.28	0.65	1.19		0.37 = 100.52
b. 50.38	15.60	0.35	6.37	1.61	9.23	13.10	. .	1.48		1.25 = 99.37

These analyses lead to the formula $\text{M}^2\text{O} \cdot 2(\text{SiO}_2; \text{ZrO}_2)$, or $\text{M}^2(\text{Si}; \text{Zr})\text{O}_2(\text{Si}; \text{Zr})\text{O}_2$, analogous to that of a metasilicate with excess of silica. The basic metal M is made up of sodium, calcium, and ferrosium. (Dana, ii. 181. — Rammelsberg, p. 893.)

Closely allied to eudialyte, if not identical with it, is *eukolyte*, from Brevig in Norway (p. 605).

EUDIOMETER and EUDIOMETRY. See ANALYSIS, VOLUMETRIC, OF GASES (i. 268).

EUDNOPHYTE. Analcime from the island of Lamö, near Brevig in Norway, supposed by Weibye (Pogg. Ann. lxxix. 303) to differ from ordinary analcime in crystalline form, being trimetric instead of monometric. According to Möller, however (J. pr. Chem. lxxix. 318), this difference does not exist.

EUGENALLOPHANIC ACID. See ALLOPHANIC ACID (i. 134).

EUGENANISYL ANHYDRIDE. $\text{C}^{10}\text{H}^{10}\text{O}^4$ = *Eugenanisyl*. *Anisugenyl*.—A compound produced by the action of chloride of anisyl on eugenic acid. It is crystallisable and insoluble in aqueous potash. (Cahours, Ann. Ch. Phys. [3] lii. 189.)

EUGENE-GLANCE. Syn. with POLYBASITE.

been determined. It forms white, nacreous laminae, having a faint taste and smell of cloves; insoluble in water, but soluble in all proportions in alcohol and ether. Nitric acid turns it blood-red.

EUGENO-BENZOIC ANHYDRIDE. $C^{10}H^{10}O^2 = \frac{C^{10}H^{10}O}{C^8H^6O} O$. *Benzenogenyl, Eugenobenzoyl.* (Formation, p. 604.)—After purification by recrystallisation and distillation, it forms colourless needle-shaped crystals, perfectly neutral, insoluble in water, moderately soluble in hot alcohol and in ether. Melts between 50° and 55° C., and boils above 360° . It is not decomposed by boiling aqueous potash, but by fusion with solid potash, it is converted into benzoate and eugenate of potassium. Bromine and nitric acid decompose it more readily, probably forming substitution-products. (Cahours.)

EUGENOL. Syn. with EUGENIC ACID.

EUGENO-CUMINIC ANHYDRIDE. $C^{20}H^{20}O^2 = \frac{C^{10}H^{10}O}{C^{10}H^{10}O} O$. (p. 180.)

EUGENO-TOLUYLIC ANHYDRIDE. $C^{16}H^{16}O^2 = \frac{C^{10}H^{10}O}{C^6H^6O} O$. *Toluenegenol.*—Resembles the benzoic compound. Dissolves easily in hot alcohol, and especially in ether. (Cahours.)

EUGETIC ACID. See ADDENDA (p. 968).

EUGLENA VIRIDIS. The granules found in these infusoria consist, according to Gottlieb, of paramylum. (See STARCH.) The green colouring matter is insoluble in water, easily soluble in alcohol and ether, somewhat soluble in alkaline liquids. The ethereal solution produces a very strong blood-red dispersion, both of daylight and candle-light. It appears to be different from the chlorophyll of phanerogamous plants, green mosses, and algae. (Salm-Horastmar, Pogg. Ann. xcvii. 331.)

EUKAIRITE. $AgCuSe$ or $(\frac{Ag^2}{Cu^2})_n Se^2$.—Native selenide of silver and copper, found in a magnesian serpentine rock, intergrown with calcspar, in an abandoned copper mine at Småland in Sweden. It is soft, slightly ductile, with a fine-grained fracture. Colour lead-grey; yields a grey powder and a shining streak. On charcoal before the blowpipe it melts, gives off a strong odour of selenium, and yields a grey, soft, but brittle metallic bead. Colours fluxes like copper. With hot nitric acid it forms a solution from which water throws down selenite of silver. Gives by analysis 23.05 per cent. copper, 38.93 silver, 26.0 selenium, and 8.9 earthy matter. (Berzelius, Schw. J. xxiii. 477.)

EUKAMPHITE. $(Al^2)^2H^2O^4.3M'SiO^2$ or $(M''al'')SiO^4 + \frac{1}{2}aq.$ (where M'' represents Mg, Fe, and a small quantity of Mn).—A mineral resembling chlorite in external appearance, found in the granite near Presburg in Hungary. It forms dark green nacreous laminae, cleaving easily parallel to the base, thin cleavage laminae exhibiting a brown or red translucence; soft and flexible. Hardness = 2; specific gravity = 2.73. When strongly heated in a glass tube, it exfoliates and gives off water. Before the blowpipe it melts on the edges to a black magnetic glass; gives the reactions of iron, silicon, and manganese with borax and phosphorus-salt, and dissolves in hydrochloric acid with separation of gelatinous or scaly silica. (Kenngott, Handw. d. Chem. ii. [3] 951.)

EUKLASE. Syn. with EUCLASE.

EUKOLYTE. A mineral from Brevig, in Norway, closely resembling eudialyte, and regarded by some mineralogists as identical therewith. The two minerals have the same form and nearly the same colour, lustre, and hardness, and agree nearly in composition; but eukolyte is distinguished by the presence of cerium, and, so far as the analysis can be trusted, by a rather larger amount of silica; it has also a browner colour, a somewhat higher specific gravity = 3.0, exhibits more distinct prismatic cleavage, and is especially distinguished by its optical properties, exhibiting negative double refraction, whereas eudialyte is positive. (Kenngott, Handw. ii. [3] 947.)

The following are analyses of eukolyte: a. by Scheerer (Pogg. Ann. lxi. 222; lxvii. 566); b. by Damour (Compt. rend. xliii. 1197).

	SiO ²	ZrO ²	TaO ²	CaO	LaO	FeO	MnO	CuO	Na ² O	Cl	Loss by ignition.
a. 47.85	14.05	2.98	.	7.42	1.94	12.06	12.31	.	1.84	=	99.55
b. 45.70	14.22	2.35	2.32	1.11	6.83	2.35	9.66	11.59	1.11	1.83	= 99.07

Scheerer's analysis leads to the formula $2M''O.3SiO^2 = (M'')^2SiO^4.2SiO^2$; Damour's to $3M''O.5SiO^2 = 3M''SiO^2.2SiO^2$, the silicon being replaced to a considerable extent by zirconium (Rammelsberg's Mineralchemie, p. 894).

EUKOLITE-TITANITE. A mineral occurring, together with eukolite, in the zircon-syenite of Brevig in Norway. It exhibits the colour and lustre of eukolite, but in crystalline form and density, = 3.67, it resembles titanite. Before the blowpipe it exhibits the reactions of silica, ferric oxide, titanio acid, and soda. It is less hard than titanite, and appears to occupy an intermediate place between titanite and eukolite (Scheerer, Jahresber. f. Chem. 1864, p. 853.)

EULYSIN. A name applied by Berzelius to a substance easily soluble in alcohol which he obtained by the action of alcoholic potash on that portion of the alcoholic extract of bile which is soluble in ether: it was probably impure choleic acid.

EULYSITE. A kind of rock which forms layers in the gneiss of Sweden. It is a granular mixture of augite (probably diallage), garnet, and nearly 50 per cent. of a mineral allied to olivine, being likewise a basic silicate in which the greater part of the magnesia is replaced by protoxide of iron or manganese. When the rock is treated with hydrochloric acid, the last-mentioned mineral is decomposed, with separation of gelatinous silica, while the granules of augite and garnet fall to the bottom. (A. Erdmann, Jahresber. d. Chem. 1849, p. 799.)

EULYTE and DYSLYTE. Two crystallisable substances of unknown composition produced, together with others, by the action of strong nitric acid upon citraconic acid; they are distinguished by their different degrees of solubility in water and in alcohol *eulyte* being the more, *dyslyte* the less soluble. (Baup, Ann. Ch. Pharm. lxxi. 96. See CITRACONIC ACID (i. 992).)

EULYTIN. Silicate of Bismuth. *Bismuth-blende*.—A rare mineral, occurring at Schneeberg in Saxony, in hemihedral forms of the regular system, the observed faces being 0, $\infty 0\infty$ and $\pm \frac{202}{2}$. The crystals are usually small and often with rounded edges. Cleavage dodecahedral, very imperfect. Twin-crystals also occur having their plane of composition parallel to a dodecahedral face. The mineral is sometimes also globular, columnar, lamellar, or granular. Hardness = 4.5 to 5.0. Specific gravity = 5.9 to 6.0. Colour brown, yellow, and yellowish-white. Lustre resinous or adamantine. Subtransparent to opaque. Streak yellowish-green or uncoloured. Fracture uneven. Rather brittle. Before the blowpipe it melts easily with intumescence to a brown bead, with brown deposit on the charcoal; with soda it yields metallic bismuth, and with phosphorus-salt a skeleton of silica. Soluble in hydrochloric acid with separation of gelatinous silica. According to an analysis by Kersten (Pogg. Ann. xxvii. 81), it contains 69.38 per cent. Bi_2O_3 , 2.40 Fe_2O_3 , 0.30 Mn_2O_3 , 22.23 SiO_2 , 3.31 P_2O_5 , 2.38 water, together with a small quantity of fluorine, whence it appears to be a silicate of bismuth mixed with a small quantity of ferric phosphate.

EUMANITE. A brown variety of titanio anhydride, from Chesterfield in Massachusetts, agreeing in crystalline form with Brookite, and probably identical therewith. Hardness = 6.0. (C. Shepard, Sil. Am. J. xii. 211.)

EUODYL. $\text{C}^{\text{H}}\text{H}^{\text{O}}$ (from *euodys*, sweet-tasting); sometimes improperly written *enodyl*. An acid radicle, homologous with acetyl, the hydrogen compound of which euodic aldehyde, $\text{C}^{\text{H}}\text{H}^{\text{O}}\text{H}$, is, according to Greville Williams (Proc. Roy. Soc.), the essential constituent of oil of rue. (See RUE, OIL OF.)

EUONYMIN. A bitter resinous substance obtained from the oil of the spindle tree, *Euonymus europæus*. It is insoluble in water, soluble in alcohol and ether, and separates from the latter in warty crystals; it does not however appear to have been obtained pure. (Riederer, Buchn. Repert. xiv. 1.—Grundner, *ibid.* xvii. 315.)

EUONYMITE. $\text{C}^{\text{H}}\text{H}^{\text{O}}$. (Kubel, J. pr. Chem. lxxv. 372.)—A saccharine substance obtained from the *cambium* (the viscid secretion which exists in the spring between the bark and the wood) of the branches of the spindle-tree. The *cambium* of the thicker branches is exhausted with strong alcohol, and on evaporating the solution, euonymite is obtained in highly lustrous monoclinic crystals. It melts at 182°C. It is isomeric with mannite, and agrees with that substance in most of its properties but is distinguished by its crystalline form and higher melting point, mannite being trimetric and melting at 166°C. Gilmer (Ann. Ch. Pharm. cxxiii. 376) regards it as identical with dulcite.

EUPATORIUM. The water-hemp, *Eupatorium cannabinum*, contains, according to Righoni (Mag. Pharm. xxv. 98), an alkaloid, called eupatorine, having a bitter rather pungent taste, insoluble in water, soluble in alcohol and ether, and forming a crystallisable sulphate.

The root of the same plant contains, according to Boudet, a volatile oil, a bitter acrid substance, starch, and the other ordinary constituents of plants.

EUPHORBIA. The roots of *Euphorbia Cyparissias*, *E. Esula*, *E. Lathyris*

F. Apios and *E. depauperata* are emetic and purgative; so likewise is the fixed oil obtained from the seeds of several species, especially of *E. Cyparissias*, *E. Lathyris*, *E. hyberna* and a few others. The seed-oil of these plants may be used in the same way as croton-oil, which is itself the produce of a euphorbiaceous plant. The seeds of *E. Cyparissias* gathered in Auvergne, yielded 6 per cent. fixed oil; those of *E. hyberna* yielded, by exhaustion with ether, 44 per cent. of a golden-yellow fixed oil, having a pleasant and not acrid odour. (Chevallier and Aubergier, J. Chim. méd. viii. 671.)

The milky juice contained in the leaves and stems of euphorbias, is sometimes used as a remedy against the bites of serpents and in syphilis; it is also said to remove warts, especially that of *E. Cyparissias*, *E. Esula*, *E. hypericifolia*, and *E. Tirucalli*. The milky juice of *E. myrtifolia* is peculiarly poisonous. It contains, according to Ricord-Madianna, a non-volatile poisonous principle, euphorbine.

The herb of *E. cotinifolia* suspended in water is said to intoxicate fish.

E. Cyparissias, a very common weed, contains, according to Riegel (J. pr. Pharm. vi. 165), an organic base, and a peculiar acid, euphorbic acid, forming a crystalline lead-salt, from which the acid may be separated by sulphuretted hydrogen in white needle-shaped crystals. It forms crystallisable salts with the alkalis, and its aqueous solution is precipitated by baryta-water, by acetate of lead, either neutral or basic, and by silver and mercury-salts. Gmelin (*Handbook*, x. 207) regards this acid as identical with malic acid. According to Dessaignes (J. Pharm. [3] xxv. 25), it is a mixture of malic and citric acids with a coloured acid, which precipitates gelatin and copper-salts and blackens iron-salts.

According to Stickel (Arch. Pharm. xl. 30), *E. Cyparissias* and *E. Esula*, also a common weed, contain, besides resin, gallic acid, &c., a white, volatile, crystalline, camphor-like body, having a burning taste and separating gradually from the alcoholic solution, and a yellow colouring matter, which is precipitated by stannous chloride or lead-salts from the extract prepared with water containing alum.

EUPHORBIC ACID.

EUPHORBINE.

EUPHORBIIUM.

See EUPHORBIA.

See EUPHORBIIUM.

EUPHORBIIUM. *Resina s. Gummi Euphorbii*. A resin, sometimes improperly called a gum or gum-resin, consisting of the concrete juice of several species of euphorbia, growing in Egypt, Arabia, the Canaries, and other hot countries, either exuding naturally, or from incisions made in the bark. Much of the article found in British commerce is obtained from *Euphorbia canariensis*, while that which occurs on the Continent is obtained from *E. officinarum*, *E. antiquorum*, and other African species, particularly from an undescribed species, called by the Arabs *dergmuse*.

Euphorbium is a variable mixture of resin with wax, caoutchouc, salts, chiefly malates, and from 10 to 20 per cent. of moisture. These constituents may be separated by treating it successively with water, and with cold and hot alcohol.

But even the resin of euphorbium, separated from the wax and other matters, is itself a mixture of three, if not of a greater number of resinous bodies. Berzelius distinguished three resins, α , β , and γ . On mixing the alcoholic solution of euphorbium-resin with alcoholic sugar of lead, a precipitate is formed from which, by means of hydrochloric acid and alcohol, a dark-brown resin, the α -resin, may be separated: it has a sharp burning taste, and dissolves in alkalis and in alcohol.

The liquid filtered from the lead-precipitate yields, when mixed with sulphuric acid, and then with water, a precipitate of the β -resin, easily soluble in alcohol, but insoluble in pure ether. On evaporating the alcoholic solution, this resin remains as a shining, brittle, transparent mass, soluble in very dilute alkalis, and in dilute aqueous acids; hence Buchner and Herberger (Buchn. Repert. vi. 145) regarded it as a base, which they called euphorbine.

Johnston (J. pr. Chem. xxvi. 145), and H. Rose (Pogg. Ann. xxxiii. 33; liii. 365), have obtained from euphorbium several easily soluble resins.—By exhausting the euphorbium with cold alcohol, a pale yellow solution is obtained, which, when evaporated, leaves a brown-red, brittle, and friable resin, $C^{20}H^{30}O^4$, insoluble in caustic alkalis, dissolving with red colour in strong sulphuric acid, and separated unchanged by water.

When euphorbium, after exhaustion with cold alcohol, is well boiled with alcohol, the liquid deposits, on cooling, the γ -resin of Berzelius in indistinct crystals, the composition of which appears to be $C^{20}H^{32}O^2$. It is a perfectly indifferent body; its alcoholic solution is not precipitated by ammonia, neutral acetate of lead, nitrate of silver, or by alcoholic potash; but aqueous potash precipitates it. By dry distillation it yields a viscid distillate having an alkaline reaction.

Euphorbium, when swallowed in small doses, produces vomiting and purging; in larger doses it is poisonous. When applied externally it produces irritation, and is therefore employed as an ingredient of vesicating unguents and plasters; but its use is now almost wholly confined to veterinary practice. (Handw. d. Chem. ii. [3] 954.)

EUPHOTIDE. Syn. with GABBERO.

EUPHRASIA. The green parts of *Euphrasia officinalis* (eye-bright), contain according to Enz (Vierteljahrsschrift pr. Pharm. viii. 175), tartaric, citric, acetic, and lactic acids, red and yellow colouring matter, fixed and volatile oil, and a tannic acid supposed to be peculiar to the plant, and called euphrasia-tannic acid; its lead-salt is said to contain $3PbO \cdot C^{22}H^{20}O^{17}$.

100 pts. of the fresh plant, at the flowering time, contained 62.0 pts. water; from the residue, ether dissolved 4.4 pts.; alcohol then 12 pts., water 6.4 pts., and hydrochloric acid 4.4 pts., leaving 10.8 pts. of insoluble residue.

EUPHYLLITE. A sub-species of mica allied to Margarodite, occurring, together with corundum and black tourmalin, at Unionville, Delaware County, Pennsylvania. It is greyish or sea-green, with faint mother-of-pearl lustre on the outside, but on the cleavage-faces, which are very perfect, it is white, with very strong nacreous lustre. The laminae are very brittle and perfectly transparent. Hardness 3. Specific gravity 2.963. Before the blowpipe it exfoliates, shines more brightly than emerylite or corundelite and melts on the edges.—The composition of this mineral is variously stated by different analysts. According to Smith and Brush (Sill. Am. J. [2] xi. 209), it contains (mean of four analyses):

SiO ₂	Al ₂ O ₃	Fe ₂ O ₃	CaO	MgO	K ⁺	Na ⁺ O	H ⁺ O
40.28	42.08	1.42	1.26	0.70	3.60	4.71	5.55 = 99.59;

whence the formula $2MPO \cdot SiO_2 + 2(3M^{2+}O_4 \cdot 4SiO_2) + 4aq.$, which, by reducing the sesquioxides to protoxides, may be converted into that of a combination of an orthosilicate and a hydrate, viz. $9K'SiO_4 \cdot 4RHO + 2aq.$

EUPHONIE. A hydrocarbon, discovered by Reichenbach (Ann. Ch. Pharm. xiii. 217), and consisting essentially, according to Frankland, of hydride of amyl, C_5H_{12} . It is produced by the dry distillation of many organic bodies, viz. of wood, coal, fixed oils, caoutchouc, resin, bones, &c.; it is, therefore, a constituent of wood-tar, and, in greater abundance, of coal-tar, but is found most abundantly in rectified bone-oil (i. 625), and in the oil obtained by the dry distillation of rape-seed and hemp-seed. According to Hesse (Ann. Ch. Pharm. xxiii. 247), it does not exist in the crude empyreumatic oils obtained from these several sources, but is produced in the process of purifying them by the action of sulphuric acid. To prepare it from rectified bone-oil, the oil is mixed with $\frac{1}{4}$ of its weight of oil of vitriol; the lighter and clearer liquid, which rises to the surface, is taken off and distilled with an equal weight of sulphuric acid and a small quantity of nitre; the distillate is again distilled with sulphuric acid, then washed with aqueous potash and with water, rectified, dried under the air-pump, and treated with potassium as long as the metal shows signs of oxidation.

Euphone is a colourless, extremely mobile liquid, having a very low refracting power. It is tasteless, and has an agreeable odour, like that of flowers. It does not conduct electricity. Specific gravity = 0.65 at 20° C. It remains liquid at 20° C., expands very much when heated, 100 vol. at 20° C. expanding to nearly 104.6 vol. at 47° C. It is very volatile, evaporating perceptibly at common temperatures. When dropped on paper, it makes a grease-stain, which quickly disappears; it evaporates instantly on the skin, boils at 47° C., and distils unaltered. It is inflammable, and burns with a smokeless flame.

Euphone is insoluble in water, sparingly soluble in aqueous alcohol, but mixes easily with absolute alcohol, ether, and oils both fixed and volatile. It dissolves sulphur and phosphorus only with aid of heat; many fats, camphor, and similar substances with facility, caoutchouc also when heated, the solution leaving a dry varnish when evaporated. Resins it dissolves for the most part with difficulty and incompletely; and most alkaloids are quite insoluble in it, even at the boiling heat.

Euphone is a very stable substance; it is not altered by light; sulphuric acid, nitric acid, alkalis, potassium, and sodium have no action upon it, and even permanganate of potassium is said not to be reduced by it. With chlorine, bromine, and iodine, it unites without undergoing decomposition.

EUPYRCHROITE. A native phosphate of calcium (phosphorite) occurring in large quantity at Crown Point, New York, and used abundantly as manure. (See PHOSPHORITE.)

EURITE. A variety of syenite occurring near Christiania; it is of a blue colour and stratified. Two specimens gave:

SiO ²	Al ² O ³	FeO	CaO	MgO	K ² O	Na ² O	H ² O	FeS ²
53.85	15.43	9.30	6.73	1.14	3.40	4.36	2.32	0.785 = 97.315
58.50	18.14	7.07	2.89	1.51	2.36	5.53	3.45	trace = 99.45

(Kjerulf, Jahresber. f. Chem. 1854, p. 882.)

EUSYNCHITE. Vanadate of lead, found in abandoned workings, at Hofsggrund near Freiburg, in the Breisgau. It is micro-crystalline, and forms spherical or botryoidal aggregates and crusts of yellowish-red or leather-yellow colour, with somewhat lighter streak; scarcely translucent on the edges; distinctly radio-fibrous. Hardness = 3.6. Specific gravity = 4.945. Melts to a lead-grey bead before the blow-pipe; yields lead on charcoal, and with phosphorus-salt, a yellow bead in the oxidising, green in the reducing flame; gives by analysis 55.70 PbO; 20.49 V²O⁵; 22.69 V²O⁵; 0.94 SiO² (total 99.82). (Fischer and Nessler, Jahresber. f. Chem. 1855, p. 964.)

EUTOMITE. See TELLURIC BISMUTH.

EUXANTHIC ACID. C²¹H¹⁸O¹¹. *Purree acid.* (Stenhouse, Ann. Ch. Pharm. li. 423.—Erdmann, J. pr. Chem. xxxiii. 190; xxxvii. 385.)—This acid, in combination with magnesia, constitutes the essential part of purree or Indian yellow, a substance imported into Europe from India and China, and consisting, according to most authorities, of the dried sediment of elephants' or buffaloes' urine; but, according to Stenhouse, of a vegetable extract, obtained by evaporating down the juice of certain plants mixed with magnesia. (See PURREE.)

To prepare euxanthic acid, the purree is exhausted with boiling water, and the residue is dissolved in boiling dilute hydrochloric acid. The solution on cooling deposits euxanthic acid in yellowish needles grouped in stars. It is sparingly soluble in cold water, but dissolves easily in alcohol and ether. When crystallised from alcohol it retains 1 at. water (C²¹H¹⁸O¹¹.H²O), and when precipitated by hydrochloric acid from its ammoniacal solution, 3 at. water (C²¹H¹⁸O¹¹.3H²O). This water of crystallisation (4 or 11 per cent.) is given off at 130° C. The acid has a sweet taste, with bitter after-taste. It is coloured deep yellow by alkalis.

Euxanthic acid cautiously heated in a tube yields a yellow sublimate of euxanthone; C²¹H¹⁸O¹¹ = C²⁰H¹⁶O⁹ + CO² + 3H²O. The same substance is produced by the action of strong sulphuric acid, together with hamathionic acid, C¹¹H¹⁰SO².

With chlorine, bromine, and cold nitric acid, euxanthic acid forms substitution-products (p. 610). Hot nitric acid converts it into coeciononic acid, together with oxalic acid, and ultimately into oxypticric or styphnic acid.

Euxanthates. Euxanthic acid is monobasic, the general formula of its salts being C²¹H¹⁷MO¹¹. The euxanthates of the alkali-metals are soluble in water. The barium- and calcium-salts dissolve sparingly in cold, easily in boiling water; the neutral magnesium-salt is also soluble, but the basic salt contained in Indian yellow is insoluble. The other salts are sparingly soluble or insoluble in water.

Euxanthate of ammonium, C²¹H¹⁷(NH⁴)O¹¹, crystallises in light yellow, highly lustrous needles. The *potassium-salt* crystallises from a warm solution of euxanthic acid in acid carbonate of potassium, in light yellow crystalline scales. The *neutral lead-salt*, C²¹H¹⁵Pb²O¹², is precipitated from the aqueous solution of the ammonium-salt by neutral acetate of lead in yellow flocks. The *basic lead-salt*, PbO.C²¹H¹⁵Pb²O¹² + aq., is thrown down from a boiling alcoholic solution of euxanthic acid by an alcoholic solution of basic acetate of lead, as a yellow precipitate.

Euxanthate of Magnesium.—On adding euxanthate of ammonium and a little free ammonia to a solution of chloride of magnesium containing sal-ammoniac, a yellow amorphous precipitate is formed, which dissolves in boiling water, but soon separates as an orange-coloured jelly, which changes on standing into a shining yellow crystalline powder, no longer soluble in water, and consisting of a basic salt, probably MgO.C²¹H¹⁵Mg²O¹² + 8aq. This salt forms the chief constituent of Indian yellow; in the pure state, however, it has a much finer colour than the pigment so called, which contains a larger and variable quantity of magnesia. Erdmann, indeed, found 46 per cent. magnesia in Indian yellow, whereas the pure salt obtained as above contains only 9.5 per cent.

Euxanthate of silver is a gelatinous yellowish precipitate, somewhat soluble in water, and turning brown when exposed to light.

A solution of euxanthate of ammonium forms with *ferric* salts, a blackish-green precipitate; with *ferrous* salts, dark green (Stenhouse); white becoming dark-coloured by contact with the air (Erdmann); with *cupric* salts, a stiff yellow jelly, somewhat soluble in pure water; with *manganous*, *nickel*, and *zinc* salts, lemon-yellow precipitates; with *mercuric chloride*, after some time, a slight yellowish precipitate.

Derivatives of Euxanthic acid.

Bromeuxanthic acid, $C^2H^4Br^2O^{11}$, is obtained by the action of bromine on euxanthic acid in presence of water. It is soluble in boiling alcohol, which on cooling deposits it in golden-yellow microscopic needles. The mother-liquor, when evaporated, yields an additional quantity of the acid in the amorphous state, the amorphous modification being much more soluble in alcohol than the crystalline acid.

The salts of bromeuxanthic acid are gelatinous; the potassium- and ammonium-salts however exhibit, after a while, a tendency to crystallise in needles.

Chloreuxanthic acid, $C^2H^4Cl^2O^{11}$, is obtained by passing chlorine into water in which euxanthic acid is suspended. It crystallises in shining golden-yellow scales, insoluble in water, easily soluble in boiling alcohol, sparingly in cold alcohol. Its salts are mostly gelatinous.

Nitroeuxanthic acid, $C^2H^4(NO^2)^2O^{11}$.—Obtained by immersing euxanthic acid in cold nitric acid of specific gravity 1.31. It dissolves sparingly in water and in cold alcohol, easily in boiling alcohol, whence it crystallises in straw-coloured laminae. Its salts are mostly gelatinous, and deflagrate when heated.

Coccinonic acid. Nitrococcinonic acid of Berzelius.—This acid was discovered by Erdmann, who assigned to it the formula $C^{12}H^2(NO^2)^2O^8$; according to Laurent, it is perhaps *nitroquinonic acid*, $C^{12}H^2(NO^2)^2O^8$, or $C^6H^2(NO^2)^2O^8$. It is produced, together with oxalic acid, when euxanthic acid is heated with nitric acid of specific gravity 1.31, and separates as the liquid cools. If the heat is not strong enough, nitro-euxanthic acid is formed at the same time; in that case, the filtrate when heated will yield an additional quantity of coccinonic acid.

This acid forms yellow crystalline grains, which become strongly electric by friction. It is especially distinguished by its property of forming, with bases, scarlet salts which burn with slight detonation. The *ammonium-salt* is soluble in water and in excess of carbonate of ammonia. The *potassium-salt* is sparingly soluble in water and in excess of carbonate of potassium.

By the continued action of nitric acid, coccinonic acid is converted into oxypticric acid.

Hamathionic acid.—A product of the action of sulphuric acid on euxanthic acid. Its composition is not quite determined. Erdmann, who discovered it, assigned to it the formula $C^{14}H^7O^{15}S$ or $C^{14}H^7O^{12}.SO^2$. A solution of euxanthic acid in cold sulphuric acid yields, on addition of water, a precipitate of euxanthone, and if the filtrate be saturated with carbonate of barium or oxide of lead, filtered from insoluble salt, and the pale yellow liquid carefully evaporated out of contact with the air, a strongly acid solution of free hamathionic acid is obtained, which dries up to a syrup by evaporation at a low temperature, but is decomposed by boiling, with elimination of sulphuric acid.

The hamathionates of the alkali-metals of barium and of lead dry up to yellowish gummy masses. The solutions decompose in contact with the air, with separation of a brown powder and liberation of sulphuric acid. The solution of the *neutral lead-salt* yields, on addition of basic acetate of lead, a yellow precipitate chiefly consisting of triplumbic hamathionate.

EUXANTHONE, $C^2H^{12}O^6$. *Purrenone* (Stenhouse), *Porrone* (Berzelius).—A neutral product of the decomposition of euxanthic acid, first obtained by Stenhouse (Ann. Ch. Pharm. li. 425), and soon afterwards by Erdmann (*ibid.* lii. 365; lx. 289). It is produced by heating the acid, or its barium- or lead-salt *per se*; or by treating the dry acid with strong sulphuric acid; or its alcoholic solution with hydrochloric acid gas. The transformation may be represented as follows:

In preparing euxanthone by the action of heat on euxanthic acid, or its barium- or lead-salt, it is best not to raise the temperature to the subliming point of euxanthone, but to keep it between 160° and 180° C. The euxanthone then remains in the residue, and may be freed from undecomposed euxanthic acid by digestion with ammonia, and then recrystallised from alcohol.

Euxanthone forms pale yellow shining needles or laminae, slightly soluble in water and in cold alcohol. When carefully heated it sublimes for the most part without decomposition. It is perfectly neutral, dissolves in strong aqueous ammonia, and easily in potash, but not in dilute acids. The alcoholic solution is precipitated by basic acetate of lead, but not by the neutral acetate, or by baryta or lime. Nitric acid decomposes it, producing first porphyric acid, $C^{12}H^2(NO^2)^2O^4$ [?], then oxyporphyrac acid, $C^{12}H^2(NO^2)^2O^7$, and lastly oxypticric or styphnic acid, $C^6H^2(NO^2)^2O^4$.

Chlorinated and brominated derivatives of euxanthone are produced, not by the

direct action of chlorine and bromine on euxanthone, but by dissolving chloreuxanthic and bromeuxanthic acid in strong sulphuric acid, and precipitating by water. The mother-liquor retains an acid containing chlorine or bromine, and sulphuric acid, and forming a soluble barium-salt [? chlor- or brom-hamathionic acid], but no hydrochloric acid.

Chloreuxanthone separates from its alcoholic solution in yellow, feathery crystals containing $C^{20}H^{12}O^6$. The formation of this trichlorinated compound from dichloreuxanthic acid seems to show that the composition of euxanthone is not adequately expressed by the formula $C^{20}H^{12}O^6$, and that its formation from euxanthic acid is not quite so simple as it is represented by the equation above given (p. 610).

Bromeuxanthone is precipitated by water as a pulverulent substance; it is probably analogous in composition to chloreuxanthone, but it has not been analysed.

EUXENITE. A mineral consisting mainly of niobate and titanate of yttrium, found at Stromoe, near Arendal, and other localities in Norway. According to Breithaupt, it forms crystals belonging to the trimetric system; but it is usually massive without trace of cleavage, and with imperfectly conchoidal fracture. Opaque in the mass, translucent in thin splinters. Lustre metallic and waxy. Colour brownish-black. Streak brown. Hardness = 6.5. Specific gravity = 4.6 to 5.0. It is not attacked by acids, is infusible before the blowpipe, gives off water when heated, becomes yellowish-brown on ignition, and forms, with borax and phosphorus-salt, yellow glasses, the latter becoming light green or colourless on cooling.

Analyses.—*a.* Brownish-black, from Jöller (Scherer, Pogg. Ann. l. 149), approximate analysis; *b.* Brownish-black from Tvedestrand (Scherer, *ibid.*); *c.* Black, from Tremoe (Strecker, J. pr. Chem. lxiv. 384). *d.* Forbes and Dahl (*ibid.* lxvi. 444; lxx. 353):

	Nb ₂ O ₅	TiO ₂	AlPO ₃	UO	FeO	YO	CeO	LaO	CaO	MgO	HO

EUZEOLITE. Syn. with STILBITR.

EVAPORATION. See HRAT.

EVERNIA. The lichen known as *Evernia* or *Parmelia prunastri*, contains, according to Rochleder and Heldt (Ann. Ch. Pharm. xlviii. 2), besides fat, cellulose, &c., a chromogen or colour-producing substance, identical with Schunck's lecanoric acid; according to Stenhouse, it contains evernic acid together with usnic acid; according to Hesse, it also contains oxalic acid.

EVERNIC ACID. $C^{11}H^{10}O^7$. (Stenhouse [1848], Ann. Ch. Pharm. lxxviii. 83.)—An acid homologous with lecanoric acid, obtained from *Evernia prunastri*. To prepare it, the lichen is exhausted with milk of lime, the yellowish filtrate is neutralised with hydrochloric acid, and the resulting light yellow flocculent precipitate is washed with water, carefully dried, and then digested at a gentle heat in weak spirit, till about $\frac{2}{3}$ of it is dissolved (the remainder consisting of usnic acid). The filtrate on cooling deposits evernic acid in yellow crystals, which may be purified by recrystallisation from weak spirit, with addition of animal charcoal.

Evernic acid forms aggregates of small colourless crystals, destitute of taste and odour. It is insoluble in cold, and sparingly soluble in boiling water; easily soluble in alcohol and ether. It melts at $164^{\circ}C$., and decomposes at higher temperatures, yielding orcin and an empyreumatic oil. Solution of hypochlorite of calcium colours it yellowish. The ammoniacal solution absorbs oxygen from the air and acquires a dark red colour.

By the action of potash or baryta-water, evernic acid is resolved into orsellinic and evernic acids, the former of which is soon further decomposed into orcin and carbonic anhydride. Evernic acid quickly absorbs bromine. When boiled with alcohol it yields everninate and orsellinate of ethyl, the latter of which quickly undergoes further decomposition.

Evernic acid is monobasic. The *barium-salt*, $C^{11}H^{10}BaO^{11}$ + aq., forms small white prismatic crystals, sparingly soluble in cold water, easily in weak spirit. The *potassium-salt*, $C^{11}H^{10}KO^7$, is colourless, with silky lustre, sparingly soluble in cold water and in aqueous carbonate of potassium, easily in weak spirit and in caustic potash.

EVERNIC ACID, or *Evernesic acid*. $C^{11}H^{10}O^7$. (Stenhouse, *loc. cit.*)—A product of the decomposition of evernic acid under the influence of caustic alkalis:

The orsellinic acid quickly undergoes further decomposition into carbonic anhydride and orcin, which remains in the mother-liquor.

The best mode of preparing everninic acid is to boil evernic acid with baryta-water. Carbonate of barium is then deposited, and the filtrate treated with hydrochloric or acetic acid, yields a precipitate of everninic acid, which may be purified by boiling with water and animal charcoal (Stenhouse). Everninic acid may also be prepared directly from *Evernia prunastri* containing a large quantity of evernic acid, by boiling the lichen with water, evaporating down the aqueous solution, and mixing it with hydrochloric acid; it then after a while deposits impure everninic acid, which may be purified as above. (Hesse.)

Everninic acid forms crystalline laminæ resembling benzoic acid, colourless, tasteless, and inodorous; sparingly soluble in cold, moderately in boiling water, very easily in alcohol and ether. The solutions redden litmus. The acid melts at 147°C. , and is decomposed at a stronger heat, emitting an agreeable odour (suffocating, according to Hesse), and yielding a white crystalline sublimate.

Everninic acid dissolves easily in cold sulphuric acid; on heating the liquid, carbonisation takes place, with evolution of sulphurous anhydride.

Dilute nitric acid scarcely acts on everninic acid; the concentrated acid decomposes it slowly in the cold, more quickly with aid of heat, forming evernitic acid, together with oxalic acid and other substances not distinctly made out. (Hesse.)

Everninic acid is coloured yellowish by hypochlorite of calcium, like evernic acid, but is distinguished from the latter by not yielding orcin when boiled with potash, and by its ammoniacal solution not turning red on exposure to the air.

Everninic acid is monobasic; a few only of its salts have been prepared. *Everninate of barium*, $\text{C}^{\text{H}}^{\text{H}}^{\text{H}}\text{Ba}^{\text{O}} + 2\text{aq.}$, is obtained by decomposing evernic acid with baryta-water as above described; the liquid filtered from carbonate of barium is evaporated, freed from orcin and colouring matter by washing with alcohol or ether, and the residue is crystallised from weak spirit. The salt forms long, hard, four-sided prisms; it is nearly insoluble in absolute alcohol, but dissolves in weak spirit.

The *silver-salt*, $\text{C}^{\text{H}}^{\text{H}}^{\text{H}}\text{AgO}^{\text{O}}$, is obtained as a white precipitate on adding nitrate of silver to an ammoniacal solution of the acid.

Everninate of ethyl or Evernic ether, $\text{C}^{\text{H}}^{\text{H}}^{\text{H}}\text{O}^{\text{O}} = \text{C}^{\text{H}}^{\text{H}}(\text{C}^{\text{H}}^{\text{H}})^{\text{O}}^{\text{O}}$, does not appear to be produced by the action of hydrochloric acid gas on an alcoholic solution of evernic acid, but is obtained from evernic acid (p. 611), by boiling that acid for 8 or 10 hours with strong alcohol, evaporating nearly to dryness, washing with cold water to separate orcin (p. 611), and recrystallising from alcohol with aid of animal charcoal. Or better: evernic acid is dissolved in alcohol, with addition of caustic potash, and the liquid is boiled, neutralised with carbonic acid gas, and evaporated. The dark brown liquid, which still contains orcin, deposits brown crystals of evernic ether, which are purified with alcohol and animal charcoal.

Evernic ether forms long colourless crystals, destitute of taste and odour, insoluble in cold, and nearly insoluble in boiling water, easily soluble in alcohol and ether. It melts at 56°C. , and crystallises on cooling. It dissolves in caustic potash without decomposition; not in ammonia, or in carbonate of potassium.

EVERNITIC ACID. $\text{C}^{\text{H}}^{\text{H}}(\text{NO}^{\text{O}})^{\text{O}}^{\text{O}}$, or $\text{C}^{\text{H}}^{\text{H}}(\text{NO}^{\text{O}})^{\text{O}}^{\text{O}} (?)$. (O. Hesse [1861] Ann. Ch. Pharm. cxvii. 300.)—An acid resembling oxypicric acid, produced by the action of nitric acid on evernic acid. This acid, digested at a gentle heat with ten times its weight of strong nitric acid, dissolves with evolution of nitrous acid; and on saturating the brownish yellow solution with carbonate of sodium, evaporating to dryness, exhausting with alcohol, evaporating to expel the alcohol, filtering to separate an amorphous deposit, and mixing the filtrate with nitric acid, needles of evernitic acid are deposited after a few hours, while oxalic acid and other foreign substances remain in solution.

Evernitic acid forms long pale yellow prisms, or a white crystalline powder. It dissolves sparingly in cold, more readily in boiling water, forming a yellow solution which has an astringent taste, but no acid reaction. It dissolves easily in alcohol forming an acid solution; it dissolves also in ether. When heated it melts and carbonises, and if quickly heated, decomposes with slight explosion. It colours the skin yellow. Dissolves in nitric acid.

Evernitic acid is dibasic; the alkali-metal salts, which are easily soluble, may be obtained by direct union of the acid with the bases. The *barium-salt* separates, on adding chloride of barium to a solution of the sodium-salt mixed with acetic acid, in brownish yellow needles, which detonate strongly when heated. A lead-salt containing 30 per cent. lead is obtained in like manner by precipitation from an acid solution in yellow detonating needles.

Evernitate of potassium, $\text{C}^{\text{H}}^{\text{H}}\text{K}^{\text{O}}(\text{NO}^{\text{O}})^{\text{O}}^{\text{O}} + \frac{3}{2}\text{aq.}$, or $\text{C}^{\text{H}}^{\text{H}}\text{K}^{\text{O}}(\text{NO}^{\text{O}})^{\text{O}}^{\text{O}} + \frac{1}{2}\text{aq.}$, is separated from the solution of the acid in potash-ley by carbonic acid, in orange-yellow needles which dissolve with yellow colour in water and alcohol; the aqueous solution

is neutral. The crystals dried over oil of vitriol give off 6·7 per cent. water, and the dried salt gives by analysis 28·8 per cent. carbon, 2·8 hydrogen, and 21·7 potassium; numbers agreeing nearly with either of the preceding formulae, the first of which requires 28·79 C, 2·66 H, and 20·88 K; the second 29·00 C 2·12 H, and 21·05 K.

EXANTHALOSE. Native sulphate of sodium. (See SULPHATES.)

EXCREMENTS. The matters discharged from the intestinal canal consist partly of undigested residues of food, partly of certain intestinal secretions, which, after having served their purpose in effecting the digestion of the food, are no longer fit to return into the blood. The excrements have mostly an acid, sometimes, however, a neutral or alkaline reaction.

From the observations of Wehsarg (*Mikroskopische und chemische Untersuchungen der Faeces gesunder erwachsener Menschen*, Giessen, 1853), it appears that a full-grown healthy man discharges on the average, in twenty-four hours, 131 grammes (about 4 oz.) of faeces, containing 26·7 per cent. of solid matter (dried at 120° C.), therefore 35 grammes (about 1 oz.) of solid matter in twenty-four hours.

The solid matter of the excrements consists mainly of insoluble remnants of food, insoluble salts, and sand. The portions soluble in water, alcohol, and ether, contain, though by no means constantly, albuminous matters, volatile fatty acids, among which are butyric and acetic acids, lactic acid, sugar, taurine, resinous products of the decomposition of bile, including choleoidic acid and dyslysin, unaltered bile-pigment, but very rarely undecomposed bile (only indeed when the alimentary matters pass rapidly through the intestines, as in diarrhæa or tuberculosis, or when the secretion of bile is abnormally increased, as by the action of calomel),—fat (sometimes in considerable quantity and in masses resembling margarin), excretin and excretolic acid, and small quantities of soluble salts, chiefly alkaline phosphates, with mere traces of sulphates and chlorides, the potassium-salts being more abundant than the sodium-salts. The portion of the excrements insoluble in water, alcohol, and ether contains,—besides food-remnants and sand—earthy and ferric phosphates, and sometimes oxalate of calcium (after the taking of food containing oxalates).

Berzelius (*Lehrbuch*, 4 Aufl. ix. 340—349) found in human faeces :

Water	75·3
Bile	0·9
Albumin	0·9
Peculiar extractive matter	2·7
Salts	1·2
Insoluble residue of digested aliments	7·0
Insoluble matters added in the intestinal canal, mucus, biliary resin, and peculiar animal fat.	12·0
	100·0

Wehsarg found in 1000 pts. of human faeces, 733 pts. of water and 267 pts. of solid matter, yielding on the average 53·4 pts. of matter soluble in water, 41·6 alcoholic extract, 30·7 ether-extract, 80·0 insoluble food-residues, and 10·95 inorganic salts precipitable by ammonia.

In the ash of human excrement Porter (Ann. Ch. Pharm. lxxi. 109) found :

K ₂ O	Na ₂ O	CaO	MgO	Fe ² O ₃	P ² O ₅	SO ₃	CO ₂	NaCl
6·10	5·07	26·46	10·54	2·50	36·03	3·13	5·07	1·33 = 96·23

Fleitmann (Pogg. Ann. lxxv. 356) found in the ash 30·58 per cent. soluble salts. According to Berzelius, human excrements contain relatively less lime and more magnesia than the food; and, according to Wehsarg, they contain only traces of phosphate of calcium, but considerable quantities of phosphate of magnesium. According to Porter's analysis, however, the proportion of lime exceeds that of magnesia. The proportion of soluble salts in the solid excrements is, under normal conditions, very much less than in the urine, and only becomes considerable in diarrhæa, cholera, and other diseases of the intestinal canal.

The following results respecting the constitution of the excrements of man and animals have been obtained by Dr. Marcet (Phil. Trans. 1854, p. 265; 1857, 403). When healthy human faeces are completely exhausted with boiling alcohol, a residue is obtained which is completely insoluble in ether, and from which boiling water extracts nothing but ammonio-magnesian phosphate. The clarified alcoholic solution deposits after long standing a precipitate which appears to contain a peculiar granular substance and an olive-coloured fatty acid, excretolic acid, which melts between 25° and 26° C. The alcoholic solution separated from this deposit and mixed with milk of lime, yields a brown precipitate, from which, after drying, ether extracts :

crystallisable substance, **excretin**. Marcet is of opinion that human faeces generally contain excretin in the free state. The lime precipitate, freed from excretin by means of ether and treated with hydrochloric acid, yields margaric acid; it likewise contains a colouring matter apparently resembling that of the blood, or that which Harley (Proc. Roy. Soc. vii. 122) has obtained from urine. The amount of margaric acid seems to depend on the quantity of vegetable food. In the acid excrements of a patient in whom the flow of bile into the intestine was obstructed by the pressure of an enlarged and disorganised pancreas, Marcet found acid stearate of sodium, together with considerable quantities of free fatty acids. (Chem. Soc. Qu. J. x. 162.)

The faeces of carnivorous animals contain, not excretin, but a substance resembling it, together with butyric acid; those of the crocodile contain cholesterin, but no uric acid; those of the boa contain uric acid, but no cholesterin; and those of vegetable-feeding animals contain neither excretin, butyric acid, nor cholesterin.

The excrements of birds and serpents, which, mixed with the renal secretion, are discharged from these animals through the cloaca, partake, to a great extent, of the nature of urine, consisting chiefly of alkaline urates and earthy phosphates. (See GUANO and URINE.)

The excrements of insects consist mainly of the remnants of the tissues, animal or vegetable, which they have swallowed as food, mixed with constituents of the urine, if the insect is not provided with special urinary organs.

For further details on excrements, see *Lehmann's Physiological Chemistry*, translated by Day, ii. 141; iii. 517.—*Gmelin's Handbuch*, viii. 93.—*Handw. d. Chem.* ii. [3] 971.

EXCRETIN. $C^{12}H^{16}O_2$. (Marcet, *loc. cit.*, also Proc. Roy. Soc., ix. 308.)—This substance crystallises readily from the alcoholic extract of the faeces, in silky crystals, very soluble in ether, sparingly soluble in cold alcohol, insoluble in water. It has an alkaline reaction, and is not decomposed by dilute mineral acids. Melts between 96° and 96° C. Human faeces contain, on the average, 0.46 grm. of impure excretin, and 0.184 grm. of pure excretin in one evacuation. The faeces of a child one year old were found to contain not excretin, but cholesterin.

EXCRETOLIC ACID. A fatty acid, obtained by Marcet from the alcoholic extract of human excrements (for the method of obtaining it, see page 613). It has a feculent odour; melts at 26° — 26° C.; and when heated on platinum-foil, emits an odour like that of burning excretin, and burns away with a bright flame. It is insoluble in water, soluble in ether, sparingly soluble in cold, easily in hot alcohol. The solution has a distinct acid reaction.

EXOPHACIN. The name given by Valenciennes and Frémy to the outer portion of the crystalline lens of the eyes of mammalia.

EXOSMOSE. See OSMOSE.

EXPANSION. See HEAT.

EXSICCATOR. A drying apparatus, consisting of an enclosed space containing substances which rapidly absorb moisture, such as oil of vitriol, dry chloride of calcium, &c.

EXTRACT. A pharmaceutical term, applied to the tough or viscid masses, obtained by treating organic substances with solvents, and then evaporating the solvent. (See *Ure's Dictionary of Arts, Manufactures, and Mines*, ii. 167; and *Handwörterbuch der Chemie*, ii. [3] 977.)

EYE. The eye consists of three coatings, the sclerotic, choroid, and retina, enclosing the crystalline lens, and two transparent liquids or humours, the aqueous and the vitreous.

The sclerotica is a hard, tough membrane, enveloping the entire globe of the eye, opaque for the most part, but transparent in front: this transparent portion, which is more convex than the rest, is called the cornea.

The sclerotica is composed of a tissue which is converted into chondrin by the action of boiling water, leaving only a small residue of vessels. Boiling hydrochloric acid first contracts and then dissolves it rapidly. Acetic acid converts it into a jelly soluble in water, forming a solution which is not rendered turbid by ferrocyanide of potassium. The sclerotica contains in 100 pts., 51.00 C, 7.08 H, 18.72 N, and 23.20 O. (Scherer.)

The cornea is also composed of tissues which yield chondrin when boiled with water and dissolved in hydrochloric acid. Acetic acid first contracts the cornea and then dissolves it completely. The solution is precipitated by potash, and by ferrocyanide of potassium.

The choroid is a tissue lining the interior of the eye-ball, next to the sclerotic coat; it yields chondrin when boiled with water.

The retina, which is the innermost coating of the eye, is soft and semitransparent,

and approaches in composition to the nerves and brain; it may, indeed, be regarded as an expansion of the optic nerve. It contains, according to Lassaigne, 92·90 per cent. water, 0·85 saponifiable and phosphoretted fat, and 6·25 albumin.

Between the choroid and the retina is interposed a layer of cells filled with a black opaque substance, called the black pigment, the *pigmentum nigrum* or *ophthalmo-melanin*. When separated by washing from the enclosing membrane, it forms a heavy black powder, perfectly insoluble in water, alcohol, and ether, sparingly soluble or insoluble in dilute mineral acids, but dissolved by caustic potash, with evolution of ammonia. It burns with an unpleasant odour, leaving a small quantity of ash containing iron. The organic matter of the black pigment contains, according to Scherer, 58·0 per cent. C, 6·0 H, 14·0 N, and 22·0 O.

The iris, which is the coloured reticular membrane, situated in front of the eye, just behind the cornea, consists chiefly of fibrin.

The crystalline lens is a transparent body, having the form of a double convex lens, situated behind the pupil. In man and mammiferous animals in general, it consists of fibres, which, in the central portions of the lens, the *exophacin*, consists of an albuminous substance (*albumin α*), which coagulates at about 65° C., but does not lose its transparency when treated with alcohol, even for a long time. In the outer portion of the lens, the *exophacin*, the fibres are united by another albuminous substance (*metalumin*), which does not coagulate at the boiling heat; both these substances differ from ordinary albumin (i. 66), in not forming a blue solution with hydrochloric acid. The crystalline lenses of birds and reptiles differ but slightly from those of mammalia. The crystalline lens of fishes is also formed of two parts, the outer of which (the *exophacin*) consists of metalumin, the inner of an albuminous substance, insoluble in water, called *phaconin*. The fibres of the crystalline lens of mammalia exhibit a close resemblance to the *phaconin* of fishes.

These several albuminous bodies do not differ much in composition, either from each other or from ordinary albumin (i. 67), as the following table will show: —

	Albumin α	Metalumin.	Phaconin.
Carbon	51·89	52·8	52·11
Hydrogen	6·75	7·3	7·69
Nitrogen	15·46	16·0	16·53
Oxygen	25·90	23·9	23·67
	100·00	100·0	100·00

In the eye of a horse which had become blind by cataract, the albumin and the metalumin were found to be insoluble in water, and a number of membranes had formed, nearly opaque, and easily separated from one another. These membranes, when incinerated, did not leave a larger proportion of ash than ordinary white of egg. (Valenciennes and Fromy, *Compt. rend.* xlv. 1122.)

The aqueous humour, which fills the space between the cornea and the crystalline lens, is a mobile saline liquid, having a specific gravity of 1·0053, and containing, according to Berzelius, 98·10 per cent. water, 1·15 chloride and lactate of sodium, and 0·76 free soda, besides a small quantity of albumin.

The vitreous humour is a gelatinous liquid, which fills up the entire space behind the crystalline lens. It has a saline taste, is colourless and transparent, but becomes opaline when boiled. It contains 98·40 per cent. water, 0·16 alkaline chlorides and lactates, and 1·42 soda and animal matter (Berzelius). The colour and composition of the vitreous humour vary, however, with age; in the fetus it is red and contains blood; in old age it sometimes becomes yellow. In the vitreous humour of a blind horse, Lassaigne found a peculiar yellow colouring matter, and 8 per cent. of albumin. (Pelouze et Frémy, *Traité de Chimie générale*, 2^{me} édition, vi. 220, 293.)

F.

FÆCES. See EXCREMENTS.

FAGIN. A substance found by Buchner and Herberger in beech-nuts, the fruit of *Fagus sylvatica*, but only imperfectly examined. It is said to be a yellow sweetish mass, easily soluble in water and alcohol, sparingly in ether, decomposed by strong acids and by dry distillation, but distilling undecomposed with the vapour of water or alcohol.

FAGUS. See BEECH (i. 526).

FAHL-BEL. See TETRAHEDRITE.

FAHLUNITE. A variety of hydrous dichroite, $2M^2O \cdot SiO^2 + 2AlO^3 \cdot 3SiO^2 + 3 aq.$

(p. 310), occurring at Fahlun in Sweden. The crystalline form is the same as that of dichroite, of which indeed it appears to be a pseudomorph. Specific gravity = 2.6 to 2.79. Somewhat harder than apatite. Colour greenish, yellowish, brownish, to black. Lustre feeble, perceptible only on the crystalline faces. Fracture splintery.

Analyses.—*a.* by Hisinger (Athandl. i. Fysik, iv. 210).—*b.* Brownish-green; *c.* Black; *d.* Crystallised: by Wachtmeister, Pogg. Ann. xiii. 70).

	SiO ₂	Al ₂ O ₃	MnO	Mn ² O ₃	Fe ² O ₃	FeO	MgO	CaO	Na ₂ O	K ₂ O	H ₂ O	F
<i>a.</i>	46.79	26.73	. . .	0.43	. . .	5.01	2.97	13.50	. . . = 95.43
<i>b.</i>	43.51	25.81	1.72	. . .	6.35	. . .	6.53	. . .	4.45	0.94	11.66	0.16 = 101.13
<i>c.</i>	44.60	30.10	. . .	2.24	. . .	3.86	6.75	1.35	. . .	1.98	9.35	. . . = 100.23
<i>d.</i>	44.95	30.70	. . .	1.90	. . .	7.22	6.04	0.95	. . .	1.38	8.65	. . . = 101.79

Bonsdorffite from Abo in Finland (p. 321) appears to have the same composition; also pepolite from Sweden and pyrrargyllite from Helsingfors. (Rammelsberg, p. 832.)

FASSAITE. A variety of augite from the Fassa valley, Piedmont, having a grass-green or pistachio-green colour, with high lustre.

FATS. The term *Fat* was originally applied to all compounds consisting of carbon, hydrogen, and a small quantity of oxygen, which, either at ordinary temperatures form viscid, oily liquids, greasy and leaving a permanent stain on paper, or are converted into such liquids by heat,—which require a strong heat to make them boil, and then distil over in a state of complete, or nearly complete decomposition,—burn with a bright flame, depositing little or no soot,—and are insoluble in water, but soluble in alcohol and in ether.

Fats were divided, according to their various degrees of fusibility, into *liquid fats* or *fatty oils*, *expressed oils*, or *fixed oils*, which, according as they dry up or remain greasy when exposed to the air in thin layers, were subdivided into *drying oils* and *non-drying oils*, and into *solid fats*, such as lard, tallow, wax, spermaceti, cholesterin, &c.

Chevreul, to whose fundamental investigations we are indebted for the greater part of our knowledge of this subject, showed, nearly at the same time with Braconnot, that fats, as they occur in nature, are for the most part mixtures or combinations of different simple fats, *e. g.* of olein, stearin, and margarin, in variable proportions, the consistence and fusibility of the mixture varying accordingly. He showed, moreover, that certain fats (non-saponifiable fats), neither dissolve nor undergo any other change when boiled with aqueous alkalis, whereas most of these bodies form soaps with aqueous alkalis and with certain heavy metallic oxides; that, in this process of saponification, the fats do not combine in their original state with the alkalis, but that they are thereby resolved into two products, viz. first, a fatty acid, which combines with the alkali and forms the soap, and differs in its composition according to the nature of the fat,—and secondly, in most cases, the substance called glycerin, which Scheele obtained by treating fixed oils with lead-oxide and water. He showed that the sum of the weights of these two products, in their utmost state of dryness, exceeds that of the fat employed, and consequently that hydrogen and oxygen from the water must likewise contribute, in equal numbers of atoms, to the formation of the product; whence he concluded that these saponifiable fats are analogous in composition to compound ethers, viz. compounds of various fatty acids with glycerin *minus* a certain quantity of water, just as compound ethers are compounds of alcohol with acids *minus* a certain quantity of water.

In accordance with the investigations of Chevreul, which have since been confirmed and extended, the family of the fats has been broken up, and its members arranged according to their chemical nature, as follows:

1. *Unsaponifiable Fats.*—These substances remain perfectly unaltered even after long boiling with aqueous potash. According to their composition, they belong partly to the hydrocarbons, such as paraffin, partly to the alcohols, as ethal and cholesterin.

2. *Fatty acids or Soap acids.*—Obtained chiefly by the saponification of saponifiable fats. They combine with salifiable bases, without any further addition, and are completely separated therefrom in their original state by stronger acids; hence they properly belong to the class of organic acids, and are in fact included therein. According to their boiling points, they may be divided into *volatile fatty acids*, as butyric, capric acid, &c.; and *fixed fatty acids*, as stearic, palmitic, oleic acid, &c.

3. *Saponifiable Fats.*—These fats do not combine in their entire state with alkalis, but in contact with alkalis and with water are gradually resolved into a fatty acid which unites with the base and forms a soapy salt, and a neutral body, which, in most fats of this kind, is glycerin, but in some, as cerin and spermaceti, is a non-saponifiable fat.

The results obtained by Chevreul have, within these last few years, been confirmed and extended by the researches of Berthelot, who has shown that fats may be artificially produced by the direct union of the fatty acid and glycerin, with elimination of 1, 2, or 3 at. water. The natural fats, stearin, olein, &c. are for the most part of the third class. (See GLYCERIDES.)

FAUJASITE. A silicate occurring, together with black augite, in the mandelstein of the Kaiserstuhl in Baden. It crystallises in dimetric octahedrons, in which the angle of the terminal edges is $111^{\circ} 30'$, that of the basal edges $105^{\circ} 30'$. Hardness = 5. Specific gravity = 1.923. Colourless to brown. Fracture, vitreous and uneven. Gives off water when heated in a tube. Intumesces before the blowpipe, and melts to a white blemmy enamel. An analysis by Damour (Ann. Min. [4] xiv. 67) gave 46.12 per cent. silica, 16.81 alumina, 4.79 lime, 5.09 soda, and 27.02 water (= 99.83). Hence the formula $\left(\frac{1}{2}\text{CaO} + \frac{1}{2}\text{Na}_2\text{O}\right) \cdot 3\text{SiO}_2 + 2(\text{Al}^{2\text{O}_3} \cdot 3\text{SiO}_2) + 18\text{aq.}$, which, by substituting $\text{al} = \frac{2}{3}\text{Al}$, and, considering part of the hydrogen as basic, may be reduced to the form of a metasilicate $(\text{M}^{1\text{al}}\text{H}^{2\text{Si}})\text{Si}^{2\text{O}} + 17\text{aq.}$

FAYALITE. An iron chrysolite (*Eisenerpidot*), Fe^2SiO_4 , occurring in pegmatite on the Mourne mountains, Ireland, also in volcanic rocks at Fayal, one of the Azore islands. It is trimetric, cleavable in two directions at right angles to each other. Hardness = 6.5. Specific gravity = 4.11—4.14; 4.006, according to Delesse. Colour, black, greenish or brownish; sometimes iridescent. Fuses readily to a black magnetic globule, and is easily attacked by acids.

Analyses.—1. Thomson (*Outlines of Mineralogy*, i. 461).—2. Delesse (Bull. géol. [2] x. 568).—3. Rammelsberg (*Mineralchemie*, p. 435.)

	SiO ²	FeO	MnO	Al ² O ³	K ² O	MgO	CaO	CuO	FeS
1. Slievearrach, Ireland	29.60	68.73	1.78						= 100.11
2. " "	29.50	63.54	5.07	trace	0.30				= 98.11
3. Fayal	28.27	63.80		3.45		trace	0.45	1.20	3.35 = 100.61

Iron-chrysolite has been observed as a furnace-product near Goslar. A volcanic glass or obsidian analysed by Klaproth (*Beiträge*, v. 222), yielded similar results: 29.50 SiO_2 , 66.00 FeO , 4.0 Al^{2O_3} , and 0.25 $\text{K}^{2\text{O}}$; but G. Rose considers it as a slag. (Dana, ii. 185.)

FAYENCE. The French name for the glazed earthenware used for common plates, dishes, jugs, and other vessels. (See POTTERY.)

FEATHER-ALUM. A name applied to native hydrated sulphate of aluminium $(\text{Al}^{2\text{O}_3}(\text{SO}_4)^3 + 18\text{H}_2\text{O})$, and to native iron-alum or halotrichite $\left\{ \begin{smallmatrix} \text{Fe}^{2\text{O}_3} \\ (\text{Al}^{2\text{O}_3})^{\text{Fe}^{2\text{O}_3}} \end{smallmatrix} \right\} 2\text{SO}_4 + 12\text{H}_2\text{O}$, both of which occur in delicate fibrous crystals or masses. (See SULPHATES.)

FEATHER-ORE. This name is applied to the capillary form of native sulphantimonite of lead, $2\text{PbS} \cdot \text{Sb}_2\text{S}_3$; but as this mineral likewise occurs massive, the name *hctromorphite* (q. v.) proposed for it by Zincken and Rammelsberg is preferable.

FEATHERS. The beard and quill of feathers were found by Scherer to contain:

	C.	H.	N.	O and S.
Beard . . .	52.47 . . .	7.11 . . .	17.68 . . .	22.44 = 99.70
Quill . . .	52.43 . . .	7.21 . . .	17.89 . . .	22.47 = 100.00

whence it appears that the two parts of the feather have essentially the same composition.

The ash of feathers, especially of birds which live on grain, contains a large proportion of silica; the feathers of birds which live on animal food or on berries yield a smaller total amount of ash, and this ash is also less rich in silica, as will be seen from the following table, containing the results obtained by Gorup-Besanez (Ann. Ch. Pharm. lxi. 46; lxxi. 321).

In birds living on:	Ash.	Silica.	Percentage of silica in the ash.
Seeds . . . the feathers contain in 100 pts.	4.84	1.93	40
Fish . . .	2.41	0.23	10.5
Flesh . . .	2.16	0.64	27
Insects, Berries	2.62	0.75	27

The feathers of old birds are richer in silica than those of young ones; the wing-feathers contain more silica than those of the tail and breast.

The permanent colours of feathers are due to peculiar pigments which may be

extracted by various solvents. The beautiful play of colours which some feathers exhibit as the light falls upon them at different incidences, arises from a decomposition of light similar to that which is produced by mother-of-pearl and other striated surfaces.

According to Bogdanow (Compt. rend. xlv. 688; xlv. 780) the yellow, green, lilac, and red pigments of feathers of constant tint are soluble in alcohol and ether; black feathers contain a pigment (*Zoomelanin*), probably identical with the black pigment of the eye, which is insoluble in alcohol and ether, soluble in ammonia and potash, and slightly in water. Feathers of varying colour yield green and brown pigments, probably identical in composition with the preceding.

Feathers when heated emit a characteristic and unpleasant odour. According to Greville Williams (Chem. Gaz. 1858, p. 309), they yield, when submitted to destructive distillation, considerable quantities of pyrrol, a mixture of volatile bases, and a gas containing sulphur, which quickly decomposes peroxide of lead.

Goose-feathers boiled for a considerable time with dilute sulphuric acid, yield leucine and tyrosine. The beard of feathers heated to 200° C. with water in sealed tubes for several hours dissolves completely, forming a yellowish liquid which smells like burnt feathers, and deposits a flocculent precipitate (Loyer and Keller, An Ch. Pharm. lxxxviii. 332).

Feathers damaged by bending may be completely restored to shape by dipping them for a minute in boiling water, and then in cold water till they are quite cool (Böttger, J. Pharm. [3] xxxiv. 399).

FELDSPAR. Syn. with FELSPAR.

FELSITE. A compact variety of labradorite, which, together with hornblende, forms the greenstone of Siebenlehn in the Erzgebirge. Specific gravity = 2.6. Contains 51.00 per cent. SiO_2 , 30.50 Al_2O_3 , 1.75 Fe_2O_3 , 11.25 CaO , 4.00 Na_2O , 1.00 water (= 99.75). (*Rammelsberg's Mineralchemie*, p. 600.)

FELSOBANYITE. Syn. with GIBBSITE.

FELSPAR. This name * is applied to a group of minerals which crystallise in monoclinic and triclinic systems, and may all be represented, either as silicates of alumina united in various proportions with silicates of the alkalis or alkaline earths, or as orthosilicates containing aluminium and an alkali- or alkaline-earth-metal combined (excepting in the case of anorthite) with excess of silica. On the former mode of representation, they are distinguished from one another by the ratio of the oxygen in the protoxide, the alumina, and the silicic anhydride; in the second, by the proportion of free silicic anhydride associated with the orthosilicate.

The following table shows the composition of the several minerals of the feldspar group:

Oxygen ratio.

Anorthite	. 1 : 3 : 4, $\text{Ca}''\text{O}.\text{Al}^2\text{O}^3.2\text{SiO}^2$ or $\text{Ca}''(\text{Al}^2)^{\text{vi}}(\text{SiO}^4)^2$	$= \frac{(\text{Si}^{\text{iv}})^2}{\text{Ca}''(\text{Al}^2)^{\text{vi}}}$
Labradorite	. 1 : 3 : 6, $\text{M}^2\text{O}.\text{Al}^2\text{O}^3.3\text{SiO}^2$ or $\text{M}^2(\text{Al}^2)^{\text{vi}}(\text{SiO}^4)^2.\text{SiO}^2$	$= \frac{(\text{Si}^{\text{iv}})^3}{\text{M}^2(\text{Al}^2)^{\text{vi}}}$
Andesine and Hyalophane	$\left\{ \begin{array}{l} 1 : 3 : 8, \text{M}^2\text{O}.\text{Al}^2\text{O}^3.4\text{SiO}^2 \text{ or } \text{M}^2(\text{Al}^2)^{\text{vi}}(\text{SiO}^4)^2.2\text{SiO}^2 \end{array} \right.$	$= \frac{(\text{Si}^{\text{iv}})^4}{\text{M}^2(\text{Al}^2)^{\text{vi}}}$
Oligoclase	. 1 : 3 : 9, $2\text{M}^2\text{O}.2\text{Al}^2\text{O}^3.9\text{SiO}^2$ or $2[\text{M}^2(\text{Al}^2)^{\text{vi}}\text{SiO}^4].5\text{SiO}^2$	$= \frac{(\text{Si}^{\text{iv}})^9}{\text{M}^2(\text{Al}^2)^{\text{vi}}}$
Albite and Orthoclase	$\left\{ \begin{array}{l} 1 : 3 : 12, \text{M}^2\text{O}.\text{Al}^2\text{O}^3.6\text{SiO}^2 \text{ or } \text{M}^2(\text{Al}^2)^{\text{vi}}(\text{SiO}^4)^2.4\text{SiO}^2 \end{array} \right.$	$= \frac{(\text{Si}^{\text{iv}})^6}{\text{M}^2(\text{Al}^2)^{\text{vi}}}$

If silica be regarded as SiO^2 , and the small atomic weights of oxygen, aluminium, calcium, &c., $\text{Al} = 13.7$, $\text{Ca} = 20$, be used [$\text{Si} = 21$; $\text{O} = 8$], the formulæ become

Anorthite	. . . $3\text{CaO}.3\text{Al}^2\text{O}^3.4\text{SiO}^2$	Oligoclase $\text{MO}.\text{Al}^2\text{O}^3.3\text{SiO}^2$
Labradorite	. . . $\text{M}^2\text{O}.\text{Al}^2\text{O}^3.2\text{SiO}^2$	Albite and Orthoclase $\text{MO}.\text{Al}^2\text{O}^3.4\text{SiO}^2$
Andesine and Hyalophane	$\left\{ \begin{array}{l} 3\text{M}^2\text{O}.3\text{Al}^2\text{O}^3.8\text{SiO}^2 \end{array} \right.$	

* It is sometimes written "Feldspar," in imitation of the German *Feldspath*, derived from *Feld* field; but "Felspar," signifying a spar found on a *rock* or *fel*, is the more correct spelling.

perfect parallel to oP ; less perfect parallel to $[\infty P\infty]$. Often massive, cleavable, granular, sometimes coarsely lamellar.

Hardness = 6. Specific gravity = 2.4–2.62. Lustre vitreous, sometimes inclining to pearly on the surface of perfect cleavage. Colour white, gray, reddish-white, flesh red, greenish-white, green. Streak uncoloured. Transparent to translucent. Fracture conchoidal to uneven.

Before the blowpipe it melts with difficulty to a semi-transparent blebby glass (the heat of the porcelain furnace, to a greyish white frothy glass). According to Turner, many altered feldspars give a slight indication of the presence of boric acid, is not attacked by acids.

The formula $K^2O.Al_2O^3.6SiO^2$ requires 64.8 SiO², 18.4 Al²O³, 16.8 K²O = 100.

Soda, as already observed, generally replaces part of the potash and sometimes predominates, as in lozoclaste. Lime and magnesia are almost always present in small amount, some glassy feldspars containing as much as $2\frac{1}{2}$ to $2\frac{3}{4}$ per cent. of lime. Feldspar also contains a small quantity of phosphoric acid. (Fownes, Ann. Ch. Phil. lx. 190.—Sullivan, Phil. Mag. [3] xxvii. 161.)

The different varieties of feldspar are distinguished by their colour, lustre, and transparency. The common subtranslucent variety, or orthoclase, is the ordinary constituent of granite: it occurs in fine crystals at Baveno on the Lago Maggiore, in Silesia, Carlsbad and Elnbogen in Bohemia, Arendal in Norway, the Land's End, the Mourne Mountains in Ireland, Alabashka, and other places in the Ural, near Janeiro, at Rossie in St. Lawrence County, New York, and other localities. *Lozoclaste* found at Hammond, in St. Lawrence County, N. Y., is distinguished by more distinct cleavage parallel to the basal and clinodagonal sections. Specific gravity = 2.6.—(Plattner.) *Natronite* is a variety which gives off a fetid odour when struck.—*Chesterite* is from Chester County, Pennsylvania.—*Adularia* is a transparent or translucent variety, found in granitic rocks. Large crystals of it are found on the St. Gothard. *Valencianite* is a variety of adularia from the Valenciana mine, in Mexico.—*Moonstone* from Ceylon, is also a variety of adularia, exhibiting pearly reflections when polished. *Sunstone* is a similar variety, containing minute scales of oxide of iron.—*Amazon feldspar* is less pellucid, and has yellow and reddish internal reflections.—The *Moonstone* of Levy is a flesh-red variety of feldspar (specific gravity = 2.51) occurring in rolled pebbles at Heavitree, near Exeter.—*Amazon-stone* is a verdigris-green variety coloured by copper, from Lake Ilmen.—*Leelite* or *Hellefinta*, from Gryphytta, Sweden, has a waxy lustre, and deep flesh-red colour.—*Variolite* is a dark green variety containing lighter globular particles, from the river Drac, in France.—The *Microlite* of Breithaupt, is a variety of feldspar from Arendal; the *Erythrite* of Thomson is a flesh-coloured feldspar, containing 3 per cent. magnesia, found in amygdaloid. Specific gravity = 2.541.—The *Perthite* of Thomson, is from Perth in Upper Canada.

All the varieties of feldspar above mentioned occur in rocks of the older formation. *Glassy feldspar*, also called *Sandstein* (from *sand*, a board, the crystals being tabular and found in trachytic and volcanic rocks of recent origin; it has a perfect vitreous lustre and is traversed by numerous cracks. A variety called *Ice-spar* is found in the Tertiary lavas; the *Rhyacolite* of G. Rose is also a glassy feldspar from Vesuvius.

According to Bischof, the mode of occurrence of feldspar, and the minerals with which it is associated, are, in most cases, such as prove it to have been formed by recent

that have taken place in the wet way, although the possibility of its formation by fusion is established by its occurrence in violet-coloured crystals on the inner walls of a smelting furnace at Sangerhausen. (*Chem. and Phys. Geology*, by Gustav Bischof, Eng. edit. ii. 162, *et. seq.*)

Alterations of Felspar.—Felspar is altered by the action of water containing carbonic acid (Forchhammer), or rendered acid by the decomposition of pyrites (Mitscherlich), or containing alkaline and other ingredients in solution, the change consisting in the abstraction of the alkali and a portion of the silica, and the assumption of water. The ultimate products of this alteration are hydrated silicates of aluminium, viz. *kaolin* and its varieties, *pholerite*, *halloysite*, *samotte*, and *bole*, and the several kinds of clay. The following are analyses of partially decomposed felspars.

a. Orthoclase from the porphyry of the Auerberg, near Stolberg, in the Harz; white, rather soft (Rammelsberg, *Mineralchemie*, p. 629).—b. Decomposed orthoclase from the granite of Karlsbad.—c. The same from the syenite of Geising, near Altenberg, in the Erzgebirg.—d. The same from the red porphyry of Ilmenau, in the Thüringerwald (Crasso, *loc. cit.*):

	SiO ²	Al ² O ³	Fe ² O ³	MnO	CaO	MgO	K ² O	Na ² O	H ² O	CaCO ³	
a.	66.26	16.98	0.31	.	0.43	0.11	14.42	0.20	1.29	.	= 100
b.	64.17	29.93	1.22	.	0.59	0.46	4.67	0.41	8.51	.	= 99.96
c.	70.79	17.09	1.15	.	0.35	0.65	5.86	0.38	3.67	.	= 99.94
d.	23.17	7.30	12.53	0.17	.	0.61	2.12	0.21	.	49.46	= 95.67

In a the alteration is rather mechanical than chemical. The deficiency in d is probably due to loss of water in the analysis.

Felspar is also gradually converted by loss of silica and alkali, into mica. This transformation, first observed by G. Rose in the felspar crystals of Lomnitz and Hirschberg in Silesia, has lately been more exactly investigated by v. Rath (Pogg. Ann. xlviii. 280). In the three following analyses, a is the flesh-red orthoclase in the interior of the mass, of specific gravity 2.544, and yielding only traces of water when heated. The zone of weathered mineral b, immediately surrounding this is greenish-white, granular, friable, of rough, uneven fracture, and filled throughout its mass with specks of silvery lustre; its specific gravity is 2.616. The external layer c consists of mica in greenish scales, which turn brown when heated; their specific gravity is 2.867. For analysis they were separated from intermixed quartz-granules.

	SiO ²	Al ² O ³	Fe ² O ³	CaO	MgO	K ² O	Na ² O	Loss by ignition.
a.	66.66	18.86	0.46	0.36	0.21	11.12	3.01	0.50 = 101.18
b.	65.48	20.34	1.32	0.54	0.30	9.21	2.98	1.34 = 100.61
c.	49.04	29.01	5.56	0.17	0.75	11.19	0.50	4.65 = 100.87

The Orthoclase, in changing into mica, parts with about half its alkali and $\frac{5}{8}$ of its silica. (Rammelsberg's *Mineralchemie*, p. 630.)

Albite. Soda-felspar. Cleavelandite. Periclin. Triclinic. Kieselspath.

Triclinic, an ordinary combination being $\infty P'$, $\infty \bar{P} \infty$, oP, P', $\bar{P} \infty$ (fig. 477). Cleavage very perfect parallel to oP; less distinct parallel to $\infty P \infty$; imperfect parallel to P'. Twin crystals are frequent, generally having the face of combination parallel to $\infty \bar{P} \infty$ (fig. 478) see p. 265; indeed the tendency of this mineral to form twins is so

Fig. 477.

Fig. 478.

great, that even crystals and crystalline fragments of apparently simple structure are generally found to consist of a large number of lamellar twins, producing on certain fractured surfaces striations which are characteristic of albite. The mineral likewise occurs lamellar and granular, sometimes almost impalpable.

Hardness = 6–6.5; in some granular varieties = 7. Specific gravity = 2.59–2.66.

Lustre, vitreous; on the cleavage-faces, pearly. Colourless, white of various shades, light red, yellow, green, and grey. Streak uncoloured. Transparent to subtranslucent. Fracture uneven. Brittle.—Before the blowpipe, it behaves very much like orthoclase, but melts somewhat more easily, and colours the flame distinctly yellow.

Analyses.—1. G. Rose (Pogg. Ann. lxxiii. 173).—2. Thaulow (*ibid.* xlii. 571).—3. Abich (Berg. u. hüttenm. Zeitung, 1842, No. 19).—4. Stromeyer (*Untersuchungen*, p. 300).—5. Abich (*loc. cit.*)—6. Hunt (Phil. Mag. [4] i. 322).—7. Rammelsberg (*Mineralchemie*, p. 620).

	SiO ²	Al ² O ³	Fe ² O ³	CaO	MgO	K ² O	Na ² O	MnO	
1. Crystallised, Arendal	68.46	19.30	0.28	0.68	9.12	. . .	=	97.84
2. „ St. Gothard	69.00	19.43	. . .	0.20	11.47	. . .	=	100.10
3. „ Minsk	68.45	18.71	0.27	0.50	0.18	0.65	11.24	trace	= 100.00
4. Massive, Chesterfield	70.68	19.80	0.11	0.24	9.06	. . .	=	99.89
5. Periclin, Pantellaria	68.23	18.30	1.01	1.26	0.51	2.53	7.99	. . .	= 99.83
								ign.	
6. Peristerite, Perth, } Lower Canada }	66.80	21.80	0.30	2.52	0.20	0.58	7.00	0.6	= 99.80
7. Hypoclerite, Arendal	67.62	16.59	2.30	0.85	1.46	0.51	10.24	. . .	= 99.57

The formula $\text{Na}_2\text{O} \cdot \text{Al}_2\text{O}_3 \cdot 6\text{SiO}_2$ requires 68.7 SiO₂, 19.5 Al₂O₃, 11.8 Na₂O = 100.

Hypoclerite, which has a specific gravity of 2.6–2.66, and is softer than albite, is, according to Rammelsberg, a mixture of albite with 5 per cent. augite.—A white massive felspar from the St. Gothard, containing nearly equal quantities of potash and soda (67.39 SiO₂, 19.24 Al₂O₃, 0.31 CaO, 0.61 MgO, 6.77 K₂O, and 6.23 Na₂O), appears to be a mixture of albite and orthoclase.

Albite often replaces orthoclase as a constituent of granite; in other instances it is associated with orthoclase, as in Pompey's pillar, and may then be distinguished by its superior whiteness. The albite granites are often repositories of several of the granite minerals, *e. g.* tourmalin, beryl, and allanite. Albite is associated with pearly spar in the Tyrol, where it occurs in large transparent crystals; with epidote and garnet at Arendal; with eudialyte and hornblende in Greenland. It is frequently one of the constituents of syenite and greenstone. (Dana, ii. 240.)

Soda-felspars yield more rapidly than potash-felspars to the decomposing action of water containing carbonic acid; and, accordingly, Mr. Sterry Hunt finds in the more recent crystalline or metamorphic rocks of Canada “a less development of soda-felspar, while orthoclase and mica, chlorite and epidote, and silicates of alumina, like chastolite, kyanite, and staurolite (which contain but little or no alkali, and are rare in the older rocks) become abundant.” He conceives the carbonate of sodium resulting from the decomposition of the albite and similar minerals of the older rocks, to have reacted with the chloride of calcium which existed in large proportion in the palæozoic ocean, thus giving rise to deposits of carbonate of calcium, and to the chloride of sodium which sea water now contains. (Proc. Geol. Soc. Lond. Jan. 5, 1859.)

Green Felspar of Bodenmais.—This mineral which occurs associated with magnetic pyrites, quartz, &c., exhibits on the cleavage-faces the striation of the triclinic felspars, and has a specific gravity = 2.546–2.549 (Kerndt), 2.604 (Potyka). Heated in splinters before the blowpipe, it melts to a blebby glass, and colours the flame reddish-yellow. Contains, according to Potyka (Pogg. Ann. cxviii. 363):

SiO ²	Al ² O ³	FeO	CaO	MgO	K ² O	Na ² O	
63.12	19.78	1.51	0.65	0.13	12.57	2.11	= 99.87;

whence Rammelsberg (*Mineralchemie*, p. 616) deduces the formula $\frac{4}{5}\text{K}^2\text{O} \left\{ \frac{2}{5}\text{SiO}_2 + \text{Al}_2\text{O}_3 \cdot 3\text{SiO}_2 \right\}$ —which is of the form $\text{M}^2\text{O} \cdot \text{Al}_2\text{O}_3 \cdot 5\text{SiO}_2$, or $\text{M}^2(\text{Al}^3)^4(\text{Si}^4)^3 \cdot 3\text{SiO}_2$. The mineral is perhaps a new member of the felspar group (p. 618), intermediate in composition between oligoclase and orthoclase, between which it also stands with regard to its density.

FELSPATHIC ROCKS. Felspar—chiefly orthoclase and its varieties—enters into the composition of a great number of rocks. *Granite* consists of felspar (generally orthoclase), quartz, and mica, crystallised promiscuously together. *Pegmatite* is graphic granite. *Gneiss* has the same composition as granite, but exhibits traces of lamination. *Mica slate* is similar, but with a distinctly foliated structure. *Beressite* is a fine-grained granite, containing pyrites, from the neighbourhood of Beresof in the Ural. *Syenite* resembles granite, but contains hornblende in place of mica. *Protophine* is a talc granite.

Dolerine is a gneissoid rock in the Alps, consisting of felspar and talc. *Granulite*,

Erinite, or *Leptynite* is a granular compound of felspar and quartz, sometimes with garnet. *Hornfels* and *Cornubianite* also consist of quartz and felspar. *Pyroxenite* consists of felspar and lamellar pyroxene. *Pyromeride* is a granitoid rock, containing thickly disseminated spherules of a felspathic rock, mixed with quartz. *Miascite* is a granular slaty rock, consisting of orthoclase, mica, and *elæolite*, sometimes with quartz, albite, and hornblende.

Porphyry consists of a compact felspathic base (*cornite* or *porphyrite*), intermixed with crystals of felspar (orthoclase, oligoclase, or labradorite). See PORPHYRY.

Clinkstone or *Phonolite* is a compact felspathic rock, of greyish colour and smooth fracture, clinking under the hammer somewhat like a metallic ore. *Trachyte* is similar in colour and constitution, but has a rough surface of fracture. *Domite* is a greyish earthy variety from the Puy-de-Dome.

Ponice is a porous felspathic scoria from volcanoes.

Trap or *Greenstone* is a dark-heavy blackish-green, green, or brownish rock, consisting of felspar and hornblende. When albite replaces orthoclase, the rock is called *diarite*. *Basalt* (i. 518) is a similar rock, consisting of felspar (generally labradorite) with augite, olivine, magnetic iron ore, and a zeolite. *Dolerite* (p. 343), is similar to basalt, but does not contain olivine, or generally zeolites. *Anamesite* is a fine-grained rock, similar to basalt, in which labradorite predominates. *Wacke* is an earthy variety or a rock consisting of basaltic earth or sand.

Petrosilix, or *Adinole*, is a compact impure felspar, like the base of porphyries. *Obsidian* or volcanic glass, is sometimes impure glassy felspar, sometimes a mixture of felspar and augite, with chrysolite and much iron, &c., according to the nature of the lava from which it is formed. (See OBSIDIAN.)

Pitchstone and *Pearlstone* are felspathic minerals, containing excess of silica, like the spherules of pyromeride, porphyry, &c. *Baudite* or *Krabbite* (i. 522) appears to be a siliceous felspathic mineral related to these concretions: it forms the basis of the trachyte, obsidian, and pitchstone of Iceland. (Dana, ii. 246.)

FENNEL, OIL OF. The essential oil of common fennel (*Feniculum vulgare* or *Anthem. feniculum*) is identical with oil of anise (i. 297). The oil of bitter fennel (? of *Phellandrium aquaticum*) is a mixture of two volatile oils differing in boiling point (i. 299).

FERGUSONITE. A rare mineral from Kikertaursak in Greenland, discovered by Hartwall (K. Vet. Acad. Förh. 1828, p. 167), further examined by Weber. It crystallises in quadratic sphenoids (p. 136) with imperfect cleavage, parallel to the pyramid of the primary form. Hardness = 5·5—6. Spec. grav. = 5·838 (Allan), 5·800 (Turner). Lustre, dull externally, brilliantly vitreous and submetallic on the fractured surface. Colour brownish-black; in thin scales, pale liver-brown. Streak pale brown. Subtranslucent to opaque. Fracture imperfect conchoidal. Infusible before the blowpipe. With fluxes it melts with difficulty, forming glasses which appear yellow while hot. The glass formed with phosphorus-salt appears reddish in the reducing flame; when saturated with soda it yields globules of tin.

The mineral is a hyponiobate (originally regarded as a tantalate) of yttrium and cerium, containing also zirconic and stannic acids, as shown by the following analyses, *a* by Hartwall, *b* by Weber:

	Nb ² O ⁵	SnO ²	ZrO ²	YO	CeO	UO	FeO
<i>a.</i>	47·75	1·00	3·02	41·91	4·68	0·95	0·31 = 99·62
<i>b.</i>	48·84	0·35	6·93	38·61	3·06	0·35	1·33 = 99·46

From Weber's analysis we may deduce the formula $M''O(ZrO_2; SnO_2) + 2(M'O.Nb_2O_5)$. (Rammelsberg's *Mineralchemie*, p. 401.)

FERMENTATION and PUTREFACTION. (Berzelius, Berz. Jahresber. ix. 454. — Liebig, Handw. d. Chem. iii. 217. — Schwann, Pogg. Ann. xli. 184. — Helmholtz, J. pr. Chem. xxxi. 429. — Döpping and Struve, *ibid.* xli. 255. — Blondesin, J. Pharm. [3] xii. 244, 333. — C. Schmidt, Ann. Ch. Pharm. lxi. 128; cxvii. 126. — Pasteur, *Vinous Fermentation*, Ann. Ch. Phys. [3] lviii. 323; *Lactous Fermentation*, *ibid.* lii. 404; Jahresber. f. Chem. 1857, p. 510; 1859, p. 553; *Mucous Fermentation*, Bull. Soc. Chim. 1861, p. 30; *Spontaneous Decomposition*, Ann. Ch. Phys. [3] lxiii. 5. — Gm. vii. 96; xv. 265.)

Certain organic compounds, when exposed to the action of air, water, and a certain temperature, undergo decomposition, consisting either in a slow combustion or oxidation by the surrounding air, or in a new arrangement of the elements of the compound in different proportions (often with assimilation of the elements of water), and the consequent formation of new products. The former process, that of slow combustion, is called *Eremacausis* or *Decay*, and has been already considered (p. 497); the latter is

called *Putrefaction* or *Fermentation*.—*putrefaction*, when it is accompanied by an offensive odour, *fermentation* when no such odour is evolved, and especially if the process results in the formation of useful products; thus the decomposition of a dead body or of a quantity of blood or urine, is putrefaction; that of grape-juice or malt-wort which yields alcohol, is fermentation.

In the processes of fermentation and putrefaction, organic compounds of a higher order are resolved, sometimes into lower organic compounds, sometimes into inorganic compounds, as carbonic acid, water, ammonia, or sulphuretted hydrogen, sometimes into simple substances, as hydrogen and nitrogen gases. In many fermentations, none of the above mentioned gases are evolved; in fact, they go on without any evolution of gas. The affinities which tend towards the formation of organic compounds of a lower order, and of inorganic products, are doubtless stronger than those by which the original substance is held together; and this circumstance is probably connected with the evolution of heat which accompanies fermentation, and may be partly the cause of the spontaneous combustion of organic bodies.

Fermenting and putrefying substances generally have a tendency to abstract oxygen from the air and other bodies. Hence, when fermentation takes place with free access of air, it is accompanied by *eremacausis* on the surface of the organic substance. Putrefying substances reduce sulphide of iron from ferrous sulphate. The war fermentation of indigo is likewise a process of the same nature.

The substances most disposed to putrefaction are numerous compounds rich in nitrogen, viz. the albuminous or protein substances, such as albumin, fibrin, casein, emulsin, legumin, gliadin, gluten, &c., and gelatinous substances, such as membrane consisting of gelatin and other tissues, glue, chondrin, &c. On the other hand, there are other compounds rich in nitrogen, such as uric acid, the alkaloids, indigo, &c. which, of themselves, at least, are not capable of putrefying, and even some substances belonging to the class of protein-compounds, but of a coherent nature, such as hair, horn, and hard-boiled albumin, are susceptible only of a slow decay. The former compounds, on the contrary, require only the presence of water and the access of air at the commencement, to bring them into a state of decomposition, which, on account of the offensive odour which accompanies it, is especially denoted by the term putrefaction. Since animals are mainly composed of these substances, they are especially liable to this putrid decomposition; but many seeds of plants, mosses, &c., which are likewise rich in protein-compounds, are also liable to pass into the state of stinking putrefaction. The bad smell which accompanies putrefaction, proceeds partly from inorganic compounds, such as sulphuretted hydrogen and ammonia, partly from newly formed volatile organic compounds, the nature of which is not exactly known.

Of other organic compounds, there are but few which are brought into a state of fermentation or putrefaction by contact with air and water, so long as gelatin and albuminous compounds are excluded. Urea dissolved in a very large quantity of water is very slowly resolved into ammonia and carbonic acid; dilute aqueous solution of many vegetable acids, and more especially of their ammoniacal salts, also of sugar, gum, and starch, are decomposed with formation of mould.

But many substances incapable of fermenting *per se*, undergo that change when in contact with gelatinous or albuminous compounds; and those which are capable of fermenting alone ferment more quickly, or with formation of different products, when they are brought in contact with these compounds. Many compounds, however—those namely, which consist wholly of carbon and hydrogen—are incapable of fermenting even under these circumstances. As gelatinous and albuminous compounds excite fermentation in other substances, they are called *Ferments*, and the compounds which are brought into the fermenting state by contact with them are called *Fermentable Substances*.

Albuminous and gelatinous compounds sometimes excite fermentation in other substances, even when they are in the fresh state, as they exist in plants and animals;—sometimes, on the contrary, they must be exposed to the air, so as to bring them into a state of incipient putrefaction, before they will act as ferments upon other bodies and, in this case, it is often found that they will bring another substance into different states of fermentation, according to the particular stage of decomposition which they have themselves attained.

The aqueous solution of salicin or amygdalin would probably remain unaltered for a long time, if left to itself; but the emulsion of almonds (*Synaptase*) added in its undiluted state, just as it exists in recently prepared sweet almond-milk, decomposes salicin into glucose and saligenin, and amygdalin into glucose, bitter-almond oil, and hydrocyanic acid.—In black mustard, the addition of water induces the formation of volatile oil of mustard, in consequence of the action of the emulsin-like substance contained in it on the myronic acid which it also contains.

Fixed oils appear to pass into a state of rancid putrefaction only when an albuminous compound is mixed with them.

Starch boiled to a paste with water, and then left to itself in a close vessel for some weeks, is in great part converted into glucose, with evolution of carbonic anhydride and hydrogen; but in contact with gluten at 60° C. the starch of the paste is converted into glucose in eight hours; lastly, if the gluten has previously passed into that peculiar condition in which it exists as germinated gluten or *diastase* in malt, it effects this conversion of the starch at 60° C. in less than an hour.

A dilute aqueous solution of glucose or cane-sugar, which remains unaltered when alone, or only forms a little mould and mucus after a long time, may be brought, according to the nature of the ferment and its stage of decomposition, and according to the temperature and dilution of the solution, into three different states of fermentation; whereby it is converted either into lactic and then into butyric acid (*Lactous* and *Butyrous Fermentation*),—or into a mucous substance allied to gum, and generally at the same time into mannite (*Mucous Fermentation*),—or resolved into carbonic anhydride and alcohol, together with small quantities of succinic acid and glycerin. (*Vinous Fermentation*.)

The putrefaction of albuminous and gelatinous substances is prevented by a variety of circumstances, which likewise interrupt its further progress when it has already begun. The same circumstances likewise prevent or interrupt the fermentation of any fermentable materials that may be mixed with the ferment. Among these circumstances are the following:

1. *Exclusion of the air*.—Keeping the substances in a vacuum, in water free from air, in hydrogen, nitrogen, carbonic anhydride, and other gases which cannot furnish oxygen to the nitrogenous substances, or covering them with oil, butter, tallow, wax, or resin. Wood immersed in the depths of lakes and peat-mosses, where no oxygen absorbed from the air can reach it, because it is intercepted on the way by organic substances diffused through the water, remains unaltered for thousands of years.—This exclusion of air may prevent incipient putrefaction, but does not usually interrupt the progress of that which has already begun. According to Schwann and others (p. 626), exclusion of air acts, not by intercepting oxygen, but by preventing the admission of the germs of microscopic plants and animals diffused through the air.

2. *Dryness*.—Perfect dryness prevents every kind of fermentation or putrefaction, and seldom allows even of slow combustion: e. g. the preservation of wood for three thousand years in Egyptian tombs, where it has been exposed only to the action of tolerably dry air.

3. *Freezing temperature*.—Water in the solid state is quite inactive, and does not allow fermentation or putrefaction to go on; but even at a few degrees above 0° C., certain kinds of fermentation do not take place, and others are very slowly produced. All kinds of fermentation and putrefaction appear to take place most readily between 20° and 40° C.—Mammoths have remained undecomposed for thousands of years in the ice of Siberia.

4. *Boiling heat* prevents incipient fermentation, and completely stops that which has already begun, either because all ferments are altered by it, in a similar manner to albumin, which, when boiled hard, is scarcely susceptible of putrefaction; or because it kills the microscopic plants and animals and their germs; or from both causes together. Fermentation prevented or interrupted by a boiling heat, does not recommence after cooling, if the air be perfectly excluded, because either oxygen or living germs are required to produce new ferment.

On this principle is founded Appert's process, by which easily decomposable articles of food and drink, such as meat, fish, vegetables, milk, &c., may be preserved for years,—viz. by packing them in air-tight bottles or soldered tin-cases, heating the vessels for several hours in boiling water and keeping them carefully closed. To explain this action, we may either suppose, with Liebig, that the small quantity of oxygen contained in the enclosed air is taken up by the organic matter, without being able to produce ferment at that temperature, or, with Schwann, that the microscopic organisms are killed by the heat.

If the air be admitted, the boiled substance passes again, after a while, into the fermenting state.—If, however, grape-juice, milk, meat, &c., be exposed once a day to a boiling heat, without being protected from the air, and the small quantity of reproduced ferment thereby rendered inactive, before it has time to act upon the rest of the mass, fermentation may be prevented for any length of time.

5. *Antiputrescent or Antiseptic Substances*.—By the addition of various substances, organic and inorganic, fermentable bodies are deprived of their tendency to fermentation, and fermentation already commenced is interrupted.

These antiputrescent bodies probably act in various ways:

a. They abstract water from the fermentable substance.

b. They form with it a compound less liable to fermentation.

c. They decompose the ferment in such a manner as to deprive it of its tendency to fermentation.

d. They take from the surrounding air, and also from the ferment already oxidised by it, the oxygen required for fermentation.

e. They probably kill the fungi and infusoria and their germs.

The action mentioned in *a* is probably exerted by powdered sugar in contact with meat and fresh cut-up vegetables; the solution of sugar thereby formed is too strong to ferment.—*a* and *b* together: The stronger mineral acids, such as sulphuric acid, alum ferri sulphate, mercuric chloride, and other salts of heavy metals; also tannin and creosote.—*c.* Chlorine, pernitric oxide, and chromate of potassium.—*d.* Probably sulphurous acid.—*e.* Arsenious acid, mercuric chloride, and several other of the substances above mentioned. Arsenious acid and mercuric chloride kill fungi and infusoria; *nutrica* only the latter.

Theories of Fermentation.—Respecting the exciting cause of fermentation and putrefaction two opposite views are entertained; the one attributing these changes entirely to the action of chemical and physical forces, the other supposing that they cannot take place without the intervention of living organisms, viz. fungi and infusoria.

In inquiring into the exciting cause of these phenomena, there are two essential conditions to be taken into account.

1. *The presence of a nitrogenous body.*—It is only nitrogenous compounds, such as albumin, gelatin, &c., that are subject to spontaneous fermentation or putrefaction. Organic compounds containing only carbon, hydrogen, and oxygen, do not ferment except when in contact with nitrogenous bodies.

2. *Contact with the air.*—This condition is necessary for the commencement of the process, but not for its continuance. A body once brought into a state of fermentation or putrefaction by contact with the air, continues to ferment or putrefy when afterwards excluded from the air, provided there is a sufficient amount of nitrogenous matter present. The juice of the grape does not ferment while enclosed in the sound skin of the fruit; but the slightest puncture which admits the air, causes fermentation to begin, and the process will then go on even in a vessel filled with carbonic anhydride or hydrogen, and hermetically sealed.

From these circumstances, Berzelius and Liebig conclude that the exciting cause of fermentation and putrefaction is to be found in the oxygen of the air. The nitrogenous matter, by contact with atmospheric oxygen, undergoes a change of composition, by which the equilibrium of the attractive forces, which hold its particles together is disturbed, and new compounds are formed; this alteration of arrangement in the atoms of the elements, produces a motion in the compound molecule of the nitrogenous body, which motion is transferred from one molecule to the next; and in this manner the decomposition is propagated throughout the whole of the nitrogenous body.—Further, when a nitrogenous substance in this state of decomposition comes in contact with another substance, such as sugar, which would not ferment by itself, the movement by which the elementary atoms of the former are affected, is also transferred to the contiguous atoms of the latter, causing the elementary atoms in its compound molecules to enter into new combinations; and in this manner, the latter substance is made to resolve itself into new products. (Liebig.)

It appears, however, from the observations of many experimenters, and especially from the recent elaborate researches of Pasteur, that fermentation is never excited except under the influence of microscopic organisms, and moreover that each particular organism sets up a peculiar species of fermentation.

According to Schwann, the air contains the germs of microscopic plants and animals and when these germs find a fitting soil, such as is offered by various nitrogenous bodies, they develop themselves therein, producing fungi and infusoria, which then, in a manner not yet explained, induce the fermentation of sugar, &c.

It appears also from the experiments of Schwann and of Helmholtz, that air which has been passed through a red-hot tube, and thereby freed from the germs of living organisms, cannot induce fermentation or putrefaction in nitrogenous bodies, and, consequently, that oxygen alone is not sufficient to bring nitrogenous matter into the condition of a ferment.

Blondeau also finds that fermentation in all its forms depends on the development of fungi. Alcoholic fermentation is excited by one particular fungus (*Torula cerevisiæ*); lactic fermentation by another (*Penicillium glaucum*). The latter fermentation takes place after the former, when a mixture of 30 grammes of sugar and 10 grms. yeast, with 200 cub. cent. water at the temperature of about 25° C., is left to itself for some time, after the termination of the vinous fermentation (which is completed in about two days). Beer-yeast mixed with a little water and left to itself is

a dark, moist place, was found to contain germs of *Torvula cerevisia* and *Penicillium glaucum*; when the liquid was filtered, the former of these remained on the filter and brought a solution of sugar into the state of vinous fermentation; but the latter being extremely small, ran through the filter, and the filtrate brought sugar-water into the state of lactous fermentation. *Acetous* fermentation depends on the development of *Torvula aceti*. The conversion of nitrogenous substances into fat (e. g. of casein in the preparation of Roquefort cheese, and of fibrin under similar circumstances), which Blondeau distinguishes by the term *fatty or adipic fermentation* (*fermentation adipose*), is produced by *Penicillium glaucum* or *Torvula viridis*; and in butyrous fermentation and urinous fermentation (the conversion of urea into carbonate of ammonia), the action depends on the development of *Penicillium glaucum*. (Blondeau.)

Against this view Liebig raises the following objections:

Beer-yeast, which is supposed by Schwann, Turpin, and others, to consist of fungi, does not possess the composition of true fungi, but of gluten. It has never yet been specified in what manner these microscopic organisms effect the decomposition of fermentable substances. Are the products of fermentation and putrefaction the excrements of these living beings, to which the fermentable substance serves as food? Or do these organisms transform the original fermentable substance into new compounds (products of fermentation) by an external exertion of their vital force?—If vinous fermentation were a consequence of the more perfect development of fungi—as we might, perhaps, suppose to be the case in the fermentation of beer and wine—beer-yeast ought not to bring sugar-water into a state of fermentation, inasmuch as the sugar-water contains no nitrogenous matter which can serve as food to the fungi composing the yeast, but on the contrary these fungi disappear during the fermentation.—Sugar-water is likewise brought into the state of vinous fermentation by contact with cheese or almond-milk, though in this case no fungoid bodies are developed like those of the vinous ferment, as in the preparation of beer, or the fermentation of grape-juice.—In thousands of cases, no infusoria can be detected in putrefying cheese, blood, urine, or bile, or they do not make their appearance till the putrefaction has gone on for some time: hence they cannot be the cause of the putrefaction, but are merely developed from germs existing in the air, because these germs find nourishment in the putrefying substance. It is true that they then accelerate the decomposition, because they feed upon the organic matter, and convert it by their vital action into carbonic acid, &c. When they have thus consumed all the nutriment, they die, and serve as food for infusoria of other species. All this may take place when the air has access to the putrefying substance, but bodies which putrefy out of contact of air, condensing for example, never exhibit infusoria, which, in fact, would be killed by the sulphuretted hydrogen evolved (Liebig). Liebig also remarks (*Handwörterbuch der Chemie*, iii. 217), that in the fermentation of milk, when that liquid is left to itself for a while in vessels containing air and bound over with blotting paper, till fermentation and formation of lactic acid are completely established, not a trace of vegetable growth can be detected. He moreover observes that in the study of fermentation, attention has been too exclusively directed to the vinous fermentation, and conclusions of too great generality have been drawn from the phenomena observed in that particular process, whereas, the explanation of vinous fermentation ought rather to be deduced from the study of fermentation in the more general sense.

C. Schmidt (Ann. Pharm. lxi. 168), is also of opinion that *fungi* are not the *prime movers* either in urinous (p. 634) or in vinous fermentation. He finds that the clear filtrate obtained by throwing almonds beaten up with water on a wetted filter, soon brings urea and grape-sugar into the fermenting state; and in the latter case, the fermentation may be in full play, although no trace of yeast-cells is discernible by the microscope, these cells not appearing till afterwards. If the saccharine liquid be left to itself for a week or a fortnight after the completion of the fermenting process, the groups of cells continue to grow in it, though no putrefaction takes place; the fungi, if washed and then introduced into a fresh solution of grape-sugar, grow in it vigorously, but excite only feeble and transient fermentation, if any: hence it appears that the growth of these plants is but a secondary phenomenon in fermentation.

R. Wagner, however (J. pr. Chem. xlv. 241), observed the simultaneous occurrence of fermentation and formation of yeast-cells under the conditions described by Schmidt.

On the whole, the question as to the exciting cause of fermentation and putrefaction, cannot be considered as quite decided; the balance of evidence appears, however, to be in favour of the view which regards the action of living organisms as essential to the commencement of these processes, as will appear from the details given in the following articles relating to vinous, lactous, and mucous fermentation; but it must still be admitted that we know nothing whatever of the mode of action of these organisms.

FERMENTATION, ACETOUS. The conversion of alcohol into acetic acid by atmospheric oxidation, is rather a case of *eremacausis* than of fermentation, and may take place under the influence of platinum-black, and other finely divided substances, which facilitate the transfer of oxygen; but as it is greatly accelerated by the presence of nitrogenous matter, and, according to Mulder, of a peculiar fungoid plant, the *Mycoderma Vini*, it is usually called *Acetous Fermentation* (i. 8).

Under this head may also be mentioned the conversion of citric and tartaric acids into acetic acid and some of its homologues, in contact with yeast or putrefying curd and a base, and even by mere exposure to the air (i. 995). Pasteur (Compt. rend. lvi. 416; Rép. Chim. pure, 1863, p. 221) has lately shown that tartrate of calcium mixed with a few thousandths parts of phosphate of ammonium and fixed alkaline or earthy phosphates,—when immersed in thoroughly de-aerated water and rigidly preserved from contact with the air, may be thrown into a state of active fermentation by the introduction of a very small quantity of the infusoria produced by the spontaneous fermentation of tartrate of calcium in contact with the air. The infusoria multiply rapidly at the expense of the tartrate which in a few days disappears entirely.

FERMENTATION, ALCOHOLIC or VINOUS. The clear juice of sacchariferous plants containing glucose, $C^6H^{12}O^6$, left to itself in contact with the air at temperatures between 20 and $24^{\circ} C.$, becomes turbid after a few hours, gives off carbonic anhydride, becomes warmer than the surrounding air, and remains in a state of transformation from 48 hours to several weeks, according to the temperature, the amount of sugar present, and the nature of the nitrogenous matters, till, in fact, the whole of the sugar is decomposed. As soon as the evolution of carbonic acid is terminated, a substance previously suspended in it, the ferment or yeast (*Torula cerevisiæ*), separates, partly carried upwards by adhering gas-bubbles, partly downwards, leaving the liquid clear, which then, in place of the sugar, contains alcohol, glycerin, and succinic acid. The yeast formed in this process, if introduced at about the same temperature into a moderately dilute solution of pure sugar, induces therein also the decomposition of the sugar into the same products.

The formation of these products is represented by the following equations:

and $49C^6H^{12}O^6 + 30H^2O = 12C^2H^4O^4 + 72C^2H^4O^2 + 30CO^2$. (Pasteur.)

By far the greater part of the sugar is resolved into alcohol and carbonic anhydride, only about 4 or 6 per cent. being converted into succinic acid and glycerin. The formation of succinic acid in vinous fermentation was first observed by C. Schmidt, in 1847, and was communicated by him in a letter to Liebig (Handw. d. Chem. iii. 224). The formation of glycerin in this process was discovered by Pasteur.

Amyle alcohol is also frequently produced in the fermentation of sugar, and under certain circumstances tritylic, tetrylic, and according to Faget (?) hexylic alcohol. (See ALCOHOLS, i. 98.)

Cane-sugar, $C^{12}H^{22}O^{11}$, does not undergo vinous fermentation, till under the influence of a peculiar substance in the yeast, or of a substance contained in the kernel of fruits, it has been converted, with assumption of 1 at. H^2O , into glucose, $C^6H^{12}O^6$ (see SUGAR). Milk-sugar is also converted into alcohol under the influence of putrid casein or gluten, and, under certain circumstances, of yeast, the formation of the alcohol being preceded, according to some observers, by the conversion of the milk-sugar into glucose. (See MILK-SUGAR.)

Solutions of sugar containing gluten altered by the process of germination or of mashing, undergo on standing an irregular fermentation, which however may be rendered regular by the introduction of a small quantity of yeast. Such is the case in the fermentation of beer-worts (Ure, J. pr. Chem. xix. 183). When albuminous substances, gluten, casein, or substances of like nature, are introduced into sugar-solutions, and the liquids are exposed for some time to the air, sometimes vinous fermentation takes place, sometimes another kind of decomposition.

A sugar-solution mixed with yeast ferments immediately, but the juice of grapes and other fruits requires access of air to bring it into the fermenting state.

Air previously heated to redness cannot induce fermentation in a solution of sugar, which has been mixed with yeast and then boiled, because, for the commencement of the process, either unboiled organic matter or unignited air which can supply the vegetable germs is necessary (Schwann, Pogg. Ann. xli. 187; Ure, J. pr. Chem. xix. 187). Wine-must, boiled and enclosed in a bladder, does not ferment even if suspended in fermenting must. It appears, indeed, that the access of a solid body from the air is essential to vinous fermentation, so that oxygen gas evolved from water by electrolysis is incapable of bringing boiled grape-juice into the fermenting state.

(Helmholz, J. pr. Chem. xxxi. 434). The ferment of the air may likewise be retained by filtration through cotton; consequently sweet malt-wort in contact with filtered air does not ferment even for weeks. (Schröder and Dusch, Ann. Ch. Pharm. lxxix. 332.)

Fresh grape-juice which has never come in contact with atmospheric air, suffers no alteration for years when kept over mercury at a temperature between 26° and 28° C. If oxygen gas previously heated to redness, or filtered through cotton be brought in contact with it, the juice after some hours becomes darker, absorbs the oxygen and gives off carbonic anhydride, but no fermentation takes place even after a long time. Common air, inasmuch as it contains bodies capable of forming yeast-cells, or the yeast-cells themselves (even such as have never been in contact with the air), can set up vinous fermentation, the continuation of which is promoted entirely by the growth of the yeast-cells. (Van den Broek, Ann. Ch. Pharm. cxv. 75.)

The fungi diffused over the surface of fruits, leaves, and fruit-stalks, likewise induce fermentation in saccharine liquids. If to a fermentable fruit-juice mixed with sugar, there be added 2 measures of water, the whole violently and continuously shaken, and the liquid which has become specifically lighter, set aside, the cells of the fungi rise to the surface, and there give rise to formation of mould, but no fermentation takes place within the liquid. (H. Hoffmann, Ann. Ch. Pharm. cxv. 228.)

If the motes floating in the air are collected in cotton or asbestos contained in a tube through which the air is drawn, and introduced into sugar-solutions which have been well boiled and cooled again, and are mixed with the mineral and albuminoid constituents of yeast, they develop into *infusoria* and *mucedineæ*, even if only ignited air has access to the liquid. Sugar-solutions mixed with the same yeast-constituents, but not containing this dust, undergo no alteration between 28° and 30° C., not even when cotton or asbestos alone is introduced into them. The same liquid remains unaltered if boiled in a glass flask, the neck of which is bent so that no dust can fall into it, the flask being afterwards left unclosed. (Pasteur, Compt. rend. l. 303.)

The better a saccharine liquid is adapted for the nutrition of yeast-cells, the more easily will they be developed (from the above-mentioned bodies in the atmosphere), when air has access to the liquid. Thus, vinous fermentation is almost always set up when the clear filtered wash-water or the decoction of yeast (which contains the soluble mineral and albuminoid constituents of that substance) is mixed with sugar-solution and left to itself (as observed long ago by Colin); it is frequently also accompanied by lactic fermentation; but the latter very seldom takes place alone, unless the wash-water of previously altered yeast has been used. (Pasteur.)

The vinous fermentation of sugar is likewise induced by the peculiar ferment of madder (Schunck's *erythrozym*) in contact with air, especially if this substance is in a state of decomposition. A mixture of carbonic anhydride and hydrogen is evolved, and the liquid after 14 days contains alcohol, acetic acid (perhaps also formic acid), a small quantity of succinic acid, and a sweet brown uncrystallisable body, probably glycerin, but no lactic acid. The same effect is likewise produced by the brown precipitate formed by adding a small quantity of hydrochloric acid to an aqueous infusion of madder after it has been rendered alkaline by lime-water. (Schunck, J. pr. Chem. xlii. 222.)

Yeast consists of very small microscopic round or egg-shaped balls (Leuwenhoek, Cagniard de Latour), of $\frac{1}{1000}$ mm. diameter (Blondeau). These balls are vegetable cells (Cagniard de Latour), with elastic walls, filled with a liquid, and a soft, horny mass, which latter is at first attached to the walls, but extends to the middle as the cell grows. Young cells are transparent, and almost destitute of granular contents (Mitscherlich, Pasteur). These cells multiply by gemmation (Cagniard de Latour, Mitscherlich); the newly-formed cells do not separate from the central cell till they have attained to nearly the same size (Pasteur). They always remain isolated, and never form ramifications or elongated cells, like those of lactic ferment. (Blondeau.)

According to Cagniard de Latour, Turpin, and Mitscherlich, yeast-cells also increase by bursting and diffusing their granular contents through the liquid, the granules then developing into cells. Schlossberger and Pasteur did not observe this mode of formation, which is likewise inconsistent with the uniform size of the free yeast cells. Yeast contains cellulose, fat, nitrogenous and mineral substances. See analyses of yeast by Payen (*Mém. des Savants étrangers*, ix. 32); Dumas (*Traité de Chimie*); Mitscherlich (*Lehrb.* 4 Aufl. 370); Schlossberger (Ann. Ch. Pharm. li. 193).

The yeast deposited in the vinous fermentation of beer, of diabetic urine, of grape-juice, or other natural fruit juices, is invariably of the same composition (Quevenne, J. Pharm. xxiv. 265). In commercial beer-yeast, the cells of *Torula cerevisiæ* and of *Penicillium glaucum* may be distinguished by the aid of the microscope. These two fungi may be separated one from the other, by washing and filtration, the larger cells

of the *Torula* remaining on the filter (and exciting vinous fermentation when introduced into sugar solutions), while the smaller cells of the *Penicillium* pass through the filter, and consequently the filtrate excites lactic acid fermentation in sugar-solutions (Blondeau.)

On the distinction between top- and bottom-yeast, see the article BEER (i. 529); also Mitscherlich (Pogg. Ann. lix. 94), R. Wagner (J. pr. Chem. xlv. 241); on beer-yeast in general, Colin (Ann. Ch. Phys. xxx. 42).

Fermentation takes place only when the solution is sufficiently diluted with water, with less than 4 pts. water to 1 pt. sugar, it takes place but imperfectly or not at all, partly, perhaps, because the resulting alcohol precipitates the nitrogenous substances, destroys the fermentative power of the yeast, or renders the liquid unfit for its further development. If, on the other hand, the liquid is too dilute, the fermentation is slow, irregular, and easily passes into acetous fermentation. Moreover, it is necessary that the yeast be in direct contact with the sugar-solution: a solution of sugar contained in a bladder suspended within a fermenting liquid, does not ferment, but merely takes up a little alcohol by diffusion (Helmholz). When a tube plugged with filtering paper and containing yeast is introduced into a sugar solution, this solution passes through the paper, and ferments within the tube, but not outside (Mitscherlich, Ann. Chim. Phys. [3] vii. 7, 30). When a solution of sugar contained in a test-tube is separated into two parts by a cotton plug, and yeast is introduced into the upper part, this part ferments, but not the lower. (H. Hoffmann, Ann. Ch. Pharm. cxv. 228.)

An increase of yeast takes place in fermentation, when the liquid, in addition to sugar contains a nitrogenous substance. When, on the contrary, yeast is left in contact with a pure solution of sugar, it diminishes both in weight and in fermenting power and, in the end, becomes totally inactive. (Payen, Quevenne.)

In the fermentation of pure sugar solutions, the yeast first increases in weight and then diminishes; because it first assimilates the constituents of sugar, and gives them up again as the fermentation progresses. (Quevenne, J. Pharm. xxvii. 593.)

Yeast may grow and increase in sugar solutions, if they are mixed with ammoniacal salts, yeast-ash, and a trace of yeast, fermentation then also ensuing.

Yeast grows and multiplies in pure sugar solutions, as well as in such as have been mixed with albuminous substances. In the former case, all the yeast cells are found at the end of the fermentation to be deprived of their soluble nitrogenous constituents, which have been used for the formation of new yeast cells; in the second case there are found, together with the exhausted cells, a large number of newly-formed cells filled with soluble mineral and albuminoid substances. (Pasteur.)

Sugar solutions containing a sufficient quantity of yeast ferment completely in two or three weeks, unless lactic fermentation takes place. But an extremely protracted fermentation ensues when yeast is mixed with excess of sugar. In this case the yeast lives at the expense of the soluble nitrogenous substances, and after these are used up, the younger cells continue to grow at the expense of the older. (Pasteur.)

During fermentation, part of the yeast is resolved into soluble products (Thénard). The yeast recovered from pure sugar solutions after fermentation is less rich in nitrogen than the original yeast, partly because its weight has been increased by the addition of non-azotised matter from the sugar, partly because a portion of its own nitrogenous substance has passed into the solution. On the other hand, it contains more cellulose and fat than before fermentation, which substances have therefore been formed from the sugar. The yeast formed in sugar solutions mixed with ammonia-salts, yeast-ash, and traces of yeast-cells, contains fat. (Pasteur.)

The nitrogen of yeast is not converted into ammonia during fermentation; on the contrary, any ammonia that may be added disappears wholly or partially. (Pasteur.)

When sugar solutions are fermented with a very large excess of yeast, the formation of alcohol and carbonic acid goes on, even after all the sugar is decomposed, at the expense of the non-azotised matter of the yeast, so that the amount of these two products obtained is more than equivalent to that of the sugar.

Yeast loses a considerable portion of its fermenting power by pressure, and still more by washing with water. After thorough drying, its power of exciting fermentation is, for the most part, destroyed: this statement is opposed to that of Cagniard de Latour. It likewise becomes inactive when heated, either alone or with water. Dried yeast excites fermentation even after cooling by solid carbonic acid (Cagniard de Latour). Yeast crushed on the grindstone no longer excites fermentation (Lüdersdorff, Pogg. lxxvii. 409), or only after a considerable time (Wagner); it then excites lactic fermentation (C. Schmidt). Yeast altered by too long continued putrefaction is inactive; but if the putrefaction has been less prolonged it may be checked and converted into fermentation by addition of sugar (Schlossberger, Ann. Ch. Pharm. li. 211). The fermentative power of yeast is destroyed by

all substances which exert a poisonous action on fungi, but not by such as kill animals (Schwann, Mitscherlich, J. Pharm. [3] iv. 218). Yeast sprinkled with alcohol loses its fermentative power, which is not transferred to the alcohol.

The action of yeast on sugar is prevented by too great concentration of the solution, whether due to alkaline chlorides, gelatin, glycerin, or sugar (Berthelot, Ann. Chim. Phys. [3] l. 352). Strong mineral acids, added even in small quantity prevent the fermentation, phosphoric acid alone acting favourably. (Wagner, J. pr. Chem. xlv. 241.)

FERMENTATION, AMYGDALOUS. The conversion of amygdalin into bitter almond oil, hydrocyanic acid, and glucose, under the influence of emulsin or synaptase (i. 201).

FERMENTATION, BUTYROUS. See FERMENTATION, LACTOUS.

FERMENTATION, GALLOUS or TANNOUS. A solution of tannic acid exposed to the air, gives off carbonic anhydride, and is converted into gallic acid:

According to Stas (Ann. Ch. Pharm. xxx. 205) and Strecker (*ibid.* xc. 328), glucose is formed at the same time:

With pure tannic acid the action is extremely slow, but in infusion of galls, which contains the nitrogenous matter of the gall-nuts, it takes place quickly; still more so in gall-nuts merely moistened with water. The change may be regarded as a fermentation process, inasmuch as it is stopped or retarded by antiseptic substances, such as alcohol, wood-vinegar, creosote, and corrosive sublimate. According to Robiquet, the fermentation is excited by the pectase of the gall-nuts, which at the same time converts the pectose contained in them into pectin.

FERMENTATION, LACTOUS. When a solution of glucose, cane-sugar, or milk-sugar is mixed with fresh sour cheese, or with milk and chalk, and the mixture is exposed to the sun, or to a temperature of 25° to 30° C. for some weeks, with frequent stirring and renewal of the water as it evaporates, the sugar is converted into lactic acid, and ultimately, with evolution of hydrogen and carbonic anhydride into butyric acid, the acid uniting with the lime. As lactate of calcium is much less soluble than the butyrate, the conversion of the former into the latter may be recognised, when strong solutions of sugar are used, by the diminution of the crystalline mass produced at first.

Since glucose and milk-sugar contain $C^{12}H^{22}O^{12}$, and cane-sugar differs from them by only 1 at. water, the conversion of these sugars into lactic acid ($C^6H^{12}O^6$, or $C^9H^{18}O^9$), consists merely in the splitting up of a molecule so constituted into two or more, and a new juxtaposition of the elementary atoms. The formation of butyric from lactic acid is represented by the equation:

In the preparation of lactic acid (as above), the precipitate formed on the bottom and sides of the vessel from the chalk and the products of decomposition of the cheese or milk is found, at the end of the fermentation, to be covered with a small quantity of a grey substance, the lactous ferment. When this substance is introduced into a cooled and clear-filtered decoction of beer-yeast, together with from 15 to 20 pts. of water, chalk, and a quantity of sugar equal to from $\frac{20}{100}$ to $\frac{1}{10}$ of the liquid, and this liquid is kept at a temperature of 30° to 35° C. for some days, a brisk evolution of carbonic anhydride and hydrogen takes place, the liquid becomes turbid and deposits a precipitate, and the chalk dissolves in the form of lactate of calcium. The new (and already purer) lactous ferment separated at this stage of the process, if introduced, together with chalk, into sugar-water, produces within an hour, an incipient evolution of gas and conversion of the sugar into lactate of calcium. (Pasteur, Ann. Ch. Phys. [3] lii. 404.)

This ferment, which appears to be necessary to lactous, as yeast is to vinous fermentation, is the *Penicillium glaucum*.

When lactous fermentation is set up in suitable sugar-solutions merely left to themselves, it is because certain bodies present in the air develop in the liquid, into cells of lactous ferment, which then set up the fermentation. If, therefore, the air is excluded, or only heated air has access to the liquid, no lactous fermentation will take place, unless lactous ferment is added. (Pasteur.)

Lactous ferment, viewed in the mass, resembles beer-yeast; it is grey, slightly glutinous, and appears under the microscope to consist of very small spherules of $\frac{1}{800}$ mm. diameter; some isolated, others united in groups, and possessing molecular motion

(Pasteur). The cells of *Penicillium glaucum* have at most a diameter of $\frac{1}{350}$ mm.; they increase at first, like the cells of yeast, by formation of new round cells, but afterwards by formation of elongated and many-branched cells, which ultimately cover the surface like a white mould. (Blondeau.)

A small quantity of lactous ferment is capable of decomposing a large quantity of sugar, provided the liquid is kept neutral by chalk; otherwise its action on the sugar is retarded by the free acid. It increases if nitrogenous matter, which may serve to nourish it, is likewise present. By desiccation or by boiling, with water, its action is weakened, but not altogether prevented. It acts best on sugar when air is excluded, inasmuch as the action is then not interfered with, either by the formation of mould, or by infusoria. If no other ferment is present, the lactous fermentation goes on regularly, and often more quickly than vinous fermentation. (Pasteur.)

In solutions of cane-sugar containing phosphoric acid and ammoniacal salts, the *Penicillium glaucum* can grow and convert all the sugar into lactic acid. (Pasteur, Compt. rend. li. 298.)

Previous to lactous fermentation, the liquid always becomes viscous, in consequence of the development of *Penicillium glaucum*, whose ramifications fill the liquid to such an extent, that it does not run out when the vessel is inverted. If this plant can develop itself in sugar solutions, lactous fermentation ensues, whether the liquid is acid or alkaline. If the liquid also contains albuminous substances, these yield ammonia and carbonic acid for the development of the *Penicillium*, and are partially converted into butyric acid, while part of the sugar is transformed into mannite. (Blondeau, J. Pharm. [3] xii. 257.)

The spontaneously developed fermentation of saccharine juices containing nitrogen, is sometimes lactous, sometimes vinous, most frequently both together. If yeast (as is generally the case) contains the cells of *Penicillium glaucum* as well as those of *Torula cerevisia*, vinous fermentation takes place first, then lactous fermentation at the expense of still unaltered sugar (Blondeau). When sugar solutions are brought into the state of lactous fermentation by cheese (or other nitrogenous substances), the lactic acid formed after a while prevents the further action of the ferment, but after repeated addition of acid carbonate of sodium (Boutron and Frémy), of chalk (Pelouze and Gélis), the whole of the sugar is converted into lactic acid. Slightly alkaline liquids are best adapted for the development of lactous ferment, neutral liquids for the development of yeast. (Pasteur.)

Sugar-solutions undergo lactous fermentation in contact with various membranes, especially calf's rennet (Frémy, Compt. rend. viii. 96, and ix. 165; see also Gay-Lussac, Compt. rend. ix. 46), with diastase altered by exposure to the air, with the previously altered nitrogenous substance of beet-juice, with decomposing animal bladder, with whey (Boutron and Frémy, Ann. Ch. Phys. [3] ii. 256; Blondeau). When urine mixed with sugar is left to itself, *Penicillium glaucum* becomes developed, and lactic acid is produced. (Blondeau.)

The soluble parts of gluten and casein, as well as the nitrogenous liquid which remains after vinous fermentation, are peculiarly well adapted for the development of lactous ferment; consequently, when these liquids are mixed with sugar and exposed to the air, lactous ferment is formed in them, even if yeast is added, the two ferments then exerting their specific actions side by side (Pasteur). See also MUCOUS FERMENTATION.

Aqueous sugar-solutions set aside for weeks or months at 40° C., a lower temperature in contact with chalk and cheese, glue, or other nitrogenous substances, undergo a fermentation different from the vinous, and not depending on the presence of yeast. In this fermentation, both the nitrogenous substance and the sugar are destroyed; carbonic acid, nitrogen, and hydrogen escape, and alcohol, lactate, and butyrate of calcium are produced. (Berthelot, Ann. Ch. Phys. [3] lv. 361.)

Berthelot designates this reaction *Fermentation alcoolique*, whereas Pasteur regards it as lactous fermentation.

FERMENTATION, MUCOUS. This is another kind of fermentation which sugar-cane undergoes, likewise under the influence of nitrogenous substances, and in contact with air; but under circumstances otherwise not exactly known, giving rise to the escape of carbonic acid and hydrogen, and the formation of mannite, a peculiar gum and a mucilaginous substance.

The mucous fermentation of sugar takes place (like vinous and lactous fermentation) under the influence of a peculiar mucous ferment. This ferment is composed of spherules from 0.0012 to 0.0014 mm. diameter, and when introduced into sugar-solutions containing albumin causes the sugar to be resolved into mannite, gum, and carbonic acid. 100 pts. cane-sugar yield, on the average, 51.09 pts. mannite, and 46. pts. gum, corresponding to the equation:

When a larger proportion of gum is obtained, the liquid is observed to contain larger spherules, probably belonging to a peculiar mucous ferment. (Pasteur, Bull. Soc. Chim. Paris, 1861, 30.)

Mucous fermentation requires access of air, and likewise the presence of nitrogenous matter; but the latter is capable of exciting mucous fermentation even after boiling. In this reaction, neither acid nor alcohol is produced. (Hochstetter.) Mucous fermentation is prevented by sulphuric acid, hydrochloric acid, or alum (Desfosses), by free mineral acids (Hochstetter, J. pr. Chem. xxix. 30).

The following are examples of this kind of fermentation:

Syrup of cane-sugar, which had been poured at the boiling heat into bottles in Martinique, the bottles being filled with it, underwent mucous fermentation on being transported to France, and poured out into open vessels. (Peligot.)

Fresh beet-juice becomes gummy by contact with air, and then contains mannite, gum, lactic acid, and uncrystallisable sugar. These changes take place with greater facility, when fermenting beet juice is added to the fresh juice, even when the greater part of the nitrogenous matter has been removed by lime, and whether the quantity of free alkali present is great or small. Alcoholic fermentation sometimes sets in if the acid is neutralised (Hochstetter). When carrot-juice is left to itself between 30° and 40° C., the cane-sugar which it contains is converted into glucose, mannite, lactic acid, and a gum isomeric with gum arabic. (Tilloy and MacLagan.)

The expressed juice of mangold-wurzel begins to ferment in 3½ days, and the fermentation is complete in 2½ days. From the solution clarified and evaporated to a syrup, alcohol of 80 per cent. precipitates a glutinous mucus, and the filtrate yields crystals of mannite. If the mucus be washed with alcohol, its aqueous solution precipitated with basic acetate of lead, the washed precipitate decomposed under water by sulphydric acid, and the filtrate evaporated to dryness, a transparent, slightly coloured gum is obtained. (Kircher, Ann. Pharm. xxxi. 337.)

The juice of the sugar-cane contains a white non-azotised (?) substance which becomes brown and moist in contact with the air, is soft and difficult to dry, soluble in water, insoluble in alcohol and ether, and is precipitated from its aqueous solution by oxide of lead, mercurous salts, and alcohol. It converts sugar into a substance intermediate between starch and gluten, this substance being formed quickly, and somewhat abundantly in syrups, and rendering them viscid, ductile, and uncrystallisable. If therefore, the juice, after being treated with lime, is left to stand for 48 hours, a jelly is produced, from which alcohol throws down a soft white nacreous precipitate, which dries up to a nacreous mass, dissolves but sparingly in hot or cold water, even when moist, but swells up in it to a transparent mass, and when treated with nitric acid, yields nothing but oxalic acid. This mass is not coloured by iodine, or converted into sugar by dilute acids, and does not give off ammonia on dry distillation. It is found abundantly at the bottom of the vats in which molasses is left to ferment for the preparation of rum. (Plagne, J. Pharm. xxvi. 248.)

Lemonade containing sugar, volatile oil, citric acid, and condensed carbonic acid, loses its fluidity, and becomes gummy by long keeping, especially in winter. If the gummy liquid be precipitated by alcohol, and the precipitate, which is friable when dry, washed with alcohol, there remains, after drying at 100° C., a viscid, semi-transparent, horny mass, while the alcohol takes up a brown uncrystallisable sugar. This mass recovers its former appearance when cold water is poured upon it, and forms with boiling water a gum which is difficult to filter, is not coloured by iodine, does not reduce potassio-cupric tartrate, or precipitate basic acetate of lead, and yields oxalic acid with nitric acid.

When yeast is well washed with cold water, then boiled with water, and $\frac{1}{20}$ part sugar dissolved in the filtrate, the liquid after a few days becomes turbid and tenacious, like decoction of linseed. At the same time, a mixture of carbonic acid and carbonic oxide, in varying proportions, is evolved. This fermentation lasts about 12 days; for a shorter time, between 20° and 25° C.; it takes place also out of contact with air, and is excited even by yeast which has been boiled out with water (Desfosses, J. Pharm. xv. 602). Under similar circumstances, lactous fermentation may likewise take place. [On Mucous Fermentation, see also Vauquelin (Ann. Ch. Phys. xx. 93.)]

Water boiled with gluten, produces in cane-sugar solution the same change as decoction of yeast. In contact with sugar-solution for 24 hours at 25° C., it gives off a smaller quantity of gas than the decoction of yeast, and renders the liquid gummy. The gaseous mixture contains hydrogen in larger proportion to the carbonic acid than that which is evolved by decoction of yeast. After the completion of the mucous fermentation, the liquid is still very sweet, but so thick that it runs out in threads when the vessel is inverted; when evaporated it leaves a non-crystallisable residue, and

on treating this with alcohol, a sacchariferous gum remains undissolved. If the remainder of the sugar be extracted from this gum by fermentation with yeast, there are obtained, for every 100 parts of sugar decomposed by the mucous fermentation, 109.48 parts of a pale yellow insipid gum, which yields scarcely any mucic acid when treated with nitric acid, is less soluble in water than gum-arabic, and yields a thicker mucilage than the latter. (Desfosses.)

FERMENTATION, PECTOUS. Many unripe fruits, fleshy roots, and other parts of plants contain a substance insoluble in water, alcohol, and ether (Frémy's pectose), which, during the ripening of the fruit, is converted, under the influence of a peculiar ferment called pectase, into various gelatinous substances which are soluble in water, viz. pectin, parapectin, and perhaps pectic acid in the ripe fruit, and metapectic acid in the over-ripe fruit. This is called pectous fermentation (Gm. xv. 393). See PECTIN.

FERMENTATION, SACCHAROUS. The conversion of starch into sugar under the influence of diastase (pp. 319, 625).

FERMENTATION, SINAPOUS. The formation of volatile oil of mustard from black mustard seed, by the action of myrosin on myronic acid (p. 624).

FERMENTATION, TANNOUS. See FERMENTATION, GALLOUS.

FERMENTATION, URINOUS. This term is applied to the conversion of urea in solution into carbonate of ammonia. Urea dissolved in pure water remains unaltered, but in the urine, which likewise contains mucus and other nitrogenous substances, it changes, with various degrees of rapidity, into carbonate of ammonia. In presence of yeast the change takes place very quickly. (C. Schmidt, Ann. Ch. Pharm. lxi. 168.)

FERMENTATION, VINOUS. (See p. 627.)

FERMENTATION, VISCOUS. Syn. with FERMENTATION, MUCOUS (p. 632).

FERMENT-OILS. (Gm. xiv. 403.)—These are volatile oils, produced by the fermentation of various plants, not originally contained therein, and essentially different from the oils which are extracted from unfermented plants by distillation with water. According to Becker (N. Br. Arch. lv. 161), they were known to the alchemists, and by them designated *quintessences*. Büchner (*Repert.* liii. 299), in 1835, first separated an oil of this nature from the fermented herb of *Erythraea Centaurium* by distillation.—Ferment-oils are for the most part much more soluble in water than ordinary volatile oils. According to Berzelius (*Jahresber.* xxvii. 541), they are perhaps peculiar alcohols, related to fusel-oil, and forming compound ethers with salt-radicles and acids.

1. *Ferment-oil of Charophyllum sylvestre.*—The flowering plant is left to ferment in water; the liquid distilled when the fermentation is ended; the distillate mixed with common salt, and shaken up with ether; and the ether removed from the aqueous solution and left to evaporate; the ferment-oil dissolved in it is then left behind. It is brown, lighter than water, with a strong and peculiar pungent odour, and an aromatic taste, not bitter, but slightly scratching. Evaporates quickly even at 18° C.: burns, when set on fire, with a clear, luminous flame, diffusing a vapour which excites coughing.—*Chlorine-water* converts it into yellow flocks retaining the odour of the oil. It dissolves iodine. It is decomposed with violence by *nitric acid*. By oil of vitriol it is coloured brown, without losing its odour; the solution is rendered milky by water. It forms an emulsion with *aqueous ammonia*, dissolves sparingly in *water*, easily in *alcohol*, *ether*, and *oils*, both *fixed* and *volatile*. It dissolves resin. (Bley, N. Br. Arch. xlv. 50.)

2. *Ferment-oil of Chelidonium majus.*—Obtained from the roots, in the same manner as the ferment-oil of *Charophyllum sylvestre*. Lighter than water; has an agreeable odour like the bouquet of wine, and a persistent, biting taste. It is not very volatile. With *iodine* it forms a violet solution. With *nitric acid* it evolves nitrous gas, and with *sulphuric acid* it forms a slightly coloured solution which is scarcely clouded by water. It dissolves sparingly in *water*, readily in *alcohol*, *ether*, and *oils*, both *fixed* and *volatile*. (Bley, N. Br. Arch. xlviii. 156.)

3. *Ferment-oil of Conium maculatum.*—Obtained from fresh hemlock in the same manner as the ferment-oil of *Charophyllum sylvestre*. Colourless; has a peculiar odour, not like that of hemlock, and a sharp, burning taste; it is not poisonous. Dissolves with facility in *alcohol*, *ether*, and *oils*, both *fixed* and *volatile*. (Landerer, *Repert.* xlv. 237.)

4. *Ferment-oil of Erythraea Centaurium.*—The plant, after maceration in water for 12 hours, gives off a perceptible odour, which increases up to 60 hours maceration and then ceases (Büchner.) The aqueous distillate is pale-yellow, with white turbidity:

has a persistent enlivening aromatic odour, which is not pleasant when close, and irritates the eyes and nose; its taste is excessively burning, like that of creosote, but not persistent. It reddens litmus, but not permanently (Büchner, *Repert.* liii. 303), and when heated with ammonia and nitrate of silver, reduces the silver to the metallic state (Büchner). To prepare the oil, the fresh herb is macerated in water for 48 hours, the whole distilled, the odoriferous distillate redistilled, and this process continued as long as drops of oil pass over with the watery vapour. It is a thin greenish oil, having a peculiar, but not disagreeable odour; it is not poisonous. (Büchner, *Repert.* liii. 299.)

5. *Ferment-oil of Echium vulgare*.—The plant in the flowering state is distilled with water after maceration; the distillate is shaken up with ether, and mixed with common salt; and the ether decanted therefrom is distilled off. Pale yellow oil lighter than water, and smelling like other ferment-oils. Easily soluble in alcohol and in ether. (Bley, N. Br. Arch. xxx. 167.)

6. *Ferment-oil of Erica vulgaris*.—The fresh herb is distilled after maceration with water; the distillate is cohobated and repeatedly distilled after addition of common salt, then shaken up with ether as long as the ether acquires any odour; and the ether is carefully distilled off from the dissolved oil. The oil obtained amounts to 0.023 per cent. Greenish-yellow, mobile, lighter than water, with a peculiar odour, and a sweetish, aromatic, burning taste; reddens litmus. When set on fire, it burns with a clear, blue-edged flame, without leaving any residue. It is not deodorized by chlorine-water. It dissolves iodine without detonation. With fuming nitric acid, it froths up, and the solution mixed with water deposits resinous flakes. With sulphuric acid, it becomes darker, without losing its colour. (Bley, N. Br. Arch. xxi. 302.)

7. *Ferment-oil of Marrubium vulgare*.—The comminuted herb is soaked in water and exposed to the sun, whereby it acquires an offensive odour; the liquid is then distilled; the distillate saturated with common salt; the flocks thereby separated are collected on a filter and dissolved in ether; and the ether is left to evaporate slowly. The distillate saturated with common salt yields, when heated, a second aqueous distillate from which the oil may be extracted by agitation with ether. It is lighter than water; has a peculiar sweet, ethereal odour, and an aromatic, slightly biting taste. When set on fire it burns with flame, without leaving charcoal. It dissolves in dilute nitric acid, and yields a bitter substance with strong nitric acid. With sulphuric acid it becomes heated and acquires a peculiar odour. With chlorine-water it emits an odour of roses and forms a film of resin. It dissolves in aqueous alkalis and in water. (Bley, N. Br. Arch. x. 67.)

8. *Ferment-oil of Achillea Millefolium*.—The fresh flowering plant is macerated in water, and left to ferment; the whole is distilled, with cohobation; the blue oil which floats on the distillate is removed; the residual water, after addition of common salt, is agitated with ether; and the ether which separates is left to evaporate. Yellow-brown oil, having a slightly aromatic odour, and an aromatically bitterish, rather sharp taste. It dissolves in alcohol, ether, and oils, both fixed and volatile. (Bley, N. Br. Arch. xxx. 167.)

9. *Ferment-oil of various species of Plantago*.—Obtained from plantain-leaves by fermentation, distillation, and agitation of the distillate with ether, in the same manner as the ferment-oil of *Achillea Millefolium*. It is yellow, transparent, has an ethereal odour slightly resembling that of mustard-oil, and an aromatic, sweet, burning taste. Very volatile. With fuming nitric acid it turns brown, with rise of temperature and intumescence; the solution first becomes greenish-yellow with milky turbidity, then clear, smells like artificial musk, and has a disgustingly bitter taste. With sulphuric acid it forms a dark brown-red mixture, from which water separates resinous flocks smelling of resin and ferment-oil. It dissolves in alcohol, ether, and oils. (Bley, N. Br. Arch. xl. 130.)

10. *Ferment-oil of Quercus Robur*.—Obtained from fresh oak-leaves by fermentation, distillation, and treatment of the distillate with ether in the same manner as the ferment-oil of *Achillea Millefolium*. Pale green. Specific gravity 0.695; has an agreeably enlivening odour, a sweet, burning taste, and reddens litmus. It is easily inflammable, burns with penetrating odour, and with a first bluish, then whitish, non-fuliginous flame. With fuming nitric acid it froths up and becomes very hot, but does not lose its odour. With sulphuric acid it becomes hot and assumes a dark red-brown colour. It dissolves sparingly in water, readily in alcohol, ether, and oils, both fixed and volatile. (Bley, N. Br. Arch. xxvi. 48.)

11. *Ferment-oil of Salix pentandra*.—Obtained from fresh willow-leaves in the same manner as the ferment-oil of *Achillea Millefolium*. Yellow, lighter than water; has an aromatic odour, like that of castoreum, and at the same time like that of willow-leaves; reddens litmus. Smells strongly when heated, and burns, when set on fire, with a very smoky flame, leaving a small quantity of charcoal. Dissolves iodine

abundantly. With *fuming nitric acid* it froths up and thickens, but does not take fire.

12. *Ferment-oil of Salvia pratensis*.—Obtained from the fresh herb, like the ferment-oil of *Achillea Millefolium*. Dark red-brown, with a repulsive, ethereal, sweetish odour, and an aromatic taste. It dissolves sparingly in *water*, easily and in all proportions in *alcohol*, *ether*, and *oils*, both *fixed* and *volatile*. It forms a liniment with *aqueous ammonia*, and is very sparingly dissolved by *aqueous potash*. (Bley, N. Br. Arch. li. 257.)

13. *Ferment-oil of Trifolium fibrinum*.—Obtained like the ferment-oil of *Achillea Millefolium*, from the dried plant, even after it has been well boiled with water and no longer has a bitter smell, by fermentation, distillation, saturating the distillate with common salt, and shaking it up with ether. It is pale yellow, lighter than water, smells strongly aromatic, like the ferment oil of *Tussilago farfara*; its taste is at first burning and sweetish, afterwards aromatic. When set on fire, it burns with a blue, slightly fuliginous flame, giving off strong-smelling vapours which excite coughing, and leaves a small quantity of charcoal. It dissolves sparingly in *water*, easily in *alcohol* and *ether*. (Bley, Jahrb. pr. Pharm. ii. 207.)

14. *Ferment-oil of Tussilago farfara*.—The fresh bruised herb is macerated in water for 10 or 12 days, during which it turns light green, and acquires the odour of pickled gherkins; the whole is then distilled; the distillate, which has a vinous odour is saturated with common salt and redistilled; this second distillate is shaken up with a large quantity of ether; and the ether is taken off and evaporated, the dissolved oil then remaining behind. Yellowish, lighter than water, very volatile, with a peculiar, strongly aromatic, penetrating odour, and an aromatic taste, neither burning nor cooling. It easily takes fire and burns at first with a whitish, afterwards with a reddish, sooty flame. It dissolves *iodine* abundantly, dissolves in sulphuric acid with yellowish colour, without losing its odour, and turns brown when heated with it. With *potash* it is said to form a whitish soapy compound. It dissolves sparingly in *water*, readily in *alcohol* and *ether*. (Bley, Repert. lxii. 406.)

15. *Ferment-oil of Urtica urens*.—Obtained like the ferment-oil of *Achillea Millefolium*, from the flowering plant, which, during fermentation, emits, first a vinous, then a sharp and intoxicating odour. Resembles the ferment-oil of *Echium vulgare*. (Bley, N. Br. Arch. xxx. 167.)

19. *Ferment-oil of Vitis vinifera*.—Fermented vine-leaves are distilled; the distillate is cohobated and shaken up with ether; the ethereal solution is distilled; and the ethereal, peculiar-smelling distillate is rectified; the ferment-oil dissolved in it then remains behind. Pale yellow, lighter than water; has a peculiar vinous odour, like vine-flowers and mignonette, and a burning, sweetish, aromatic taste. It reddens litmus slightly but permanently. It evaporates in the air, diffusing a strong odour. Heated with *fuming nitric acid*, it resinises and assumes a grass-green colour. With *sulphuric acid*, it forms first a white, then a light-red, and ultimately a brown mixture, without losing its odour. It is not deodorised by agitation with *chlorine water*. With *aqueous potash* it forms a clear mixture, from which the oil afterwards separates, with red-brown colour, but with its original odour. It dissolves sparingly in *water*, without alteration in *hydrochloric* and *acetic acid*. With *sulphide of carbon* it forms a milky liquid, from which it afterwards separates unaltered; with *carbonate of potassium*, a liniment from which it also separates unaltered; with *aqueous ammonia* a soapy mixture. It dissolves abundantly in *alcohol*, *ether*, and *fixed oils*; in *oil of turpentine* and *oil of lemon*, it forms at first a milky solution, which afterwards becomes clear. (Bley, Repert. Pharm. lxxviii. 301.)

An oil, different from that just described, may be obtained from wine, by leaving it to freeze, distilling off the volatile part of the remaining liquid, and shaking up the residue with ether. (Bley.)

17. *Ferment-oil of diseased Apples*.—*Maloil*, *Oil of Apples*.—Produced in cellulo-stasis, a disease of the apple, which imparts a musky odour to that fruit. It is obtained from the diseased apples by distillation with water. Yellowish-grey, lighter than water; boils at 109° C. Smells of musk, tastes rough and sharp. Contains 64.15 per cent. C, 20.65 H, 15.15 O, and 0.05 N. It volatilises completely when heated, and burns, when set on fire, with a feeble flame, diffusing a small quantity of smoke. *Chlorine* decomposes it, with elimination of hydrochloric acid. With dry *hydrochloric acid gas*, it forms a crystalline compound (*Chlorhydrate de Maloile*). It dissolves readily in *alcohol* and *ether*, and imparts a musk-like odour to *water*. (Rossignon, J. Pharm. xxvii. 168.)

FERRATES. Salts containing iron, analogous to the manganates, and therefore represented by the general formula $M^{\circ}O.FeO^{\circ}$, or $M^2Fe^{\circ}O^4$. They are very unstable, and only the potassium- and barium-salts have been examined.

Ferrate of Potassium was first prepared by Frémy in 1840 (Ann. Ch. Pharm. xl.

261; xlv. 254), and has been further examined by H. Rose (Pogg. Ann. lix. 315) and J. Denham Smith (Phil. Mag. [3] xxiii. 217). But, according to Kopp (*Geschichte der Chemie*, i. 192), Stahl appears to have observed that iron calcined with nitre yields with water a purple or amethyst-coloured solution. Ekeberg also observed, in 1802, that the mass obtained by fusing gadolinite with hydrate of potassium yields with water a dark-red alkaline solution, the colour of which proceeded, not from manganese, but from iron, and Becquerel in 1832 (Ann. Ch. Phys. [2] li. 105) remarked that ferric oxide fused with hydrate of potassium gives off oxygen, which he attributed to the decomposition of peroxide of potassium.

Ferrate of potassium is prepared: 1. By projecting a mixture of 1 pt. iron-filings, and 2 pts. nitre into a capacious crucible kept at a dull red heat, and removing the crucible from the fire as soon as the mixture begins to deflagrate and form a white cloud; if the heat is too strong, the compound decomposes as fast as it is formed. The soft, somewhat friable mass of ferrate of potassium thus obtained may be taken out with an iron spoon and preserved in well-stoppered bottles. Or the salt may be obtained in solution by treating the fused mass with ice-cold water, leaving the liquid to stand, to allow the undissolved ferric oxide to settle down, and then decanting; the solution must not be filtered, as it is immediately decomposed by contact with organic matter.—2. By igniting ferric oxide with hydrate of potassium in an open crucible, or with a mixture of hydrate of potassium and nitre.—3. By passing chlorine gas through a very strong solution of caustic potash containing hydrated ferric oxide in suspension, fragments of solid potash being continually added to maintain a large excess of alkali in the liquid. The ferrate of potassium, being almost insoluble in the strong alkaline liquid, is deposited in the form of a black powder, which may be freed from the greater part of the mother-liquor by drying it on a plate of porous earthenware (Frémy).—4. By electrolysis. A cylinder of porous earthenware is filled with strong potash-ley and placed within a beaker-glass containing the same liquid. A cast-iron plate connected with the positive pole of a powerful voltaic battery dips into the liquid outside the porous cylinder, and a plate of iron or platinum connected with the negative pole is immersed in the liquid within the cylinder. The whole of the liquid is cooled as much as possible by surrounding the beaker with ice. The potash-solution surrounding the positive pole quickly assumes a red colour, and after a while becomes dark and opaque; sometimes also the positive plate becomes coated with microscopic crystals of ferrate of potassium. (Poggendorff and Rose, Pogg. Ann. lix. 315.)

Ferrate of potassium is soluble in water, less soluble in presence of potash. The deep cherry-red solution is, when concentrated, transparent only in thin layers. In the concentrated state, and when mixed with free potash, it may be preserved for some time, and may even be boiled without decomposition, but the more dilute and the warmer the solution is, the more easily does it decompose, with evolution of oxygen and precipitation of ferric oxide; a dilute solution is constantly decomposed by boiling. Acids, even nitric and sulphuric acid, decolorise the red solution immediately, with evolution of oxygen, and if only a small quantity of acid is present, with separation of ferric oxide; with hydrochloric acid it gives off chlorine. The solution is decomposed by metals, and by many metallic salts, including alum; from salts of manganese and nickel, it throws down peroxides of these metals. It is quickly decomposed and decolorised by deoxidising substances, such as sulphurous acid, nitrous acid, ammonia, ammoniacal salts, and especially by organic bodies. Sulphydric acid and sulphide of ammonium impart to the concentrated solution a dark green colour, becoming light green on dilution with water, brown when heated, green again on cooling; in this reaction a sulphur-salt appears to be formed, containing a polysulphide of iron analogous to ferric acid.

By passing sulphurous acid gas through the aqueous solution till the colour is destroyed, and determining the quantity of ferric oxide precipitated, and of sulphuric acid produced (by supersaturating the filtrate with hydrochloric acid and precipitating with chloride of barium), it is found that 699 pts. (3 at.) sulphate of barium, BaSO_4 , correspond approximately to 150 pts. (1 at.) ferric oxide, Fe_2O_3 . Hence ferrate of potassium is K^2FeO_4 or $\text{K}_2\text{O}.\text{FeO}_3$, and the decomposition is represented by the equation:

Consequently, ferric acid, if it could be obtained in definite form, would be H^2FeO_4 , or $\text{H}_2\text{O}.\text{FeO}_3$, and ferric anhydride FeO_3 . (H. Rose.)

Ferrate of sodium is obtained similarly to ferrate of potassium. The other salts, which are insoluble, are obtained by precipitation.

Ferrate of barium, $\text{BaO}.\text{FeO}_3$ + H_2O (?), or $\text{Ba}^2\text{Fe}^2\text{O}^4$ + aq. (?), is obtained by decomposing the potassium-salt with chloride of barium, as a bulky cochineal or purple-red precipitate, becoming brick or rose-red after washing and drying at 100°C . It is tolerably stable, may even be boiled for a while with water, and dissolves with red

colour in acetic acid; but by nitric or sulphuric acid, or by strong heating, it is immediately decomposed and decolorised. (Denham Smith.)

FERRIC ACID, or *Ferrate of Hydrogen*, has not been obtained in definite form, or even in aqueous solution, as it decomposes and gives off oxygen as soon as liberated from its salts by the action of an acid (p. 637).

FERRIC OXIDE. *Sesquioxide of Iron*. Fe_2O_3 . See IRON.

FERRIC SALTS. *Sesquisalts of Iron*. See IRON, and the several ACIDS.

FERRICYANIDES or **FERRIDICYANIDES**. See CYANIDES OF IRON (p. 243).

FERRITES. Compounds of ferric oxide with alkalis. (See IRON, OXIDES OF.)

FERROCOPALTIME. Cobaltine, $\text{Co}^2\text{As}^2\text{S}_2$, in which a considerable proportion of the cobalt is replaced by iron. (See COBALTIME, i. 1057.)

FERROCYANIDES. } See CYANIDES OF IRON (p. 222).

FERROPRUSSIATES. }

FIBRIN is the name given to the substance which is separated in the solid state from blood on coagulation. A similar matter is contained in the solid muscular flesh of animals, but differs from blood-fibrin in certain properties. Lehmann has named this fibrinous substance *syntonin*. Fibrin is also contained in lymph.

1. *Preparation*.—Fibrin may be obtained immediately by lashing fresh blood with a bundle of birch-twigs; it attaches itself to the twigs in amorphous, fibrous filaments, which retain a red-colour from adhering blood globules. In order to free the fibrin from colouring and other matters, it is placed on a sieve or a cloth and subjected to prolonged washing under a copious stream of water, and the portions which retain the red colour most obstinately are picked out and thrown aside. It is finally washed with distilled water charged with carbonic acid. A few drops of acetic acid may be advantageously added to the last wash-waters; this causes the fibrin to swell up, and renders it easier to distinguish the impure portions. The product, finally washed with pure water, assumes the semi-transparent, fibrous aspect, peculiar to fibrin. (Gerh. iv. 459.)

When fresh blood is allowed to stand, it coagulates spontaneously, the clot, at the same time, enclosing all the blood-globules. It is therefore necessary to cut the clot into thin slices, and wash it with still greater care than artificially coagulated fibrin. Fibrin obtained by either method always contains many impurities, especially fat-globules; these may be removed by ether and alcohol, after the product has been dried.

Gerhardt recommends the following method for preparing fibrin in a state approaching to purity. The blood, as it leaves the veins, is allowed to flow upon the twelfth or fifteenth of its weight of moist sulphate of sodium, which prevents the fibrin from coagulating. The mixture is agitated and thrown on a filter, which retains by far the greater part, if not all the globules. If the filtrate is slightly red, it is mixed with an equal volume of water, and again filtered; and this process is repeated till the liquid begins to deposit fibrin. The fibrin is then collected, strained off, and washed with water, alcohol, and ether.

Liebig prepares muscular fibrin (*syntonin*) by finely mincing fresh meat, and exhausting with cold water. The residue is then treated with water containing 0.1 per cent. hydrochloric acid, and the solution is filtered and neutralised with ammonia. The fibrin is purified in the usual manner.

Baumhauer uses fish for preparing *syntonin* (*Chemische Unters. v. Mulder*, German transl. iii. 301), but the method does not appear to be advantageous.

Impurities.—Fibrin is generally mixed with fat-globules, but only such as are found adhering to the different constituents of blood. Lehmann discovered cholesterol in this fat, also acetic acid, perhaps formed by the oxidation of ether, and another fatty acid (*Gmelin's Handbuch*, viii. [2] 171). Fat always adheres to fibrin, and appears to consist principally of ammonia- and lime-soaps (Berzelius, *Lehrb. d. Chem.* ix. 88). Schmidt extracted from 7.4 to 8.7 per cent. fat from the fibrin of the blood of the portal vein. Lehmann found between 3.189 and 3.218 per cent. of fat in fibrin (*Gmelin's Handbuch*, viii. [2] 141). Virchow extracted, by means of alcohol and ether, between 2.50 and 2.76 per cent. fat from venous fibrin. The fibrin of chyle is richer in fat than blood fibrin. Virchow found phosphoglycerate of calcium in blood-fibrin, and much phosphate of calcium in its ash. Fibrin always leaves a mineral residue on incineration, consisting chiefly of phosphate of calcium, amounting to 1.7 per cent. (Mulder), 0.66 per cent., with a little carbonate of calcium (Virchow). A little phosphate of magnesium is likewise found in the ash, but no iron when the fibrin has been properly purified. According to Liebig, the ash of *syntonin* always contains iron. Fibrin of the arterial blood of the horse contains 2.172 per cent. ash; that of the

jugular blood 1.907 per cent. In chyle-fibrin, which had been properly freed from fat, washed, and dried, 1.77 per cent. strongly alkaline ash was found (Lehmann). Virchow thinks it probable that the fat adhering to fibrin contains *myelin*, a substance which he considers to be identical with nerve-marrow, and to bear a certain resemblance to cerebrie acid. It is found in various normal and morbid structures; when treated with water, it swells up like starch.

Formation of Fibrin from Albumin.—When defibrinated serum is subjected to the action of a current of oxygen gas, at a temperature of 98° — 100° Fahr., the albumin contained in it is gradually converted into fibrin*, which separates after about 36 hours in clots, and when freed from blood-cells and other impurities by washing with water, presents the appearance of ordinary fibrin. A similar result is obtained when a mixture of blood-serum and egg-albumin is treated with oxygen gas, time being allowed for the two liquids to mix well together. Egg-albumin alone, when purified by beating it up with a small quantity of acetic acid, and filtering, also yields fibrin when a stream of oxygen is passed through it. The introduction of coils of platinum wire into the liquid greatly facilitates the formation of the fibrin, which is then deposited on the coils in beautiful white parallel threads. Alkalis and alkaline salts interfere with the production of fibrin in the manner above described, the greatest amount being obtained when the albumin is neutral or slightly acid. Viscidity of the liquid promotes the formation of fibrin by detaining the bubbles of oxygen for a longer time among the particles of the albumin. Albumin artificially digested in gastric juice yields fibrin by oxidation, even after it has been passed through a dialyser. *Gluten* dissolved in gastric juice also yields fibrin by oxidation, even at ordinary temperatures. (A. H. Snow, Proc. Roy. Soc. xii. 399.)

Properties.—Fibrin has been said to separate from the blood in laminae. This is not certain, but when completely washed, it consists of soft, elastic, transparent filaments, which do not cohere by pressure. It is completely insoluble in cold water, in alcohol, and in ether.

Freshly prepared fibrin loses about 80 per cent. water in vacuo (Chœvreul), and is converted into a hard, horny, transparent mass, of yellowish or greenish colour, and completely devoid of taste and smell. It takes up about three times its weight of water, without, however, entirely regaining its former appearance. When well-washed fibrin is boiled for a long time with water, the distillate contains much ammonia, and a peculiar substance is extracted from the residue by water (Dumas and Cahours). The substance extracted from fibrin by boiling water, has, according to Bouchardat, all the properties of gelatin; the proportion varies considerably, being insignificant in healthy fibrin, but increasing to a considerable amount in inflammatory diseases of the cellular tissue. The substance obtained by Dumas and Cahours did not become gelatinous on cooling, but appeared to resemble albumin; it was precipitated by tannin and nitric acid, contained 11 per cent. ash, and the organic part gave 47.9 per cent. C, 6.8 per cent. H, 15.0 per cent. N, and 30.3 per cent. O.

Heated with water in a sealed tube to 160° C., fibrin dissolves almost completely, leaving a slight residue. The solution produces abundant precipitates with acids, and even when very dilute, is precipitated by nitric acid. The precipitate produced by acetic acid is readily soluble in an excess of the acid.

When moist fibrin is exposed to the air, it is gradually converted into a thick viscid liquid, smelling like old cheese. This liquid coagulates by heat; the coagulum has the composition and properties of albumin (C 53.9, H 7.0, N 15.6, S 1.6 per cent.; ash 0.28 per cent. Strecker). Putrefying fibrin also yields sulphide of ammonium, butyric and valeric acids; leucine; an oily acid precipitated by acetate of lead; an acid syrup which is dissolved by acids, thereby assuming a violet colour and being converted into tyrosine; and a crystalline volatile substance of unpleasant odour (Bopp, Ann. Ch. Pharm. lxi. 30). When fibrin putrefies out of contact with the air, it yields acetic, butyric, valeric, and capric acids, as well as ammonia (Brendecke). Fibrin, in contact with oxygen, gives off carbonic acid; and fibrin, which has been long exposed to the air, and perhaps also fibrin from arterial blood, dissolves with difficulty or not at all in saline solutions. Peroxide of hydrogen is decomposed by fibrin. If fresh fibrin, moistened with water and saturated with oxygen, is enclosed in 8 times its volume of air, and maintained between 20° and 25° C., the gas, after 24 hours, contains 6.81 per cent. O, 11.17 CO₂, and 82.02 N.

Fibrin has been analysed by a great many chemists; the results are not sufficiently in accordance to lead to the conclusion that it is a homogeneous substance. It appears to vary considerably in composition, according to the source from which it has been obtained.

* A black substance, analogous to if not identical with Virchow's *hæmin*, is formed at the same time.

Mulder (*Chemische Untersuchungen*) gives, for the composition of fibrin, 52.7 per cent. C, 6.9 H, 15.4 N, 1.2 S, 0.3 P, and 23.5 O. Comparing this result with the analysis of blood-albumin by the same chemist (i. 67), it will be seen that the oxygen in fibrin exceeds that in albumin by 1.5 per cent, the quantities of the other elements being proportionally less. This difference is quite in accordance with the fact observed by Smee (p. 639), that albumin is converted into fibrin by oxidation, with separation of sulphur, phosphorus, and carbonic acid. On the other hand, it must be observed, that, according to the analyses of other chemists, albumin and fibrin do not present any essential difference of composition: indeed, the analyses of each of these substances by different chemists (see above and i. 67), differ from one another quite as much as the analyses of either substance differ from those of the others. If they are really identical in composition, the conversion of albumin into fibrin by the action of oxygen, must be regarded as a case of contact-action.

According to MM. Lobonté and Goumoens, fibrin is composed of two bodies; exhibiting, under the microscope, yellowish-white fibres, parallel and wavy on the sides, as well as very numerous granulations disseminated upon the surface of its fibres and enclosed by them. (Gerh. iv. 464.) See p. 641.

Decompositions.—1. Fibrin is decomposed at a high temperature; it melts, swells considerably, takes fire and burns with a smoky flame, leaving a residue of porous charcoal. By dry distillation, it yields the same products as albumin.

2. Fibrin dissolves in *caustic potash*, even in very dilute solutions; at first it swells up and becomes gelatinous, and between 50° and 60° C. gradually dissolves, forming a slightly opaline yellow solution, which becomes clear on filtration. Fibrin does *not* neutralise the alkali, but decidedly lessens its alkaline properties; the solution has the characteristic of albuminate of potassium, yielding precipitates with acetic and with tribasic phosphoric acids, soluble in excess of the precipitant. According to Mulder, if fibrin is digested with very weak alkali, and the solution neutralised with acetic acid till it begins to be precipitated, compounds with metallic oxides may be obtained on the addition of their salts. Gerhardt thinks that these precipitates are identical with the metallic albuminates (i. 68). When fibrin is boiled with caustic potash, ammonia is evolved, and the liquid contains sulphide of potassium. Heated with potash-lime between 160° and 180° C., it evolves ammonia and other volatile products, while a small quantity of a volatile fat acid is formed, which remains combined with potash (Wurtz). When fused with potash, it yields hydrogen and ammonia, leucine, tyrosine, and probably butyrate, valerate, oxalate, &c., of potassium. (Bopp.)

3. Fibrin is scarcely acted upon by *ammonia*.

4. Concentrated fuming *hydrochloric acid* causes fibrin to swell, and dissolves it when heated, forming a violet solution. When this solution is boiled in an open vessel, it

* Appears to have lost nitrogen in the form of ammonia.

turns brown, and is then found to contain chloride of ammonium, leucine, tyrosine, a brown substance not yet examined, an uncrystallisable body slightly soluble in water and very soluble in alcohol, and a sweet syrupy matter (Bopp). According to Mulder, fibrin absorbs 7.1 per cent. of gaseous hydrochloric acid, yielding a compound almost insoluble in water.

According to Liebig, blood-fibrin is perfectly insoluble in *dilute hydrochloric acid*; he says that fibrin, macerated in water containing 10 per cent. hydrochloric acid, is gradually converted into a jelly, which shrinks on the addition of more concentrated acid, and again swells up with pure water, without, however, any appreciable quantity of fibrin being dissolved. Syntonin however dissolves in the dilute acid more or less completely, according to the source from which it has been obtained. Dumas and Cahours found that water containing 0.001 per cent. hydrochloric acid caused fibrin to swell, without, however, dissolving it after 48 hours' digestion. But the addition of a few drops of hydrochloric acid, or of rennet, rapidly effected its solution at 36° C. The experiments of Bouchardat seem the most reliable, and have since been confirmed by v. Baumhauer (Ann. Ch. Pharm. xlvii. 320); they prove that fibrin is not a homogeneous substance, but that it is composed of at least two bodies. When moist fibrin, prepared from whipped or coagulated blood, is steeped in water containing 0.0005 per cent. hydrochloric acid, and therefore scarcely acid to the taste or to litmus, it immediately swells up and is converted into a mass of very bulky flakes. The swollen vesicles are rent by prolonged maceration, and the greater part of the fibrin dissolves; always leaving, however, a certain portion insoluble in excess of the acidulated water. The soluble portion (albuminose) scarcely reddens litmus, rotates the plane of polarisation to the left, is precipitated in light flakes by heat, and yields a precipitate with excess of hydrochloric or nitric acid, with tannin, mercuric chloride, ferrocyanide of potassium, and possesses generally all the characteristics of egg-albumin (Gerh. iv. 466). The precipitate produced by carbonate of ammonia in the solution has the following composition (it left no ash on incineration):

	v. Baumhauer.	Verdel.
C 52.9	
H 6.9	
N 15.9	
S	1.6
O	

Bouchardat terms the undissolved portion *epidermos*, and considers it to be identical with the chief constituent of the epidermis and of horny substances.

5. *Nitric acid* turns fibrin yellow, and readily dissolves it by ebullition, forming an orange-yellow acid substance, xanthoproteic acid. (Mulder.)

6. Concentrated *sulphuric acid* causes fibrin to swell, and dissolves it by heat. The dilute acid does not dissolve fibrin.

7. Glacial *acetic acid* dissolves the granulation of fibrin, without attacking the fibrous portions (Lebonte and Goumoens). Concentrated acetic acid immediately converts fibrin into a colourless jelly, dissolving readily in hot water (according to F. Simon, the gelatinous mass does not dissolve). The acetic acid solution, evaporated at a gentle heat, becomes covered with a film, and then assumes a gelatinous appearance; the dry residue is insoluble in water. The solution is precipitated by sulphuric and hydrochloric acids; also by alkalis, but the precipitate redissolves in excess of the precipitant.

8. *Tribasic phosphoric acid* renders fibrin gelatinous; the jelly dissolves in water and is not precipitated by excess of acid. *Metaphosphoric acid* behaves like sulphuric acid.

9. According to Lehmann and Zimmermann, the several kinds of fibrin dissolve, for the most part, in *alkaline salts*; syntonin, however, is insoluble in dilute nitre solution (Lehmann). Neither arterial nor venous fibrin, when boiled in water or exposed to the air for some time, is soluble in nitrate of potassium. (Denis, Scheerer.)

10. Denis employs the following process for dissolving fibrin in *nitrate of potassium*:—50 pts. well-washed moist venous fibrin are triturated with $\frac{1}{2}$ of their weight of nitre; water equal to 4 times the weight of the fibrin employed is gradually added; and then $\frac{1}{2}$ pt. of caustic soda or potash. The whole is allowed to digest at about 37° C., with constant agitation. The mixture first becomes gelatinous, then viscid, and, after a few days, liquid; a small residue always remaining. The liquid thus obtained coagulates by boiling, like albumin, and is precipitated by alcohol, mercuric chloride, acetate of lead, &c. If alkali be not added, the solution is precipitated by the addition of a large quantity of water (Gerh. iv. 468). The solution, exposed for some time to the air, gradually becomes turbid, and deposits flakes which are insoluble in the mother-liquor.

11. If fibrin be dissolved in potash, and acetic or phosphoric acid added to the solution till the precipitate first formed redissolves, a liquid is obtained, from which white flakes are precipitated by neutral salts (Panum). The potash-solution is precipitated by *mercuric chloride, sulphate of copper, and acetate of lead.*

12. *Tannin* of gull-nuts precipitates fibrin from its saturated solutions; it combines with moist fibrin, forming a hard imputrescible mass.

13. *Ferrocyanide of potassium* produces with the acetic acid solution a white precipitate, which at first redissolves but afterwards becomes permanent. It is not dissolved by diluted acids, but is decomposed by alkalis and even by ammonia.

14. *Sulphuric acid* with *peroxide of manganese, or acid chromate of potassium*, yields with fibrin the same products as with albumin (i. 67).

Sources and physiological relations of Fibrin.—Lehmann (*Gmelin's Handbuch*, viii. [2] 167), considers that fibrin is formed from albumin in the animal organism, possibly by the latter taking up oxygen, a mode of formation rendered highly probable by the results obtained by Smee (p. 639), in the artificial production of fibrin from albumin. The occurrence of fibrin in the chyle is not opposed to this view, partly because fibrin may be conveyed to this fluid by the lymphatics and blood-vessels, and partly because all the juices of the animal body contain free oxygen (Lehmann). Neither is the formation of fibrin from albumin by oxidation contradicted by the fact that in pneumonia, when a portion of the lung is rendered impermeable to air, and consequently the supply of oxygen must be diminished, the quantity of fibrin in the blood is increased. The fact is, that the conversion of albumin into fibrin is only the first stage in the process of oxidation, which, when further continued, transforms the fibrin into urea, and various other oxidised products, which pass into the excretions, so that the scanty supply of oxygen which the blood receives in certain diseases, may be sufficient to convert the albumin into fibrin, but not to oxidise it further.

Fibrin is not simply suspended in the blood, as Hunter and others supposed. It is not true that it is kept in solution by alkalis or alkaline salts, and that the coagulation is caused by the neutralisation of the solvent with carbonic acid from the air, since blood saturated with carbonic acid is found to coagulate much more slowly than blood deficient in the gas, and the addition of alkaline carbonates retards or entirely prevents the coagulation of blood. The cause of spontaneous coagulation is not known. Blood stagnated in veins, and thus shut out from the air, is always much longer in coagulating than when there is a free access of air. Hence the presence of air seems necessary for the coagulation of blood, as is rendered highly probable by numerous experiments, from which it has also been concluded, by trying the action of different gases, that oxygen is the principal, if not the sole agent. The coagulation of blood in closed vessels is probably due to the slow evolution of oxygen dissolved in the fluid of the blood-cells, and the rapid coagulation of blood in an exhausted receiver may arise from the sudden and rapid evolution of the gas. (*Gmelin's Handbuch*, viii. [2] 155-7.)

C. Schmidt thinks that, in the circulation, the fibrin is combined with neutral albuminate of sodium, forming an acid salt, which is resolved into its components on leaving the circulation. The fibrin forms the clot, while the albumin, which is precipitated from the serum on boiling, he supposes to have been previously in combination with chloride of sodium, which remains in the mother-liquor, together with the neutral albuminate. (*Gmelin's Handbuch*, viii. [2] 155.)

According to W. B. Richardson, the coagulation of fibrin is consequent upon an exhalation of ammonia from the blood; but this seems very doubtful. According to Lister (*Proc. Roy. Soc.* xii. 580), the coagulation is brought about catalytically by contact with foreign matter: whence blood remains fluid in the vessels, not because their walls exert any influence opposing coagulation, but because during life, and for some time after death, they do not act as exciters of coagulation.

It has been supposed that blood coagulates more slowly the less fibrin it contains; but this in many instances is not the case, and the coagulation of blood appears to be modified by other causes.—The blood of amphibious animals coagulates the most slowly, that of birds the most rapidly. The blood of the small veins contains more fibrin than that of arterial blood, in the proportion of 6 : 4, so that a considerable quantity of fibrin appears to be formed in the capillaries, although it must be remembered that the fibrin, owing to the diminution of blood-cells, is in part only relatively increased. The percentage of fibrin in the blood of the *vena cava* is, even when this blood is unmixed with the liver-blood (which does not contain fibrin), very small in proportion to that of arterial blood,—about 214 : 410. In accordance with these data, Lehmann considers that fibrin is principally formed in the arteries, increased in the capillaries, and disappears in the larger veins (*loc. cit.* p. 699).

Normal human blood contains about 2.55 per cent. fibrin (Nasse). Blood is said to yield less fibrin by agitation than by spontaneous coagulation, to the amount of $\frac{1}{10}$ less (Marchal de Calvi). Abbeille, however, says that more fibrin is obtained from

ed by agitation than by spontaneous coagulation, and that blood heated to 60° C. coagulates by agitation more fibrin than at the common temperature, but that agitation has a greater effect on the quantity of fibrin than the temperature; blood coagulated at 10° C., yields less fibrin than at the common temperature. It was found that the blood of rabbits did not coagulate when carbonate of sodium or of potassium had previously been injected into the vein.

Coagulating blood cools much more slowly than non-coagulating blood at the same temperature. The passage of fibrin from the soluble to the insoluble state is either the cause of the evolution of heat, or hinders the process of cooling (Lehmann). According to Nasse and Poggiale, the blood of new-born children contains much less fibrin than that of adults, the augmentation being especially large at the age of maturity. According to Nasse, the blood of women contains on the average 2.20 per cent. of fibrin; according to Andral and Gavarret, the proportion increases during pregnancy, especially in the last three months. Lehmann found more fibrin in his blood when living exclusively on animal diet, than on vegetable diet, a result which Nasse had arrived at by experimenting upon dogs (*Gmelin's Handbuch*, viii. [2]). The quantity increases by fasting or by blood-letting, while the number of red-cells decreases.

The fibrin of portal blood is described by Schmidt as a viscid, gelatinous mass. That of chyle is distinguished from blood-fibrin by a lower degree of contractility and does not gelatinise. Like the fibrin of many morbid secretions, and that of fish, it sometimes, and especially in warm atmospheres, redissolves a few hours after coagulation. *Lymph-fibrin* is exactly like that of blood. Gorup-Besanez (*Ann. Ch. Pharm.* xciv. 166-9) found a peculiar kind of fibrin in an infiltrated liquid obtained from the chest of a tuberculous patient. It swelled up in water, and then formed a turbid solution on being heated. The residue from the evaporated solution dissolved readily by a gentle heat in hydrochloric acid of 1 per cent., but was insoluble in a solution of nitre containing 6 per cent. of the salt. Fibrin is not generally found in normal infiltrations.

The following table contains the percentages of fibrin in the blood of different animals:

	Nasse.	Poggiale.	Andral, Gavarret, and Delafond (average).
Ox	3.6—4.0	5.0	3.6
Cow	3.6—4.0	5.0	3.8
Sheep	3.0—3.8	3.2	3.2
Goat	3.35—3.9	5.0	3.15
Horse	2.4—2.85	5.0	4.0
Pig	3.6—3.9	5.0	4.6
Dog	1.7—1.9	2.2	2.1
Fowl	5.85	5.0	
Goose	3.4		
Pigeon		5.0	

Gmelin's Handbuch, viii. [2] 188.)

Fibrin is dissolved by bile free from mucus. (Hünefeld.)

Fibrin is more easily digested than coagulated albumin or casein. With dogs it appears to digest entirely in the course of three hours. Its digestibility, however, is naturally influenced by the state of aggregation; boiled fibrin is more slowly digested than raw fibrin.

Mulder (*Jahresb. f. Chem.* 1859, p. 538) remarked that fibrin placed in a full stomach, with a little diastase, swelled up and partly dissolved, but after a time resumed its primitive form. He thinks this is owing to the fact that a given quantity of diastase can only effect the solution of one and the same quantity of fibrin, which, after the diastase has performed its office, again returns to its former state.

Fibrinous casts of the uriniferous tubes of the kidney are sometimes met with in the urine of persons suffering from Bright's disease; moreover the so-called *chylous urine* sometimes spontaneously coagulable, from the solidification of fibrin.

Fibrin occurs in milk only when the latter contains blood.

In inflammatory diseases of the mucous membranes (*Diphtheria, Pneumonia, Dysentery, Bright's disease, &c.*), fibrin is found in the secreted mucus. C. E. L.

FIBRIN, VEGETABLE. *Insoluble vegetable albumin* (Berzelius). *Zymome* (Ladde).—The portion of the gluten of cereal plants, which is insoluble in alcohol; in the gluten of wheat it is mixed with gliadin; in that of rye and barley, also of buckwheat, with fatty and resinous substances.

To prepare it, wheat-gluten is repeatedly boiled with alcohol, till the liquid no longer gives any residue on evaporation. It then remains in the form of a greyish-white,

elastic mass, still contaminated with small quantities of starch and chaff, from which it may be freed by solution in dilute potash, and precipitation with acetic acid; also with fat, which may be removed by subsequent treatment with ether. The gluten, after exhaustion with alcohol, may also be dissolved in very dilute hydrochloric acid, which easily takes up the fibrin, and yields it as a precipitate on neutralisation with ammonia. The hydrochloric acid solution behaves just like that of muscle-fibrin, and is precipitated in thick flakes by chloride of sodium.

Vegetable fibrin, when dry, forms a brownish horny mass, which recovers its former character by maceration in cold water. It dissolves in *acetic, hydrochloric, and phosphoric acids*, in the *fixed alkalis*, and in *ammonia*, and is precipitated from these solutions on neutralisation.

100 pts. of vegetable fibrin yield by analysis:

	Scherer.*		Jones†	Dumas and Cahours.‡			Verdill§
	a	b	c	d	e	f	g
Carbon . . .	54.2	54.2	53.1	53.2	53.4	53.4	53.7
Hydrogen . . .	7.3	7.5	7.0	7.0	7.0	7.1	7.1
Nitrogen . . .	15.8	15.8	15.6	16.4	16.0	15.8	
Sulphur . . .							1.0
Oxygen . . .							

a, c, d, e, f were extracted from gluten of wheat; b from gluten of rye, d and e had been treated with diastase; f' was the same as e, but had been kept in boiling water for three days, then washed and dried at 140° C.; g was extracted from rye.

These analyses show that vegetable fibrin has essentially the same composition as animal fibrin. The ash does not contain any soluble alkalis. (Liebig.)

Vegetable fibrin undergoes gradual alteration in contact with moisture, and is transformed in a similar manner during the germination of cereal grains, giving rise in the latter case to the peculiar ferment called diastase (p. 319).

The green deposit which separates from expressed vegetable juices on standing, probably contains vegetable fibrin, but it has not been examined.

FIBROFERRITE. A basic ferric sulphate occurring in Chile in botryoidal masses, having a radio-fibrous structure and pale golden green colour. According to an analysis by F. Field (Chem. Soc. Qu. J. xiv. 156), it contains 31.94 per cent. SO₃, 31.89 Fe₂O₃ and 35.90 water, whence the formula:

When exposed to the air for some weeks, it gives off 2 at. water; at the heat of the water-bath 7 at., and the remaining 3 at. at 250° C., leaving the anhydrous salt Fe₂O₃ · 2SO₃. It dissolves partially in cold water, imparting a slight acid reaction. In water of 43° C., it is resolved into an insoluble yellow ochrey substance = 2Fe₂O₃ · SO₃ + 3H₂O, soluble neutral ferric sulphate, and free sulphuric acid:

The insoluble ochrey substance is often found associated with fibroferrite. (Field.)

FIBROÏN. A substance allied in composition to horny tissue, and constituting, according to Mulder (Pogg. Ann. xxxvii. 294; xl. 266), the fibre of silk and of gossamer-threads. It is obtained pure by exhausting raw silk successively with boiling water, alcohol, ether, and acetic acid; these solvents removing albumin, a glutinous substance, fat, and colouring matter. The silk, after this treatment, is very white, soft to the touch, and destitute of lustre. It contains, after deduction of ash, 48.53 per cent. carbon, 6.50 hydrogen, 17.35 nitrogen, and perhaps a little sulphur, besides oxygen. The ash, which is in considerable quantity, contains lime, magnesia, ferric oxide, oxide of manganese, and soda, in combination with carbonic, sulphuric, hydrochloric, phosphoric, and silicic acids.

Fibroïn, when calcined, emits the odour of burnt horn. By dry distillation, it yields a large quantity of carbonate of ammonia, water, empyreumatic oil, and an abundant residue of charcoal. Dilute aqueous potash does not act upon it in the cold, but dissolves it at the boiling heat. Strong potash-ley dissolves it, forming a solution which is precipitated by acids and even by pure water. Solid hydrate of potassium converts it into oxalate. Fibroïn does not dissolve in ammonia or in alkaline carbonates. Strong sulphuric acid dissolves it in the cold, forming a thick liquid, which forms with water a solution precipitable by infusion of gall-nuts and by caustic potash; the precipitate formed by potash dissolves, however, in excess of the reagent. Strong

* Ann. Ch. Pharm. xl. 1.
‡ Ann. Ch. Phys. [3] vi. 483.

† Ibid. xl. 67.
§ Ann. Ch. Pharm. lvi. 317

hydrochloric acid dissolves fibroin, the solution turning brown when heated. Dry fibroin absorbs 7·4 per cent. hydrochloric acid gas. Fibroin likewise dissolves in strong nitric acid, yielding oxalic acid when heated, and in phosphoric acid.

The organic matter of sponges exhibits the same characters as the fibroin of silk; after exhaustion with dilute hydrochloric acid, alcohol, and ether, and drying at 100° C., it contains:

	C	H	N	S	P	I	O	
48·61	6·31	16·15	0·50	1·90	1·08	27·55		Crookewit (Ann. Ch. Pharm. xlviii. 43).
48·60	6·29	16·15	ash	3·69				Posselt (<i>ibid.</i> xlv. 192).

According to Mulder, the organic matter of sponges is a combination of fibroin with sulphur, phosphorus, and iodine; but these elements, with the exception of sulphur, do not form an essential part of the organic matter. (Gerh. iv. 499.) See SPONGE.

FIBROLITE. A fibrous variety of SILLIMANITE (*q. v.*)

FICHELITE. A fossil resin, isomeric with oil of turpentine, found together with kōnilit, at Redwitz in the Fichtelgebirg. It forms small monoclinic crystals, melts at 46° C., and solidifies at 36° in the crystalline state. Slightly soluble in alcohol, easily in ether, and separates therefrom in tabular crystals, exhibiting the combination $oP. + P. - P. - P\infty. + P\infty.$, but with the pair of faces $-P$ wanting on the right of the orthodiagonal, and the pair $+P$ on the left. Inclination of $oP : -P\infty = 127^\circ 45'$; $oP : +P\infty = 106^\circ 25'$; $-P : -P$ (on the orthodiagonal) $= 99^\circ 0'$; $+P : +P$ (on the same axis) $= 108^\circ 40'$; $-P\infty : +P\infty$ (at the base) $= 125^\circ 50'$ (Clark, Ann. Ch. Pharm. cxix. 226). Schrötter (Pogg. Ann. lix. 37), by exhausting the pine-wood found at Redwitz, which is impregnated with fossil resin, with ether, obtained xyloretin (*q. v.*), which crystallised from the solution, and an oily mass which deposited a small quantity of brown resin, and then a light yellow liquid, smelling like benzoin, sparingly soluble in alcohol, easily in ether, and having the same composition as fichtelite; it may be called liquid fichtelite. Analysis gave:

	Solid Fichtelite.		Liquid Fichtelite.
	Bromels.	Clark.	Schrötter.
Carbon	88·07	87·13	88·58
Hydrogen	10·70	12·87	11·34
	98·77	100·00	99·92

Both these substances, as well as hartite and tekoretin, have the composition $C^{10}H^{16}$. (Rammelsberg's *Mineralchemie*, p. 976.)

FICARIA. The plant called pile-wort (*Ranunculus Ficaria*, L. *Ficaria ranunculoides*, Dec.), is said, by St. Martin (Rép. Chim. app. i. 425), to contain a peculiar substance called ficarin, closely resembling saponin, and differing therefrom only in not being coloured by ferric chloride. It is said to be obtained by treating the aqueous extract with alcohol, or the alcoholic extract with water, and evaporating. The leaves give only traces of it, the tubers more, and the roots a still larger quantity.

The plant is also said to contain an acrid volatile acid, easily decomposed by heat, and probably occurring in all plants of the ranunculaceous order.

FICARIN. See FICARIA.

FICINITE. See VIVIANITE.

FICUS. The stems and branches of plants of this genus yield a viscid milky juice, containing caoutchouc or resinous substances resembling it: caoutchouc is most abundantly contained in the juice of the stem of *Ficus elastica*, from which a considerable portion of the caoutchouc of commerce is obtained.

The milky juice obtained from the young stems of the common fig-tree (*Ficus carica*) has an aromatic odour, and sharply aromatic, bitter taste, reddens litmus slightly, does not coagulate when boiled, but deposits a white viscid substance. It contains an odoriferous substance, eerin, a very small quantity of a hard resin insoluble in ether, caoutchouc, a deliquescent extractive matter having a sharp, bitter, nauseous taste; also gum, albumin, sulphates, chlorides, the salts of vegetable acids, and a free vegetable acid. (Geiger and Reimann.)

The juice which exudes from the milky husks of green figs contains cerin, a resin having a sharp burning taste, and a substance like caoutchouc. On exhausting the husks with alcohol, and distilling the alcoholic extract, an acrid distillate is obtained, which deposits crystals; the residue is a resin quite free from acidity (Landerer.) Dried figs contain, according to Bley, fat, sugar, extractive matter, chloride of calcium,

a salt of phosphoric acid, vegetable fibre, and (?) seed-germs. (*Rockleder's Phytoche-mie*, p. 203.)

The milky juice of the young branches of *Ficus elastica* contains viscin (a ductile, soft resin, insoluble in alcohol), resin, wax, gum, extractive matter, and a lime-salt. That of the stem is similarly constituted, but contains caoutchouc instead of viscin. (Nees v. Esenbeck and Clamor-Marquart.)

The fresh acid creamy juice of *Ficus sylvestris* (St. Hilaire), and *F. doliaria* (Mart.), South American species, dries up in the sun to a reddish-yellow elastic mass, resembling gutta-percha, easily soluble in ether and chloroform, nearly insoluble in alcohol. The fresh juice, when filtered, leaves on the filter a white leathery mass, containing a substance resembling caoutchouc (amounting to 11.1 per cent. of the entire juice), an amorphous substance (5.2 per cent.), and a granular substance (0.47 per cent.) soluble only in hot alcohol and ether, a substance (1.15 per cent.) soluble in cold alcohol and ether, a resinous bitter substance (0.2 per cent.), and a waxy substance (0.3 per cent.) The filtered light brownish liquid contains 4 per cent. of a substance resembling uncrystallisable sugar, and a gummy substance soluble in water (together with the salts of an organic acid, albumin, tannin, and a small quantity of a free organic acid, in all 17.0 per cent.). Peckolt (*Arch. Pharm.* [2] cv. 31; *Jahresber. f. Chem.* 1861, p. 743).

Ficus rubiginosa, an Australian species, yields a resinous exudation, resembling euphorbium in appearance, varying in colour from dirty yellow or red to almost white, solid, generally brittle, but tough in the interior of large pieces, opaque, with dull and wax-like fracture; at 30° C., it softens and becomes plastic, like gutta-percha, but not sticky, provided it has been previously wetted with water. In its natural state, it has neither taste nor odour, but evolves an odour like that of wax when heated, and evinces a characteristic taste on being masticated. It is quite insoluble in water, either hot or cold. The greater part of it is soluble in cold alcohol, and a considerable portion of the remainder in hot alcohol, and by treating it with these solvents in succession, it may be separated into the following constituents:

Resinous substance, Sycoretin, easily soluble in cold alcohol	73
White crystalline substances, chiefly Acetate of sycoceryl, $C^{22}H^{43}O.C^2H^3O$	14
Insoluble in cold but soluble in warm alcohol	14
Caoutchouc, fragments of bark, sand, and loss	13

Warren de la Rue and Hugo Müller (*Chem. Soc. J.* xv. 62). See SYCOCERYL and SYCORETIN.

FIELDITE. A massive mineral, resembling grey antimonial copper, from the neighbourhood of Coquimbo in Chile, soft and unctuous to the touch, with dark greenish-grey colour, and red streak. An analysis by Field (*Chem. Soc. Qu. J.* iv. 332), gave:

S	Sb	As	Cu	Zn	Fe	Ag
30.35	20.28	3.91	36.72	7.26	1.23	0.07 = 99.82;

whence Rammelsberg (*Mineralchemie*, p. 993) deduces the formula $4M^2S.Sb^2S^3$ or $M^2S.2M^2Sb^2S^3$, the antimony being partly replaced by arsenic, and the symbol M standing for Cu, Zn, and Fe.

FIGURE STONE. See AGALMATOLITE (i. 60).

FILICIC ACID. $C^{12}H^{16}O^8$ or $C^{22}H^{43}O^{10}$? (Luck, *Jahrb. pr. Pharm.* xii. 129; *Jahresber. f. Chem.* 1861, p. 558.)—An acid obtained from the root of the common male fern, *Aspidium Filix mas*. The extract of the root (especially of that collected in autumn), prepared with anhydrous ether, and concentrated to an oily consistence, deposits the acid after a few days in the form of a greenish-yellow powder, or a yellow crust, which may be purified by washing with a mixture of alcohol and ether, and recrystallisation from ether; or the impure filicic acid, after washing with ether-alcohol and pressing, may be suspended in warm alcohol, and dissolved by addition of a little ammonia, the solution filtered, the filtrate being allowed to drop into dilute hydrochloric acid, and the washed precipitate treated with warm alcohol of 80 per cent., till it no longer colours the alcohol.

Filicic acid thus prepared is a whitish-yellow or light yellow crystalline powder, insoluble in water, weak alcohol, and acetic acid; sparingly soluble in strong alcohol, more soluble in ether (especially in presence of a small quantity of fixed oil): the solution reddens litmus. It dissolves also in fixed oils, oil of turpentine and rock-oil, and very easily in sulphide of carbon. It melts at 161° C., and solidifies in the amorphous state; decomposes at a higher temperature. Luck expresses its composition by the improbable formula $C^{22}H^{43}O^8$.

Filicic acid dissolves readily in alkalis. The sodium-salt forms an amorphous gummy mass, whose solution yields with neutral acetate of lead, a yellowish-white curdy precipitate, which, when dried in vacuo (as were also the following substances), has, according to Luck, the composition $PbO.C^{24}H^{14}O^{10}$; it should perhaps be $C^{24}H^{14}PbO^{10}$, or $C^{12}H^{14}PbO^5$.

Chlorofilicic acid, $C^{12}H^{13}ClO^5$, or $C^6H^{13}ClO^{10}$ (?), produced, with evolution of hydrochloric acid, by the action of chlorine gas on solid filicic acid, is a turpentine-like mass, which, after solution in alcohol and spontaneous evaporation, separates in yellow-brown amorphous drops. The alcoholic solution forms with acetate of lead, a loam-coloured precipitate, which contains $PbO.C^{24}H^{14}ClO^{10}$, according to Luck; more probably $C^{12}H^{14}PbClO^5$. When treated with strong alcohol, it gives up part of its acid. Trichlorofilicic acid, $C^{12}H^{13}Cl^3O^5$, or $C^{24}H^{13}Cl^3O^{10}$ (?), is obtained by the action of chlorine on filicic acid suspended in water, as a yellow powder insoluble in cold water, but soluble in hot water, and in alcohol, ether, and oils, both fixed and volatile. Its alcoholic solution forms with acetate of lead, a loam-coloured precipitate containing $PbO.C^{24}H^{13}Cl^3O^{10}$ (Luck), more probably $C^{12}H^{13}PbCl^3O^5$.

FILIMELISIC ACID. See FILIPELOSIC ACID.

FILIMELISI-SULPHURIC ACID. Filicic acid dissolves without decomposition in cold sulphuric acid of ordinary strength, but by triturating it with fuming sulphuric acid, a solution is formed which, when dropped after a few hours into a dilute solution of sulphate of sodium, yields a precipitate of filimelisi-sulphuric acid; this, when purified, forms a golden-yellow powder, somewhat soluble in water, more soluble in alcohol and ether. Its barium-salt is amorphous, of red-lead colour, soluble in water. The formation of the acid as above described, is attended with that of butyric acid. Luck (*loc. cit.*) assigns to the acid the formula $C^{24}H^{14}O^8.SO^2$, and to the barium-salt, $BaO.C^{24}H^{14}O^8.SO^2$, both of which are improbable.

FILIPELOSIC ACID. $C^{12}H^{12}O^4$, or $C^{24}H^{12}O^8$ (?) (Luck, *loc. cit.*).—Obtained by dissolving filicic acid in warm, very dilute potash-ley, exposing the solution to the air for a week, and precipitating the filtrate with dilute sulphuric acid; purified by washing, drying, solution in ether-alcohol, and spontaneous evaporation. When filicic acid is heated for some time with dilute alcoholic ammonia to 80° or 100° C. out of contact with the air, the liquid then precipitated by dilute sulphuric acid, and the precipitate purified as above, Luck's filimelisi acid is obtained.

The product obtained by the first method, is an amorphous loam-coloured powder; the second yields an ochre-coloured powder, composed of microscopic spherules. Both are tasteless, insoluble in water, soluble in alcohol, ether, oils both fixed and volatile, and sulphide of carbon.

Luck regards the two products thus obtained as different, assigning to the former (his *filipelosic acid*) the formula $C^{24}H^{12}O^8$, and to the latter (his *filimelisi acid*), the formula $C^{24}H^{10}O^8$, though they agree in their properties, and in the composition of their lead-salts, that of the former yielding 31.96 per cent. lead-oxide, and that of the latter 32.62 per cent.; the formula $C^{24}H^{12}PbO^8.2H^2O$ requires 33.7 per cent. lead-oxide.

Chlorofilipelosic acid, $2C^{12}H^{11}ClO^4 + H^2O$ (?), is a light brown amorphous substance formed by the action of chlorine on dry filipelosic acid; and *Dichlorofilipelosic acid*, $C^{12}H^{10}Cl^2O^4$ (?), produced by the action of chlorine on filipelosic acid suspended in water, is a loam-coloured powder, whose lead-salt appears to contain $Pb^2H^2O^2.C^{24}H^{10}PbCl^2O^8 + \frac{1}{2}aq.$ (?) (Luck, *loc. cit.*)

FILIXOLINIC and FILOSMYLIC ACIDS. When a recently prepared ethereal extract of the root of *Filix mas* is diluted with a little ether and alcohol, and then shaken up with twice its volume of water and a little ammonia, two layers are formed after a while; the lower of which is brown, and is said to contain filicic or filimelisi acid, while the upper, which is dark green and oily, yields a transparent oil, green by reflected, Colombo-red by transmitted candle-light, and remaining liquid even at very low temperatures. This oil is said to yield by saponification a non-volatile acid, filixolinic acid, $C^{24}H^{14}O^4$ (barium-salt, $BaO.C^{24}H^{14}O^4$), and after saponification a volatile acid, filosmylic acid, whose barium-salt contains $BaO.C^6H^6O$. (Luck, *loc. cit.*) These, like the formulae assigned by Luck to most of the preceding compounds, are very improbable.

FILIX. The root of *Aspidium Filix femina* (A), and of *Aspidium Filix mas* (B), also the frond of the latter (C), all in the dried state, have been analysed by H. Bock (Arch. Pharm. [2] lxx. 257; Jahresber. f. Chem. 1851, p. 567). The results are given in the following table:

	A.	B.	C.
Volatile oil	0.02	0.04	trace
Fixed oil	1.2	6.0	
Stearin		1.0	
Resin	0.4	4.0	
Wax			0.5
Vegetable gelatin	1.3	0.4	
Gum	2.0	3.3	
Albumin	5.0	3.5	5.4
Mucus			5.7
Starch	7.5	10.0	
Sugar		11.0	
Pectin	4.0	2.1	3.5
Chlorophyll			8.7
Tannic and gallic acids	11.9	10.0	11.0
Fibre containing starch	1.5	1.5	
Ash	4.94	2.1	5.0
Woody fibre and loss	60.24	45.06	60.2
	100.00	100.00	100.0

The ash contains :

Silica	0.2	0.01	0.2
Sand	0.9		
Sulphate of calcium	0.3	0.11	0.3
Ferric phosphate	0.08	trace	0.1
Phosphate of calcium	0.1	0.16	0.4
Phosphate of magnesium		0.04	
Carbonate of calcium	1.2	0.94	1.3
Chloride of sodium	0.1	0.04	0.3
Chloride of potassium	0.4	0.22	0.6
Carbonate of potassium	1.3	0.55	1.5
Loss	0.36	0.03	0.3
	4.94	2.10	5.0

The granular deposit which gradually settles down from the ethereal extract of the root of *Aspidium Filix mas*, and was formerly observed by Trommsdorff and Osann, is regarded by Bock as the more solid portion of the fixed oil. According to Luck, it consists chiefly of flicic acid (ii. 646).

The decoction obtained by boiling fern-roots with alcohol yields, on addition of water, a little hydrochloric acid, and sulphate of sodium, a precipitate containing two tannic acids, viz. pteritannic and tannaspidic acids (g. v.)

FILTRATION. The separation of a liquid from solid matter suspended in it by passing through a porous substance which retains the suspended matter, but allows the liquid to pass through. Various materials are used for this purpose, according to the nature of the liquid to be filtered; viz. paper, linen, calico, woollen cloth, sand fine and coarse, pounded glass, charcoal, &c.; but for analytical operations, and for most laboratory preparations, the material used is unsized paper. For straining viscid liquids, such as syrups and white of egg, which will not readily pass through paper, cloth filters are used; and corrosive liquids, such as strong acids and caustic alkaline solutions, may be filtered through pounded glass.

Paper for filtration must be sufficiently porous to allow liquids to pass through it quickly. The degree of porosity required varies of course with the particular purpose to which the paper is to be applied: for analytical operations, it must be sufficiently close-grained to arrest the passage even of very fine solid particles. In some manufacturing, the requisite degree of porosity is given to the paper, by leaving the wet sheets to freeze at a winter temperature; the expansion of the water in freezing, separates the fibres of the paper from one another, and gives it a regular porosity which cannot be attained by any other method. Paper which filters slowly may be improved in quality by this treatment.

All paper contains a certain quantity of inorganic material, and mostly leaves, when incinerated, a quantity of ash sufficient to induce appreciable error in analytical operations. Hence it is necessary, either to remove the inorganic matter by digesting the filters in dilute nitric acid, and afterwards washing them thoroughly with distilled water, which is a tedious and troublesome operation — or else to determine the quantity of ash left by the filter and allow for it. For this purpose, ten or twelve filters of each size used in the laboratory for analytical purposes, should be burnt, the ash of each

lot weighed, the quantity of ash left by an individual filter thence calculated, and a record kept of the results.

This trouble may, however, be saved, and analytical operations greatly facilitated, by using the Swedish filtering paper, which is prepared at Fahlun and Lessebo, with a spring-water nearly as pure as distilled water. This paper, besides having the property of filtering very quickly, being prepared in winter as above mentioned, is singularly free from inorganic matter, giving up scarcely anything to dilute acids, and leaving when incinerated only 0.2 per cent. ash. A sample of this ash analysed by Plantamour yielded 63.23 per cent. silica; 12.83 lime; 6.21 magnesia; 2.94 alumina; and 13.92 ferric oxide.

Paper filters are of two forms, plain and folded. They are sold ready cut in circles of various sizes. To make a plain filter, it is only necessary to fold the paper twice, so as to give it the form of a quadrant; and this when half opened, forms a cone whose edges meet at an angle of 60° ; the funnel on which the filter is laid, should therefore also have its sides inclined at 60° . For collecting precipitates which are to be afterwards removed from the filter by washing or otherwise, the plain filter is decidedly the best form; but when the precipitate is only a refuse product, or need not be very carefully removed from the filter, and the principal object is to filter quickly, folded filters are to be preferred, because the folds leave channels between the paper and the surface of the funnel, which facilitate the passage of the liquid.

The following method of making a folded filter is given by Mohr (*Lehrbuch der pharmaceutischen Technik*, p. 217). The circular filter is first folded in halves along the line $a'd'$ (fig. 479), and then in quarters, making the fold m . The filter is then again half opened, as in the figure, and a is laid on m , forming the fold b , also a' on m , forming b' . Next a is laid on b' , forming c , and a' on b , forming c' ; then a is laid on b , forming d , and a' on b' , forming d' . All the folds thus produced are turned the same way, namely, with their convexities upwards. The next thing to be done is to make folds between each of these turned the contrary way.

Fig. 479.

For this purpose, a is first laid on b in the fold d , and then turned back to d' , making the fold α ; then a, d , as they lie together, are turned over to c and folded back to b , making β ; a, d, b is laid on m in the fold b and turned back to c , making γ ; and lastly, a, d, b, c is laid on c' and turned back to m , making δ . Corresponding folds are then made on the other side, viz. by laying a' on b' and turning it back to d' , then a', d' on c' and back to b' ; then a', d', b' on m and back to c' , and a', d', b', c' on c and back to m . If the filter be now opened, all the folds will be found directed alternately outwards and inwards, excepting a on the one side, and a' on the other; all four of which have their convexities outwards. Intermediate folds turned inwards must therefore be made halfway, between a and a' , and between a' and a ; and then all the alternate folds will be in contrary directions. The whole thing is much easier to do than to describe.

A folded filter of simpler construction, and containing a sufficient number of folds for most purposes, is made as follows. The circular disk of paper is first folded in halves and quarters as before. It is then half opened as in fig. 479; a is turned over to m , making the fold b , and a' to m , making b' ; then a is turned back to b , making d , and a' to b' , making d' ; lastly, a, d, b is turned backwards to m , making c , and a', d', b' also backwards to m , making c' . On opening the filter, all the folds are found to be alternate in direction excepting a, d and a', d' , between which intermediate folds are to be made as before. Folded filters fit best into funnels of about 60° aperture.

Before collecting a precipitate on a filter, the filter must be moistened all over with water or alcohol, as the case may be; otherwise the first portions of the precipitate are very apt to run through and render the filtrate turbid; it is also advisable to leave the precipitate to settle down in the precipitating vessel to a considerable extent, then to pass the clear liquid through the filter, and afterwards pour the precipitate upon it, (see DECANTATION, p. 308). Most precipitates filter best after boiling. The size of the filter should be such as to leave at least half an inch of clear margin when the whole precipitate is collected upon it; otherwise, portions of the precipitate are very apt to creep over the edges during washing.

In washing precipitates for quantitative analysis, it is desirable to use as little water as possible, as the evaporation of wash-waters always takes a considerable time: care should therefore be taken, after adding each portion of water, to let the last drop run through before adding any more, and the wash-water must be tested from

time to time by evaporating a drop of it on platinum-foil, the washing being continued till a drop thus evaporated leaves no residua. It must not be forgotten, however, that many precipitates are slightly soluble in water, and, therefore, the wash-water which runs from them will always leave a trifling residue. In such case, testing with reagents must be resorted to.

When the quantity of water used for washing is immaterial, as in most preparations, a continuous mode of washing may be adopted. There are many ways of effecting this. The simplest is to fill a flask with water and invert it with its mouth dipping

Fig. 480.

Fig. 481.

below the water in the filter, supporting it on a stand, as shown in *fig. 480*. As the liquid by filtration falls below the lip of the bottle, air will enter, and let down a fresh supply of water to feed the filter.

Another convenient apparatus for continuous washing is the siphon-bottle, shown in *fig. 481*. The bottom of the bottle is placed on a level with the surface of the water in the filter; air is blown in through the tube *m* till the siphon-tube *a* is filled with water; and *m* is then drawn up to such a height that air-bubbles may pass through it as the liquid sinks in the filter.

Fig. 482.

Liquids holding in solution substances which separate out on very slight reduction of temperature, often require to be filtered at the boiling heat. For this purpose the glass funnel containing the filter is placed within a double funnel (*fig. 482*), closed on all sides excepting at the apertures *a a*, one for pouring in water, the other for the escape of vapour, and having on one side a projecting tube closed at *b*, to which heat is applied by a spirit or gas-flame. The vessel is filled with water or oil according to the temperature required.

Water for economical purposes may be freed from turbidity by filtering through sand. A large earthen funnel, or stone bottle with the bottom beaten out, may have its neck loosely stopped with small stones, over which smaller stones may be placed, supporting layers of gravel increasing in fineness, and lastly covered to the depth of a few inches with fine sand, all thoroughly cleansed by washing. This apparatus is superior to a filtering stone, as it will cleanse water in large quantities, and may readily be renewed when the passage is obstructed, by taking out and washing the upper stratum of sand.

A similar method is used for filtration of water on the large scale. (See *Graham's Elements of Chemistry*, 2nd. ed. vol. i. p. 317; also the article *FILTRATION* in *Ure's*

Dictionary of Arts, Manufactures, and Mines, ii. 208, which likewise contains many useful details relating to filtering in manufacturing operations.)

FIORITE. *Pearl sinter.*—A variety of opal, occurring in the cavities of volcanic tufa, in smooth, shining, globular and botryoidal masses, having a pearly lustre.

FIREBLÉNDE. A mineral containing 62·3 per cent. silver, together with sulphur and antimony, found in the Kurprinz mine, near Freiberg, and at Andreasberg. Forms delicate monoclinic crystals grouped like stilbite. Hardness = 2, specific gravity = 4·2–4·3. Lustre pearly, adamantine. Colour hyacinth-red. Translucent. Sectile and somewhat brittle. (Dana, ii. 88.)

FIRE-CLAY. Fire-clays are hydrated silicates of alumina, capable of resisting exposure to high temperatures without melting or becoming in a sensible degree soft or pasty. They occur immediately below the several seams of coal in the carboniferous formation, and would appear, from the frequent remains of *Stigmaria* which they contain, to represent the soils of those luxuriant forests, which by heat and pressure have been converted into coal.

The plasticity of clays depends upon the combined water which they always contain, and which is expelled at a red heat. Hence, a clay once burned, recovers none of its plasticity when wetted.

The relation of the silica and alumina in fire-clays is very variable, as is also the amount of silica which exists in them in an uncombined condition, or as sand. Thus in five German clays examined by Dr. Percy, the total percentages of silica existing as sand, as hydrate, and in combination with bases, were as below:

	1	2	3	4	5
Silica as sand	56·95	47·40	16·20	29·63	18·29
„ as hydrate	1·39	1·06	1·05	·91	·98
„ combined with bases .	18·69	26·98	45·53	37·74	45·53
Total silica	77·03	75·44	62·78	68·28	64·80

The most celebrated and refractory fire-clays are those obtained at Stourbridge, in Worcestershire, and there extensively manufactured into furnace-bricks of all kinds, gas-retorts, glass-house pots, &c., the very finest and purest samples being alone devoted to this last application. The clay, as brought from the mine, is sorted into qualities (best, seconds, offal, &c.), according to its appearance and the size of the lumps, all such portions as exhibit streaks or spots of iron pyrites or other metallic substances, being rejected.

A pure silicate of alumina is the ideal type of a pure clay, and the nearest approach to this standard is presented by some of the French clays, of which analyses are given below. The impurities commonly present are oxides of iron, lime, magnesia, and the alkalis; frequently also small quantities of organic matter, the occurrence of which is usually unimportant, as it is burnt off in the process of firing.

The silicates of alumina are, as is well known, almost infusible, while the double silicates of alumina with other bases are readily melted at a comparatively low temperature. The importance of selecting clays free from these impurities is, therefore, obvious, since the fusibility of the substance increases directly with their amount; it is found in practice that 4 or at the most 5 per cent. is the maximum of oxides of iron, lime, magnesia, and alkalis together which can be present without rendering the mineral useless for its finer applications, while the samples most sought after contain not more than from 2 to 3 or 3½ per cent. of those bases. It is also found that the presence of a certain percentage of silica is essential to constitute a “strong” clay, while any considerable increase in the proportion of alumina tends to produce a “weak” clay, deficient in cohesion and unable to stand the severe tests to which it is subjected in the manufacture.

It may be here observed that the colour of a raw clay generally presents no indication whatever of its value, the variations in its shade being caused by minute quantities of organic matter. Neither does the colour of a burnt clay afford by any means an accurate criterion of its quality; for although the presence of a large quantity of iron is sufficiently palpable, the other and equally injurious impurities produce no effect upon its tint.

A firebrick or pot of good quality and properly burned, is nearly white, or of a pale cream or pinkish colour, free from black spots; the colour of a potsherd or fragment of a glass-house pot, after exposure to the intense heat of the furnace for many weeks, approaches to dark grey, or black, the fracture being almost vitreous, and the texture compact. A brick or pot which has been exposed, as, for instance, in the crown of a glass-house furnace, for a shorter time, presents, upon the face next to the fire, the

same appearance as a potsherd, gradually changing from the surface inwards, and being replaced first by a reddish colour, and finally by the original shade of the brick or pot.

It is probable that the first effect of heat is merely to peroxidise the iron, producing a red colour, while the application of a continued higher temperature produces a real combination, with a corresponding development of the grey or black colour of the silicate of aluminium and iron, and possibly a reduction of the iron to the state of magnetic oxide.

The drying and burning of the clay is attended with a considerable diminution of bulk, and it becomes a matter of much importance to reduce this shrinking to a minimum; a result effected by the admixture with the tempered clay of a certain quantity of calcined clay and potsherds ground to a coarse powder. The proportion of potsherds and calcined clay added to raw-clay varies much, according to the plasticity of the latter, and the judgment of the manufacturer. A proportion of $\frac{1}{3}$ potsherds to the raw clay is adopted by many.

The importance of this admixture was well illustrated in a recent trial, in which the defendant alleged that the quality of clay supplied to him by the plaintiff was inferior, while the plaintiff affirmed that the destruction of the crown of the arches in defendant's glass furnaces was the natural consequence of his using an unusually and improperly small amount of potsherds, whereby the shrinking had been increased, and the fissures thus produced between the bricks had acted as *points d'appui* for the fire, at which fusion had taken place. The consequence was the production of droppings or "tears" of melted clay, which had fallen into the glass below and destroyed it in large quantities.

A brick manufactured from best Stourbridge clay, without admixture of potsherds, and 9 inches in length, contracted on burning $\frac{1}{8}$ of an inch, and subsequently, after 21 days exposure to a white heat $\frac{1}{16}$ more; a very fine clay from Tamworth (No. 9 in Table II.), rich in silica, contracted only $\frac{1}{8}$ of an inch; while an inferior and highly aluminous clay, soapy to the touch and extremely plastic, shrank under like circumstances $1\frac{1}{2}$ inch.

Tables I. and II. exhibit the composition of several fire-clays, British and foreign:

Riley (Chem. Soc. J. xii. 13; xv. 311) has shown that nearly all clays contain small quantities of titanium, which may be detected and estimated by treating the silica (separated in the usual way by fusion) with carbonate of soda, and with hydrofluoric acid containing a little sulphuric acid. The silicon is then volatilised as fluoride, while the titanium remains in the form of titanic anhydride, TiO_2 . (For the details of the method, see SILICON AND TITANIUM.)

 10. Potsherd, made from Stourbridge clay.
 11. Fragment of a faulty pot, useless.
 12. Best clay, used by Messrs. Chance (Perry's Metallurgy).
 13. Clay from Newcastle on Tyne, used for bricks (Perry's Metallurgy).
 14. Clay from Dowals (Perry's Metallurgy).
 15. Clay from Glasgow, well adapted for saggers, glass-house pots, crucibles, and bricks (Perry's Metallurgy).
 16. Interior clay, approaching to shale.
 17. Residue from distillation of bituminous shale.
 18. Brick-clay.

W. W.

FIRE-DAMP. The explosive mixture of marsh-gas and air, which accumulates in coal-mines. (See COAL.)

FIRE-OPAL. See OPAL.

FIRE-STONE. A stone which will bear the heat of a furnace without injury. The term is generally applied to the sandstone occurring at the top of the upper greensand in the south of England, which is frequently used for lining kilns and furnaces. (See *Ure's Dictionary of Manufactures*, &c. ii. 224.)

FIRE-WORKS. See PYROTECHNY.

FIRE-WOOD. See WOOD.

FISCHERITE. Native phosphate of aluminium from Nischne Tagilsk. (See PHOSPHATES.)

FISH-OIL. See OILS.

FIXED AIR. Carbonic acid gas.

FIXITY. The converse of volatility.

FLAKE-WHITE. A term applied indiscriminately to pure white lead, and to basic nitrate of bismuth.

FLAME. The nature of flame, and many of the conditions on which its heating and illuminating power depend, have already been considered in the article COMBUSTION (i. 1094–1102). We have here, however, to give an account of the results obtained by Frankland respecting the manner in which the heat and light of flames and of burning bodies in general are affected by the density of the surrounding air. (Phil. Trans. 1862, p. 629; abstr. Proc. Roy. Soc. xi. 137, 366.)

Rate of Combustion.—From comparative experiments made on the combustion of stearin candles on the summit of Mont Blanc and in the valley of Chamounix, and from further experiments on the burning of candles and coal-gas in artificially rarefied atmospheres, it is found that the rate of burning of candles and other bodies, the flames of which consist of matter volatilised, and subsequently burned in contact with the air, is not sensibly affected by the pressure of the medium which supports the combustion. But in self-supporting combustibles, like the time-fuses of shells, the rate of combustion depends essentially on the pressure of the medium in which they are deflagrated. This fact was first pointed out by Quarter-master Mitchell, an artillery officer stationed in India, who found that the fuses of shells burnt longer at elevated stations than when ignited near the sea-level. From his observations, and from experiments performed by Dr. Frankland on the combustion of time-fuses in artificially rarefied air, it is found, that in the combustion of shell-fuses, *the increments of time are proportional to the decrements of pressure*, each diminution of one inch of barometric pressure causing a retardation of one second in a thirty-second fuse; or each diminution of atmospheric pressure to the amount of one mercurial inch increasing the time of burning by one-thirtieth.

This remarkable difference in the influence of atmospheric pressure on the rate of combustion of candles, &c., on the one hand, and of self-supporting combustibles on the other, arises from the different conditions of combustion in the two cases. In the combustion of a candle there is, at all pressures, a sufficient supply of combustible matter kept up at the base of the exposed portion of the wick: for the capillarity of the wick is not affected by pressure, and the temperature of the flame remains nearly constant, the greater mobility of the gases in the rarefied atmosphere compensating for the smaller number of particles of oxygen within a given space: hence the rate of combustion is, within certain limits, independent of the pressure. In the fuse, on the contrary, the composition contains within itself the oxygen necessary for its combustion, and a certain degree of heat only is necessary to bring about chemical combination. If this heat were applied simultaneously to every part of the fuse-composition, the whole would burn almost instantaneously. Under ordinary circumstances, however, the fuse burns only at a disc perpendicular to its axis; and the time occupied in its deflagration depends on the rapidity with which each successive layer of the composition is heated to the temperature at which combustion takes place. This heat necessary to deflagration is derived from the products of the combustion of the layer immediately preceding, and the amount of heat thus communicated to the still unburnt layer, depends in a great measure, on the number of particles of these heated products which come into contact with that layer. Now, as a large proportion of these products are gaseous, it follows, that if the pressure of the surrounding medium be diminished, the number of ignited gaseous particles in contact at any one moment with the still unignited disc of composition will also be diminished. Hence the slower rate of deflagration in rarefied air.

Influence of pressure on the Luminosity of Flames.—On the summit of Mont Blanc, candles burned with a very feeble light, and subsequent experiments with ordinary coal-gas, and with naphthalised gas (which has twice as much illuminating power as common coal-gas), in artificially rarefied atmospheres, have shown that the brightness of ordinary flames increases and diminishes with the pressure of the supporting medium, and that when the air is rarefied, from the ordinary atmospheric pressure down to a pressure of 14 inches of mercury, the light of the flame decreases in exact proportion to the density of the air; below this limit, the luminosity diminishes at a somewhat lower rate. Between the limits of pressure above mentioned, the amount of diminution is expressed by the following law: *Of 100 units of light emitted by a gas-flame burning in air at a pressure of 30 inches of mercury, 5·1 units are extinguished by each reduction of one mercurial inch of atmospheric pressure.*

Under increased pressure, the brightness of a flame fed with amyleic alcohol, was found to increase in direct proportion to the pressure, up to a limit of 2 atmospheres; beyond which, the increase of light was much more rapid, and attended with a great deal of smoking.

The cause of these variations of luminosity is as follows. The light of ordinary flames is derived almost wholly from the separation of carbon particles within the flame, and is increased by the augmentation of the amount of carbon thus precipitated, and by an increased temperature in the flame*, whilst it is diminished by the separation of less carbon (and, therefore, *cæteris paribus*, by more complete combustion) and by a reduction of temperature. Now Davy found, and his conclusion has been confirmed by Frankland, that, within certain limits, rarefaction and compression do not exert any considerable influence on the heat of flame: in fact, though the temperature produced within the flame is lowered by rarefaction, the escape of heat from its exterior is hindered by the same process, the result being that the actual temperature undergoes but little alteration. Hence the loss of light in rarefied air does not proceed from reduction of temperature. Neither is it due to imperfect combustion: for the gases evolved from a candle-flame, burning under a pressure of only eight mercurial inches, are found to have the same composition as those from a flame burning under the ordinary pressure. On the other hand, the separation of carbon particles is augmented by increased pressure. Candles evolve much smoke when burnt under a pressure of two atmospheres; and even a small alcohol flame, which burns with a pure blue light at ordinary pressures, becomes highly luminous in air four times compressed. Flames which smoke at ordinary pressures, become smokeless in rarefied air, and undergo more complete combustion. Whilst, therefore, the light of flames is due to the separation of carbon particles, the latter owe their momentary existence to the absence of sufficient oxygen for their combustion; consequently, any influence, which causes the more rapid interpenetration of the flame-gases and the external air, must reduce the amount of precipitated carbon, and consequently the luminosity of the flame. Rarefaction exercises precisely such an influence, by increasing the mobility of the gaseous particles, and thus causing the access of a larger amount of oxygen to the region of the flame where precipitated carbon produces luminosity.

The luminosity of a flame is not, however, entirely due to the ignition of minute carbon particles floating within it, a small portion of the light being derived from the incandescence of the gaseous matters. This latter source of illumination does not ordinarily furnish more than about 1 per cent. of the total amount of light, but at very low pressures, at which but little carbon is separated, it becomes much more prominent. Now this light emitted by incandescent gaseous particles is not affected by pressure, and hence arises the deviation from the law of diminution of light in proportion to pressure, which is observed when the pressure is reduced to a very small amount. (Frankland.)

FLAVIN. A yellow dye stuff imported from America, in the form of a dark brown powder, and used as a substitute for quercitron bark (*Napier's Manual of the Art of Dyeing*, Glasgow, 1863.) According to König (J. pr. Chem. lxxi. 98), it is identical with quercitrin, and splits up, under the influence of acids, into sugar and quercetin; but according to Bolley (Dingl. pol. J. cxlv. 134), it is not of constant composition, sometimes containing, not quercitrin, but quercetin, which possesses much greater colouring power.

FLAVINDIN. (Gerh. iii. 563.) A substance apparently isomeric with indin and indigo-blue, produced, together with hydrindin (q. v.), by the action of potash on indin or on disulphisæthide. It remains in the alkaline mother-liquor from which the hydrindin has separated; and on adding an acid to this liquid, a light, flocculent, yellowish precipitate is obtained, which is a mixture of hydrindin, sulphur, sometimes a small quantity of indin, and flavindin. The flavindin may be obtained in larger quantity by,

* See the article COAL-GAS in *Ure's Dictionary of Arts, Manufactures, and Mines*, i. 736.

continuing the ebullition with potash for a longer time; it is purified by solution in water containing a few drops of ammonia, and precipitation with hydrochloric acid.

Flavindin is of a pale yellow colour; it dissolves sparingly in boiling alcohol, and separates therefrom in microscopic stellate needles. When heated, it appears to be almost wholly transformed into a white substance, which sublimes in needles resembling benzoic acid.

Flavindin gives by analysis 72.6 per cent. carbon, and 3.82 hydrogen, whence it appears to have the same composition as indigo-blue. Its ammoniacal solution yields with nitrate of silver a yellow precipitate, which leaves on calcination 42 per cent. silver ($C^6H^4AgNO^2$?).

FLAVINE. $C^{12}H^{11}N^2O$. (Laurent and Chancel, Compt. Chim. 1849, p. 115.) An organic base, isomeric with diphenyl-carbamide (i. 756), produced by the action of sulphhydrate of ammonium on dinitrobenzophenone (i. 562),

It forms fine, pale yellow, or colourless needles, nearly insoluble in water, but soluble in alcohol and ether. Gives off phenylamine when fused with potash.

Hydrochlorate of Flavine crystallises in elongated laminae, very soluble in water, somewhat less soluble in alcohol; it is decomposed by distillation, yielding a small quantity of white, pulverulent sublimate, and leaving a bulky residue of charcoal. The *chloroplatinate*, $2(C^{12}H^{11}N^2O.HCl).PtCl^4$, is a yellow, pulverulent precipitate, obtained from dilute solutions.

Flavine was regarded by Laurent and Chancel as identical with diphenylcarbamide, $N^2(CO)(C^6H^5)^2H^2$; but, according to Hofmann (Proc. Roy. Soc. x. 602), it does not exhibit the properties of a carbamide or urea.

FLAX. *Linum usitatissimum*. This plant is extensively cultivated in Ireland, Belgium, France, and Russia, both for its fibre, which is the raw material of linen, and for its seed, which yields by pressure a fixed oil, called linseed oil, and a residual mass, called linseed-cake, or oil-cake, extensively used as food for cattle. The flax-plant takes up from the soil a large amount of mineral matter, especially of the most valuable constituents, potash and phosphoric acid, and was therefore formerly regarded as one of the most exhausting crops. But neither the pure fibre nor the oil contains any of these mineral constituents. The inorganic matter of the seed remains in the cake, which, being used to feed cattle, may be returned to the soil as manure. On the Continent, inferior qualities of cake are ground to a coarse powder, and either applied to the soil as a top-dressing, or steeped in a liquid manure, and the mass spread out on the land in that state. (See LINSEED.)

The stem of the flax plant consists of an inner part or core, sometimes hollow, but more frequently solid, composed of ligneous matter, surrounded with a bark of fibres, the true linen fibres, which are united to each other by a gum, the whole being sheathed in a fine epidermis. To separate the linen-fibre from the gum and woody matter, the stems, when pulled and separated from the seed-capsules, are steeped in a pond or running stream, for a period varying from 7 to 21 days; they then undergo a kind of fermentation or putrefaction, attended with the evolution of sulphuretted hydrogen and other foetid gases, which decomposes the gum and loosens the fibres from one another and from the woody core; this process is called retting. The stems are then washed, and the fibre is mechanically separated from the woody core by an operation called scutching, which consists in bruising the stems thoroughly, so that, while the fibre, from its tenacity, remains intact, the brittle woody part is flattened and broken in such a manner as to admit of its being easily beaten off by the action of the scutch-blade or scutch-mill. The greater part of the mineral matter is removed in the steeping and wash-water, in which state of solution it is easily returned to the soil. Another portion remains attached to the woody matter, which is generally used as fuel, the mineral substances of course remaining in the ash, which may likewise be used as manure. By thus returning to the soil the mineral matters removed by the growing plant, flax may be rendered one of the least instead of one of the most exhaustive of agricultural plants.

The following analyses of the ash of the stem and seed of flax will show that it contains large quantities of alkali and phosphoric acid.

1-7. Belgian and Irish flax (Kane, Phil. Mag. [3] xxiv. 98; xxxi. 36, 105; J. pr. Chem. xxxii. 364; xli. 434; Jahresber. f. Chem. 1847-8, p. 1086).—8-11. Russian (Mayer and Brazier, Chem. Soc. Qu. J. ii. 78; Jahresber. 1849, p. 686).—12-18. English (Way and Ogston, Roy. Agr. Soc. J. ix. [2] 517; Jahresber. 1850, p. 669).—19-20. (Reich, Jahresber. 1850, p. 670).—21, 22, 24, 25. (Way and Ogston, loc. cit.).—23. Rammelsberg (Jahresber. 1847-8, p. 1076).

* ? Dried or undried.

In Kane's analysis, the amount of sulphuric acid varies inversely as that of the carbonic acid (*i.e.* of the organic acids); and notwithstanding the great variations in the relative quantities of the several bases (the ferric oxide in the variety from Armagh amounting to 13·62 per cent.), the capacity of the bases in the ash for organic acids is nearly the same in all, being represented by an amount of 13·28 per cent. oxygen in the Belgian and Dutch, and 13·63 per cent. in the Irish flax.

The results of Mayer and Brazier's analyses agree nearly with those of Kane, so far as regards the lime and phosphoric acid; but in all other respects they differ considerably. In most of Kane's analyses, the potash and soda are nearly equal; whereas in those of Mayer and Brazier, the potash greatly exceeds the soda. Kane also found alumina in most of his samples, whereas Mayer and Brazier, and indeed all other chemists who have analysed flax-ash, found none.

Analyses 12, 13 (Way and Ogston) show that the coarse-fibred varieties remove from the soil a larger quantity of potash and of mineral constituents in general than the fine-fibred kinds. In all cases, however, comparatively little of the more valuable mineral constituents remain with the scutched fibre, the greater part being dissolved out in the retting or steeping process, and another portion remaining with the woody matter separated by scutching.

The soils on which the samples of flax analysed by Kane were grown, were mostly sandy loams, very light and porous, rich in nitrogenous matter, and coloured the water in which they were boiled, small quantities of alkalis and salts then passing into solution. Their composition is given in the following table:

TABLE II.—*Composition of Flax-soil.*

	Soils dried at 100° C. from :					
	1 Heestert near Courtray.	2 Escamaffles, best flax- land of the Courtray district.	3 Hammezog, best flax-land of the Ant- werp dis- trict.	4 A district yielding only wild flax and poor crops.	5 A good flax dis- trict in Holland.	6 Crowle in Lincoln shire, the so-called "warps."

	100·000	100·000	100·000	100·081	100·000	100·204

The samples 1-4 of flax in the table (p. 657) were grown on soil No. 4; sample 5 in the same table on soil No. 5.

The so-called "warps" is found on the river Humber, and forms the muddy bottom of the flax-lands of the west coast (of Ireland?).

Kane regards the fertility of the celebrated Belgian flax-soils, *i.e.* their great lightness, as well as their amount of alkalis, phosphoric acid, and magnesia, as the result of diligent cultivation with animal manure, such cultivation requiring only a light sandy soil, with enough loam to make it coherent.

TABLE III.—*Composition of Russian Flax-soils. Mayer and Brazier*
(Chem. Soc. Qu. J. ii. 78).

	Liefland.	Kurland.	Lithuania.	Esthland.

FLAX.

Steep-water.—Kane has analysed several waters (Table V.) in which flax is steeped. 1. Water of a large pool (forming a peat-bog) fed by the Scheldt, clear, with the exception of a small quantity of suspended matter.—2. Of a pool used for flax-steeping near Hammezog in Belgium, also fed by the Scheldt. The flax is left in it for six weeks. At the beginning of the process, the surface of the water becomes covered with a vegetable growth, which disappears as the retting proceeds: the workmen then shovel up the mud from the bottom, and make the flax sink with it; it was at this stage, that the sample of water, very muddy, was taken for analysis.—3. Another pool from a different part of the country, nearly clear.—4. From the river Lys, which rises in the north of France, and flows through the west of Belgium: it is regarded as the best steep-water in the world; and yet there is nothing in its chemical composition to account for its being so peculiarly favourable to the steeping of flax.—5. From Hol. land.

The following are two analyses of retting waters by C. Schmidt (Ann. Ch. Pharm. lxxxiii. 321); *a* from the Linnajerw-see surrounded by marshes, six miles south of Dorpat; it generally yields a beautifully white flax, but in windy weather somewhat coloured. *b* from the Kullajerw-see in the same neighbourhood; which being protected from the wind by surrounding woods, yields a uniform product. Both waters are clear and colourless, and leave, when evaporated, a brownish residue, which effervesces with acids, after being carbonised. 1 cubic metre of the water yielded the following quantities in grammes.

TABLE VI.—*Steep-waters.*

	<i>a.</i>	<i>b.</i>
Chlorine	21·85	43·45
Sulphuric anhydride	1·06	2·03

Organic matter and ammonia	68·10	99·62
Anhydrous substance	134·82	274·30

Hot-water steeping.—The ordinary steeping process takes from one to six weeks, according to the temperature and state of the weather. In 1847, however, a new system of retting was introduced into Ireland, by Mr. Schenck of New York. This consists in immersing the flax-stems in a large tank containing water kept at the temperature of about 90° F., by means of a coil of pipe through which steam is passed. The higher temperature greatly accelerates the process, which is completed in about 40 or 90 hours, according as the water used is soft or hard. The gas evolved during the process is usually stated to contain sulphuretted hydrogen; but, according to Hodges, it consists in 100 vol. of 22·29 carbonic anhydride, 44·30 hydrogen, and 33·41 oxygen. Three samples, *A*, *B*, *C*, of scutched flax, which had been retted by this process, were found by Hodges (Chem. Gaz. 1854, p. 37; Brit. Assoc. Rep. 1857, p. 126; Jahresber. f. Chem. 1854, p. 800; 1858, p. 667) to have the composition given in the following table. All three samples were dried at 100° C.; *A* losing 9·10, *B* 8·61, and *C* 12·0 per cent. water:

	<i>A.</i>	<i>B.</i>	<i>C.</i>
Wax; volatile oil and acid; resin	2·200	2·620	1·360
Sugar and substances soluble in alcohol	1·541	0·624	5·630
Inorganic substances soluble in alcohol	0·281	0·116	2·830
Gum and pectin	0·698	0·280	0·360
Salts insoluble in alcohol	0·078	0·044	0·080
Azotised substances soluble in water, casein, &c.	3·560	1·386	6·834
Azotised substances insoluble in water	2·940	4·310	4·269
Inorganic substances united with the fibre	0·238	1·490	2·500
Woody fibre	87·974	89·136	82·137

A sample of *Courtray* flax, retted by the ordinary method and scutched, gave, when dried at 100° C. (with loss of 8.40 per cent. water), 2.30 per cent. wax and oil, 6.60 azotised substances, casein, &c.; 7.59 gum, sugar, and colouring matter, 1.05 inorganic matter (ash), and 82.66 woody fibre.

The sample *A* of flax retted by Schenck's process, yielded (after drying at 100° C.) 1.40 per cent., *B* 1.54 per cent. ash, having the following composition:

K ₂ O	Na ₂ O	NaCl	CaO	MgO	F ₂ O ₃	P ₂ O ₅	SO ₃	CO ₂	SiO ₂
7.94	2.19	2.75	29.24	4.64	3.72	5.23	6.00	28.17	10.45 = 100.44
1.85	7.63	1.77	27.08	0.70	7.40	10.40	3.12	19.10	21.31 = 100.52

Several methods have been proposed for disintegrating flax fibre by mechanical means, without previous fermentation, and cleansing it by the use of acids and alkalis; but they have not been adopted in practice to any great extent. For a description of these methods, and for full details relating to the mechanical operations to which the fibre is subjected to convert it into linen, the reader is referred to the excellent article on *FLAX* in *Ure's Dictionary of Arts, Manufactures, and Mines*, ii. 225.

FLESH. The flesh of animals is, anatomically considered, a complex tissue made up of several morphological elements, viz. true muscular fibre, connective tissue, nerves, blood-vessels, and lymphatics. Muscular fibre is of two kinds, striped or striated, and non-striated or plain; the former constituting the basis of the voluntary muscles; the latter occurring in the muscular coat of the stomach and intestines, and in several other viscera. The primitive bundles of striped fibre are enclosed in a thin horny tissue, called the *sarcolemma*; a number of these bundles are united by connective tissue into larger bundles, and these again into entire muscles, the connective tissue being more or less filled up with fat-cells. The plain or non-striped fibres have either no *sarcolemma*, or a very indistinct one, not generally recognised, and are merely joined together by connective tissue. The entire mass of a muscle, whether striped or plain, is moistened with an acid liquid called the *flesh-juice* or *muscular juice*; which, however, is much more abundant in the striped than in the plain muscles.

The chemical differences between striped and plain muscular fibre will be considered in the article *MUSCULAR TISSUE*. At present we shall treat of the flesh as a whole, as it is used for food.

* The asterisks indicate that the albumin was not coagulated, and contained a portion of blood-clot.

Marechal (Compt. rend. xxxiv. 591) has determined the proportion of water, dry muscular substance, and fat in 100 pts. of the muscular flesh—free from connective tissue, bone, &c.—of the following animals, commonly used as food:

	Pig.	Ox.	Sheep.	Fowl.	Calf.
Water	69.7	72.5	73.6	73.7	74.4
Muscular flesh free from fat	24.3	25.0	23.4	24.9	22.7
Fat	6.0	2.5	3.0	1.4	2.9

It appears, from these results, that the flesh of the ox contains the largest proportion of nutritive (flesh-forming) matter, and in decreasing series, that of the fowl, pig, sheep, and calf. This must, however, be understood as applying to the real muscular substance, not to the entire flesh as sold in the market.

Girardin (Compt. rend. xli. 746) has determined the composition of American salt beef and bacon (imported into France in 1855) as compared with French beef and bacon.

TABLE II.—Composition of Salt Beef and Bacon.

	Salt Beef.				Bacon.			
	French.		American.		French.		American.	
	Fresh.	Dried at 100° C.	As taken from the cask.	Dried at 100° C.	Fresh.	Dried at 100° C.	As taken from the cask.	Dried at 100° C.

Inorganic constituents of Flesh.—The quantity of ash left by muscular flesh appears to vary between 2 and 8 per cent. The ash is composed chiefly of alkaline and calcic phosphates, with smaller quantities of chloride, sulphate, and carbonate of sodium.

The following tables exhibit the composition of the ash of various kinds of flesh.

* Including 19.554 chloride of sodium.

† Including 14.623 chloride of sodium.

‡ Calculated approximately from the composition of the salted herrings.

TABLE VI.—Ash of Muscular Flesh (von Bibra, *loc. cit.*).

Water in fresh substance	72.63	77.64

R. Weber (Pogg. Ann. lxxvi. 372; lxxxii. 92) analysed the ash of horse-flesh in so ways: *a*. By lixiviating the charred flesh with water, then with hydrochloric acid, and incinerating both the extracts and the solid residue. — *b*. By lixiviating the charred flesh with water and with hydrochloric acid, then carbonising and incinerating it; also incinerating the extracts. In both cases the flesh operated on was that of the fore-leg of a lean horse, freed from blood by injection with water. The composition of the total quantity of ash (solid residue and extracts) obtained in the two cases was as follows:

	NaCl	Na ² O	K ² O	CaO	MgO	Fe ² O ³	P ² O ⁵	SO ³
<i>a</i> .	1.47	4.86	39.95	1.80	3.88	1.00	46.74	0.30 = 100.00
<i>b</i> .	7.21	6.08	34.45	2.32	3.46	0.98	46.21	. . = 99.72

The total quantity of ash obtained by the second method amounted to 0.85 per cent. of the fresh flesh, and 4.14 per cent. of the flesh dried at 100° C. 77.63 per cent. of the ash was contained in the aqueous extract, 18.45 in the hydrochloric acid extract, and 3.92 in the residue.

FLESH-JUICE. It has been stated in the preceding article that the muscular flesh of animals of the higher orders is moistened with an acid liquid, which is more abundant in the striped than in the plain muscles. This liquid has been examined chiefly by Liebig (Ann. Ch. Pharm. lxii. 257), Scherer (*ibid.* lxi. 313), and Strecker (Chem. Soc. Qu. J. x. 121). It is of reddish colour, reddens litmus paper strongly, and is partially coagulated by heat. It contains albumin, casein, creatine, creatinine, sarcine, lactic acid, inosic acid, several volatile acids of the series CⁿH²ⁿ⁺²O₂, among which, formic, acetic, and butyric, are the most conspicuous, a red pigment, similar to, but, according to Lehmann, not identical with, the colouring matter of the blood, and inorganic salts, chiefly alkaline chlorides and phosphates.

A small portion of the flesh-juice runs out on pressure, but the greater part remains in the tissue, and can only be extracted by treatment with water. The mode of obtaining it, and separating the creatine from it has been already explained (see CREATINE, p. 95, *b*). The albumin separates on boiling; the casein is detected by acetic acid, or by the application of rennet, either of which produces turbidity.

The mother-liquor from which the creatine has crystallised, if further evaporated, mixed with small portions of alcohol till milky turbidity is produced, and then left to stand for some days, deposits yellow or white granular, laminar, or needle-shaped crystals, which are a mixture of creatine, phosphate of magnesium (if the phosphoric

* The flesh was soaked in lime-water and washed.

acid has not been previously quite separated by baryta, ii. 95), and the potassium and barium-salts of inosic acid, $C^6H^8N^2O^8$ (?).

On mixing the liquid from which the inosates have separated, with about five times its volume of alcohol, it separates into two layers, the lower of which is thick, syrupy, and brownish-yellow, and the upper more mobile and amounting to 20 times the volume of the lower. The heavier liquid cooled to $-5^{\circ}C$. deposits a large quantity of crystals of chloride of potassium. If separated from the lighter liquid and mixed with an equal volume of common ether, it becomes milky, and, on leaving it at rest, there gradually collects at the bottom of the vessel an amber-yellow syrupy liquid consisting almost wholly of lactate of potassium. The supernatant liquid also contains a little of this salt, but is chiefly a solution of creatinine.

If the liquid from which the inosates have separated be evaporated over the water-bath, and the residue treated with alcohol, all the lactates are dissolved; and if the alcoholic solution be separated from the insoluble syrup, and the alcohol evaporated, there remains a yellow syrup, which, after a week or ten days, solidifies to a soft crystalline mass, consisting of creatine, creatinine, and the potassium-salt of a nitrogenous acid, different from inosic acid; the mother-liquor contains lactate of potassium. As the lactic acid from flesh-juice exhibits certain peculiarities, it is sometimes called sarcolactic acid. (See LACTIC ACID.)

When the hot mother-liquor of creatine (ii. 95, b) is diluted and mixed with acetate of copper, or better with nitrate of silver, a precipitate is formed, containing, together with other substances, a compound of sarcine with the oxide of copper or oxide of silver, which, when decomposed by sulphydric acid, yields sarcine, $C^6H^8N^2O$, in the form of a white, indistinctly crystalline powder. (Strecker.)

Inorganic constituents of Flesh-juice.—The juice, when evaporated to dryness and incinerated, yields an ash, difficult to burn white, and consisting of alkaline phosphates and chlorides. The soluble salts extracted from it by water contain the three modifications of phosphoric acid. (Liebig.)

The flesh-juice of all animals is very rich in potash; it contains chloride of potassium and only a small quantity of chloride of sodium; in the blood the proportion between these alkalis is reversed. It appears, from numerous determinations made by Liebig, that the quantities of potash present in the blood of certain animals, for 100 pts. of soda, are as follows:—

	Hen.	Ox.	Horse.	Fox.	Pike.
In the blood . . .	40.8	5.9	9.5		
In the flesh-juice . .	381.0	279.0	285.0	214	497

F. Keller (Ann. Ch. Pharm. lxx. 91) has examined the ash of the decoction of flesh [of what kind?], and that of the boiled flesh. Of the total quantity of ash obtained, 82.2 per cent. came from the decoction and 17.8 per cent. from the boiled residue.

	Ash of decoction.		Ash of residue.		Total amount of ash.

From these analyses, it appears that of the inorganic salts contained in meat nearly four-fifths are extracted by boiling with water. Part of the earthy and ferric phosphates passes into solution through the medium of the alkaline phosphates; but meat, even after long boiling, is still rich in alkaline phosphates, although the earthy phosphates predominate.

Broth.—When meat is boiled with water, sulphurate of ammonium is evolved, together with odoriferous compounds and an acid resembling acetic acid. The extract, called *broth*, contains fat, a portion of the odoriferous compounds just mentioned, saline, soluble salts, and the various proximate principles existing in the meat. The following is its composition, according to Chevreul.

Water						988.51
Fixed organic matters dried at 20° C. in vacuo						12.70
Soda	}					2.90
Potash						
Sulphuric and phosphoric acids, chlorine						
Phosphate of magnesium						
Phosphate of calcium	}					0.23
Oxide of iron						
						0.10
						<hr/> 1004.60

Boiled meat retains the fibrin, together with part of the albumin, and the earthy and ferric phosphates contained in the raw meat.

The quality of the broth and of the boiled meat depends greatly on the mode of boiling. To make good broth, the meat should be placed in cold water and gradually raised to the boiling heat. By this means, the soluble constituents of the meat are extracted before the albumin has time to coagulate in the tissue and oppose their extraction. In fact the coagulation of the albumin then takes place in the liquid only, not in the substance of the meat; and as the albumin becomes insoluble, it rises to the surface, carrying with it certain calcium-salts which would render the broth turbid, and forms a *scum* which prevents the volatilisation of the odoriferous matters. To obtain savoury and nutritious boiled meat, the meat should be at once plunged into boiling water, so that a thin layer of coagulated albumin may at once form on the surface and retain the soluble matters within the tissue.

The broth does not, however, contain the whole of the substances extracted from the meat by boiling, inasmuch as a portion of these substances undergoes decomposition and produces the aroma; hence, boiled meat and its broth taken together, are, for the same weight, somewhat less nutritious than roast meat.

Liebig's Broth for invalids.—Half a pound of finely chopped meat (beef or poultry), from a recently killed animal, is macerated for an hour with 1½ lb. cold distilled water to which 4 drops of pure hydrochloric acid and a drachm of common salt have been added; the liquid is then separated from the residue by straining, without pressure, through a hair-sieve, and the residue is still further exhausted by gradually pouring on it half a pound of distilled water. In this way, a pound of cold meat-extract is obtained, of reddish colour and agreeable taste. It must be taken cold, as, if heated, it becomes turbid, and deposits a thick coagulum of flesh-albumin and blood-red. The advantages of this mode of preparation are that it yields an extract containing certain ingredients which are wanting in ordinary broth prepared by boiling, those, namely, which serve for the formation of blood-albumin. Besides flesh-albumin, it contains a certain quantity of blood-red, and a much larger quantity of iron (which is necessary for the formation of blood-corpuscles), besides the hydrochloric acid, which assists the digestive process.

In warm weather this extract ferments, though without any bad odour. It should therefore be prepared with quite cold water in a cool place. (Liebig, *Ann. Ch. Pharm.* lxxvii. 350.)

FLEXIBLE SANDSTONE. A fissile variety of sandstone, thin slabs of which exhibit a certain degree of flexibility, apparently owing to the dissemination of small scales of mica through the mass. Sandstones of this character occur at Villa Rica, Brazil, and in the gold region of North Carolina.

FLEXIBLE SILVER-ORE. See STERNBERGITE.

FLINT. A variety of quartz, somewhat allied to chalcedony, but more opaque and of dull colour, usually grey, smoky brown, and brownish black, occasionally with zoned and striped delineations. It occurs in nodules embedded in chalk. Internal lustre barely glimmering, subvitreous. Fracture conchoidal. Fragments sharp-edged. Translucent. Harder than rock-crystal. Easily frangible. Sp. gr. 2.59. Infusible without addition, but whitens and becomes opaque. It consists mainly of silica (about 98 per cent.), with small quantities of lime, alumina, oxide of iron and water. The flint of the chalk-formation consists largely of the remains of infusoria, sponges, and other marine productions. The silica of flint, according to Fuchs, is partly soluble silica, easily taken up by a solution of potash. When two pieces of flint are rubbed together in the dark, they phosphoresce, and emit a peculiar smell.

FLINTY SLATE. See SLATE.

FLOATSTONE. A light spongy variety of quartz, the *quartz nectique* of Haüy, consisting of fibres or filamentary crystals aggregated into a spongy or porous mass, and so light as to float on water. Colour, white of various shades. It occurs in the chalk formation of Ménéil-Montant, near Paris, and in some of the Cornish mines.

FLOS FERRI. A coralloïdal variety of arragonite occurring in beds of iron-ore.

FLOUR. The powder of the graminaceous seeds. (See BREAD and WHEAT; also *Ure's Dictionary of Arts, &c.*, ii. 277.)

FLOWERS, COLOURS OF. (Schübler, Schw. J. xlv. 285.—Decandolle, *ibid.* lv. 472.—Clamor-Marquart, *Die Farben der Blüthen*, Bonn, 1835. Frémy and Cloez, J. Pharm. [3] xxv. 249. Martens, Institut. 1855, p. 168. Filhol, *Compt. rend.* xxxix. 194; l. 345, 1132; Jahresber. f. Chem. 1860, p. 535.)—The petals of flowers, while still enclosed in the bud, are mostly green, and acquire their characteristic colours only under the influence of light. Sometimes, however, they are white in the first instance, or the buds exhibit the same colours as the expanded flowers. The blue and red pigments of flowers are generally soluble in water, whereas many of the yellow pigments are of resinous nature and dissolve only in alcohol and ether. Schübler and Decandolle endeavoured to prove the existence of two essentially different series of flower colours, the xanthic, producing the yellow tints with their transitions into red, and the cyanic, producing the blue tints with their modifications; and that the colours of both series are formed from chlorophyll, the xanthic by oxidation, the cyanic by deoxidation; but these views are not borne out by observation.

The extractive blue, violet, and red pigments, which are likewise contained in brown and orange-coloured flowers, were designated by Clamor-Marquart, as anthocyan, the resinous yellow pigment as anthoxanthin. According to Frémy and Cloez, blue flowers contain a colouring matter, called cyanin (ii. 274), which is identical with Marquart's anthocyan, and occurs also, coloured by acids, in red flowers. Yellow flowers on the other hand contain two distinct colouring matters, xanthin and xanthein, the former insoluble, the latter soluble in water.

According to Martens, all plants secrete, in cells situated in the parenchyma below the epidermis, a pale yellow juice, which becomes continually darker in colour by the action of air and light, and sometimes gradually turns red. This extractive matter, likewise called xanthein by Martens, is generally associated in plants with a blue pigment, the anthocyan of Marquart and the cyanin of Frémy. Alkalis turn cyanin green, and deepen the yellow colour of xanthein.

According to Filhol, nearly all flowers contain a substance which forms colourless solutions with acids, and acquires a fine yellow colour when treated with alkalis: this substance was designated by Marquart as resin of flowers, and by Hope (J. pr. Chem. x. 269) as xanthogen (*q. v.*), which name is also retained by Filhol. He describes it as solid, of a light yellow colour, with faint greenish iridescence, soluble in water, alcohol, and ether, and very much like luteolin, with which it is associated in weld (*Res. dulcis*), but neither crystalline nor volatile. Xanthogen is not contained in mosses, in plants which grow in the dark, or in the flowers of *Pelargonium zonale*, *P. inquinans*, *Papaver Rhæas*, or the various species of *Salvia* and *Camellia*. All these flowers, when treated with alkalis assume a blue or violet colour, without any admixture of green, and the colouring matter contained in them is much more stable than that of most other flowers.

The xanthein (*q. v.*) of Frémy and Cloez exists also, according to Filhol, in many flowers either alone or associated with cyanin. The xanthin of the same chemists exhibits peculiar relations to chlorophyll. Its alcoholic solution is coloured green slowly by dilute, quickly by concentrated hydrochloric acid, and the liquid, if exposed for some time to the air, turns yellow and deposits a blackish substance which dissolves with blue colour in alcohol and ether. By agitation with a mixture of hydrochloric acid and ether, it is still more quickly resolved into a blue and a yellow colouring matter. Both xanthin and chlorophyll treated with hydrochloric acid containing a trace of nitric acid yield a nearly pure blue. Xanthin is less easily altered by sunshine than chlorophyll.

Certain yellow flowers, especially those of *Crocus luteus*, contain a peculiar colouring matter, which is amorphous, of golden-yellow colour, soluble in water and in alcohol, insoluble in ether, distinguished from xanthin by its solubility in water, and by not being perceptibly altered by hydrochloric acid.

The cyanin of blue and red flowers (ii. 274) is free from nitrogen and identical with the colouring matter called onolin or onocyanin, obtained by Glénard from red wine. The cyanin of red flowers dissolves in alcohol and in water without perceptibly colouring the liquid; but the addition of a few drops of acid brings out the colour: hence Filhol regards cyanin as identical with Hope's erythrogen (ii. 503).

Some red flowers, several kinds of aloe for example, contain a colouring matter dif-

ferent from cyanin, sparingly soluble in water, easily in cold alcohol, nearly insoluble in ether, and not altered in colour by acids or by bases.

All flowers contain uncrystallisable sugar (Filhol).

The statement of older observers, that the blue colours of flowers are produced from red by the action of alkalis developed in the plant, is not confirmed by experiment. Alkalis, in fact, either produce no effect on red flowers, or turn them green, but certainly not blue.

The colours of flowers are, for the most part, very fugitive, and therefore of little use in dyeing. On carthamin, the red dye obtained from the flowers of *Carthamus tractorius*, see vol. i. p. 808.

FLUAVIL. A constituent of gutta percha, constituting from 4 to 6 per cent. of that substance. It is yellow, resinous, somewhat heavier than water, hard and friable at 0° C., soft at higher temperatures, pasty at 50°, liquid at 100°--110°. At a stronger heat it boils and decomposes, turning brown and giving off acid vapours and hydrocarbons. It dissolves at common temperatures in alcohol (which it obstinately retains), in ether, benzene, oil of turpentine, sulphide of carbon, and chloroform, remaining as an amorphous mass when the solutions are evaporated. Sulphuric and nitric acids act upon it in the same manner as upon gutta percha; strong hydrochloric acid dissolves it without decomposition (Payen, *Compt. rend.* xxxv. 109). See GUTTA PERCHA.

FLUCERINE. Syn. with FLUCERITE.

FLUELLITE. A fluoride of aluminium crystallised in minute acute rhombic octahedrons, with truncated apex, and occurring on quartz, together with wavellite and uranite, at Stannaw-gwyn in Cornwall. Hardness = 3. Colour white, transparent. (Levy, *Ed. J. Sci.* 1825, p. 168.—Dana, ii. 98.)

FLUOBORIC ACID. See BORON, FLUORIDE OF (i. 633).

FLUOCERINE. *Basicerine.* Basic fluoride of cerium from Finbo (i. 834).

FLUCERITE. *Flucrine.* Normal cerous fluoride, occurring at Finbo and Broddbo in Sweden (i. 834).

FLUOCHLORE. A name applied by Hermann to those varieties of pyrochlore which contain fluorine but no water. (See PYROCHLORE.)

FLUOLITE. Pitchstone from Iceland.

FLUOR. See FLUOR-SPAR.

FLUORHYDRIC or **HYDROFLUORIC ACID.** HF. This acid, which is the only known compound of fluorine and hydrogen, was first prepared, though in an impure state, containing silica, by Scheele in 1771. Gay-Lussac and Thénard, in 1808, first obtained it in the pure state, but regarded it as an oxygen-compound. Ampère, in 1810, suggested that it was a hydracid analogous to hydrochloric acid; and this view was afterwards experimentally confirmed by Davy.

Formation and Preparation.—Hydrofluoric acid is produced by the action of sulphuric acid on metallic fluorides, fluor-spar, which is a fluoride of calcium, being almost always used for its preparation:

To obtain the acid pure, a leaden or platinum vessel must be used, as it corrodes glass or earthenware with great rapidity. To prepare the aqueous acid in its strongest form, fluor-spar perfectly dry is mixed with twice its weight of strong sulphuric acid (specific gravity 1.85), in a leaden retort (*fig. 483*) having a bent leaden tube adapted to it, the lower part of which is immersed in a freezing mixture. The joints are made secure with clay-lining secured with a band of paper. No tin solder must be used in the construction of the apparatus, as the acid attacks tin rapidly. On applying a gentle heat, hydrofluoric acid is given off in vapour, and passing into the bent tube is there condensed into a liquid.

The acid thus prepared contains water, from which it may be freed by distillation with phosphoric anhydride; it is then obtained as a gas (Lonyet, *Compt. rend.* xxii. 980); according to Frémy, however, the dehydration effected in this manner is not complete. A better mode of obtaining the dry gas is to ignite the double fluoride of hydrogen and potassium, which then splits up into its component fluorides, KF and HF. The gas may also be obtained by passing dry hydrogen over ignited fluoride of lead or other metallic fluorides.

Fig. 483.

Hydrofluoric acid also results from the decomposition of certain fluorides by water. Thus fluoride of silicon reacts with water to form hydrofluosilicic and silicic acids:

and the hydrofluosilicic acid gradually breaks up into fluoride of silicon, which evaporates, and hydrofluoric acid, which remains in solution.

Hydrofluoric gas is colourless, has a strong acid reaction, fumes in moist air, and is rapidly absorbed by water. When absolutely dry, it has but little reaction on glass. According to Frémy, it condenses at -20°C . into a very mobile liquid, which reacts violently with water, forms white fumes in the air, and attacks glass readily. The concentrated aqueous acid is a colourless mobile liquid, which boils at 15°C .; the fume is highly caustic and irritating, and the liquid itself is a most virulent caustic, a single drop producing a painful ulcer very difficult to heal. Its union with excess of water is accompanied by a hissing noise and a considerable development of heat. The most concentrated acid has a sp. gr. 1.06. The acid of greatest density, namely, 1.15, is more dilute, and is usually regarded as a definite hydrate, $\text{HF}\cdot 2\text{H}_2\text{O}$, containing 35.9 p.c. HF, boiling at 120°C ., and distilling unchanged under the ordinary atmospheric pressure. According to Roscoe, however (Chem. Soc. Qu. J. xiii. 162), no definite hydrate of hydrofluoric acid exists, a weaker or stronger acid giving off water or hydrofluoric acid when boiled, till the residue contains from 36 to 38 p.c. HF. By leaving the aqueous acid of any strength to evaporate over quick lime at common temperatures, a residue is obtained containing 32.5 p.c. HF.

From the analogy of hydrofluoric acid to hydrochloric, hydrobromic, and hydriodic acid, it is supposed to contain equal volumes of fluorine and hydrogen gases united without condensation, its composition being therefore 1 pt. hydrogen united with 19 pts. fluorine and its atomic weight 20. This composition by volume has not, however, been determined directly; for fluorine itself has not been isolated in a satisfactory manner, and even the specific gravity of hydrofluoric acid gas is unknown.

Reactions.—Hydrofluoric acid acts with energy on many elementary bodies, especially the *metals*, dissolving them with evolution of hydrogen, and sometimes, as in the case of *potassium*, with explosion, and forming a fluoride. It acts in this manner, not only on the metals which are dissolved by hydrochloric acid, but likewise on those which that acid does not attack, *copper* and *silver* for example. It also dissolves many elementary bodies which are insoluble in all other acids, namely, *silicon*, *boron*, *zirconium*, *titanium* and *tantalum*, giving off hydrogen, and forming a compound of the resulting fluoride with hydrofluoric acid; with *silicon* (unignited), for example, it forms hydrofluosilicic acid, $2\text{HF}\cdot\text{SiF}^4$. Ignited silicon and titanium are not attacked by hydrofluoric acid alone, but dissolve in a mixture of hydrofluoric and nitric acids with evolution of nitric oxide. *Gold* and *platinum*, on the other hand, are not attacked, either by the pure acid or by its mixture with nitric acid.

Silica and the *silicates* are very energetically attacked by hydrofluoric acid. *Silica* dissolves in it with great rise of temperature, forming a colourless solution of hydrofluosilicic acid, $2\text{HF}\cdot\text{SiF}^4$ or H^2SiF^6 ; if the hydrofluoric acid is concentrated, the liquid boils and fluoride of silicon escapes as gas. With *silicates* it forms water, fluoride of silicon, and a metallic fluoride which unites with the fluoride of silicon; e.g. with silicate of calcium:

With silicates of different composition, an excess of metallic fluoride or of fluoride of silicon is formed, which unites with the hydrofluoric acid.

On this reaction depends the use of hydrofluoric acid for the decomposition of silicates in mineral analysis (see *SILICATES*), and for etching on glass. For the latter purpose, the glass is covered with etching wax; the design is traced upon it with a pointed instrument; and the glass is either exposed to the vapour of the acid, or the aqueous acid is poured upon it. The vapour is preferable to the liquid in this respect, that the lines which it forms on the glass are opaque, whereas those formed by the liquid are transparent and not so easily seen. Etching with hydrofluoric acid vapour is the best mode of marking scales of equal parts on glass tubes and jars.

FLUORIDE OF ALUMINIUM. (i. 157.)

FLUORIDE OF AMMONIUM. NH^4F . This salt crystallises from a solution of hydrofluoric acid saturated with ammonia and left to evaporate over quick lime, in thin hexagonal laminae, or very brittle hollow hexagonal prisms; the crystals are somewhat deliquescent.—*Fluoride of Ammonium and Hydrogen, or Acid Fluoride of ammonium*, $\text{NH}^4\text{F}\cdot\text{HF}$, forms slightly deliquescent rhombic crystals of $91^\circ 50'$, with the terminal faces *oP*, and frequently also with the prismatic edges truncated: it is not isomorphous with the corresponding potassium-salt. (Marignac, *Ann. Ch. Pharm.* xlv. 330.)

FLUORIDE OF ANTIMONY. See *ANTIMONY, FLUORIDE OF* (i. 322).

FLUORIDE OF ARSENIC. See ARSENIC, FLUORIDE OF (i. 371).

FLUORIDE OF BENZOYL. $C^7H^5O.F$. (Borodine, Cimento, xv. 305; Rép. Chim. pure, 1862, p. 336.)—Obtained by mixing in a platinum retort 1 at. chloride of benzoyl and rather more than 1 at. acid fluoride of potassium, distilling as soon as vapours of hydrofluoric acid cease to go off, and collecting in a small platinum receiver the portion which distils between 155° and 160° .* The product may be further purified by fractional distillation. The reaction is represented by the equation:

Fluoride of benzoyl is a colourless oily liquid, heavier than water, and having an odour even more irritating than that of the chloride. It boils at 161.5° (corrected) under a pressure of 746 mm. When pure, it scarcely attacks glass; nevertheless its vapour-density cannot be taken in glass vessels. It dissolves without decomposition in ether; is converted by water into benzoic and hydrofluoric acids; forms with potash benzoate and fluoride of potassium; with alcohol, benzoic ether, and with ammonia, benzamide. It does not appear to unite with metallic fluorides.

FLUORIDE OF BARIUM. See BARIUM, FLUORIDE OF (i. 504).

FLUORIDE OF BORON. See BORON, FLUORIDE OF (i. 632).

FLUORIDES OF CADMIUM, CALCIUM, CERIUM, COBALT, COPPER, &c. See the several metals.

FLUORIDE OF ETHYL. See ETHYL, FLUORIDE OF (ii. 533).

FLUORIDE OF HYDROGEN. See FLUORHYDRIC ACID (ii. 669).

FLUORIDE OF PHOSPHORUS. See PHOSPHORUS, FLUORIDE OF.

FLUORIDE OF SILICON. See SILICON, FLUORIDE OF.

FLUORIDES, METALLIC. These compounds are formed: 1. By heating hydrofluoric acid with certain metals.—2. By the action of that acid on metallic oxides or carbonates.—3. By heating electro-negative metals, antimony for example, with fluoride of lead or fluoride of mercury.—4. Volatile metallic fluorides may be prepared by heating fluor-spar with sulphuric acid and the oxide of the metal.—5. Insoluble fluorides, such as fluoride of calcium may be formed by precipitation.

Fluorides have no metallic lustre; most of them are easily fusible, and for the most part resemble the chlorides. When dry, they are not decomposed by ignition, either alone or when mixed with charcoal; but when ignited in contact with the air, in a flame which contains aqueous vapour, many of them are converted into oxides, while the fluorine is given off as hydrofluoric acid. All fluorides are decomposed by chlorine and converted into chlorides. They are not decomposed by phosphoric anhydride, unless silica is present. They are decomposed at a gentle heat by strong sulphuric acid, with formation of a metallic sulphate and evolution of hydrofluoric acid.

The fluorides of tin and silver are easily soluble in water; those of potassium, sodium, and iron are sparingly soluble; those of strontium and cadmium very slightly soluble, and the rest insoluble. The solutions of fluoride of ammonium, potassium, and sodium have an alkaline reaction. The aqueous solutions of fluorides corrode glass vessels in which they are kept or evaporated. They form with soluble calcium-salts a precipitate of fluoride of calcium, in the form of a transparent jelly which is scarcely visible, because its refractive power is nearly the same as that of the liquid; the addition of ammonia makes it plainer. This precipitate, if it does not contain silica, dissolves with difficulty in hydrochloric or nitric acid, and is reprecipitated by ammonia. The aqueous fluorides give a pulverulent precipitate with acetate of lead.

The fluorides of antimony, arsenic, chromium, mercury, niobium, osmium, tantalum, tin, titanium, tungsten, and zinc, are volatile without decomposition.

Double Fluorides.—Fluorine has a great tendency to form double salts, consisting of a fluoride of a basic or positive metal united with the fluoride of hydrogen, boron, silicon, tin, titanium, zirconium, &c., e.g.:

Fluorhydrate of potassium	$KHF^2 = KF.HF.$
Borofluoride of potassium	$KBF^2 = KF.BF^2.$
Silicofluoride of potassium	$K^2SiF^4 = 2KF.SiF^2.$
Titanofluoride of potassium	$K^2TiF^4 = 2KF.TiF^2.$
Stannofluoride of potassium	$K^2SnF^4 = 2KF.SnF^2.$
Zirconofluoride of potassium	$K^2ZrF^4 = 2KF.ZrF^2.$

It will be observed that the double fluorides of silicon, titanium, tin, and zirconium are represented by corresponding formulæ. It appears indeed from the experiments of Marignac (Ann. Ch. Pharm. cvii. 94; cxl. 380; cxvi. 359.—Ann. Ch. Phys.

* The tube of the thermometer should be protected by placing it within a small tube of platinum passing through the tubulure of the retort.

[3], p. 257. — Jahresber. f. Chem. 1858, p. 144; 1859, p. 106; 1860, p. 134), that the corresponding double fluorides of silicon, tin, and titanium crystallise for the most part with the same number of atoms of water, and are isomorphous with each other. Thus the silicofluorides and stannofluorides of strontium crystallise each with 1 at. water, have nearly the same degree of solubility in water, and form monoclinic crystals in which $\infty P : \infty P$ is, in the former, $= 84^\circ 16'$, in the latter, $= 82^\circ 23'$. The zinc-fluorides of tin and silicon crystallise with 3 at. water in hexagonal prisms with rhombohedral faces, in which $R : R = 127^\circ 16'$, and similar forms are exhibited by the corresponding salts of nickel ($R : R = 127^\circ 30'$) and cadmium ($R : R$ for the stannofluoride $= 127^\circ$). The corresponding salts of cobalt, iron, manganese, and copper are likewise isomorphous with the preceding, and agree with them in their optical properties. The zirconfluorides or fluozirconates exhibit isomorphism with the corresponding silicofluorides, &c., in a few cases, but by no means in all.

The great tendency of fluorine to form double salts, has led to the idea that it should be regarded as diatomic and analogous to oxygen, with the atomic weight 38, rather than as monatomic and analogous to chlorine, with the atomic weight 19. On this supposition, denoting the larger atom of fluorine by Ff, the formulae of the fluorides would be as follows:

Hydrofluoric acid	$= \begin{matrix} H \\ H \end{matrix} \} Ff.$
Fluoride of potassium and hydrogen	$= \begin{matrix} H \\ K \end{matrix} \} Ff.$
Fluoride of potassium	$= \begin{matrix} K \\ K \end{matrix} \} Ff.$
Fluoride of boron	$= B^2 Ff.$
Borofluoride of potassium	$= \begin{matrix} K \\ B \end{matrix} \} Ff^2.$
Fluoride of silicon	$= SiFf^2.$
Silicofluoride of potassium	$= \begin{matrix} K^2 \\ Si \end{matrix} \} Ff.$

The question cannot be directly decided, because, as already observed, the vapour-densities of fluorine and of hydrofluoric acid are not known; but the recent experiments of Borodine (Cimento, xv. 305; Rép. Chim. pure, 1862, p. 334) tend strongly to the conclusion that fluorine is monatomic, as hitherto supposed, and that the double fluorides are analogous to the double chlorides, iodides, &c., rather than to the double sulphides and oxides, or to the double salts of dibasic acids.

The fluorides of potassium and sodium have a great tendency to unite with hydrofluoric acid, and form acid fluorides, and consequently they readily give up half their metal even to the weakest acids. Thus a solution of fluoride of potassium mixed with dilute acetic acid yields, by evaporation, crystals of the salt $KF.HF$:

A similar action takes place with fluoride of sodium.

An aqueous solution of benzoic acid does not act on fluoride of potassium; but an alcoholic solution of that acid mixed with the aqueous solution of the fluoride yields a crystalline precipitate, which is a mixture of acid benzoate and acid fluoride of potassium, $C^2H^3KO^2.C^2H^4O^2 + KF.HF$. A similar action is exerted by valeric, citric, oxalic, and tartaric acids. Hence it appears that all organic acids decompose the fluorides of potassium, or of sodium, forming an acid fluoride, but do not themselves unite with the alkaline fluoride in the same manner as hydrofluoric acid does.

FLUORIDES, ORGANIC. Only a few compounds of fluorine with organic radicles have been obtained, viz. the fluorides of benzoyl (p. 671), ethyl (p. 533), and methyl (q. v.).

FLUORINE. Atomic weight, 19; symbol, F. This element is widely diffused, but not in large quantities. It occurs most abundantly as fluoride of calcium, and is also found in fluoride of cerium, topaz, cryolite, warwickite, and yttracrite; and in small quantity in fluor-apatite, wagnerite, amblygonite, wavellite, and many other minerals. It also occurs in bones and teeth, both recent and fossil, and in urine. Professor Wilson, of Edinburgh, has shown that fluorine exists in a great number of plants, especially in the siliceous stems of grasses and equisetaceous plants, always, however, in very small and variable quantities. He supposes that soluble fluoric compounds diffuse themselves through the rising sap of the plant, and are converted, by the silica contained therein, into soluble silico-fluorides. These fluorine also occur in the trap-rocks near Edinburgh and in the neighbourhood of the

Clyde, in the granites of Aberdeenshire, and in the soils formed by the disintegration of those rocks. Wilson has also found slight traces of fluorine in the ashes of ox-blood, milk, and cream-cheese, and very slight traces in the ash of the whey of milk. (Edin. Phil. J. liii. 356; Chem. Gaz. 1850, p. 366.)

Small quantities of fluorine have been found in the waters of the Seine, Rhone, Saone, Loire, and other rivers (Nicklès, Compt. rend. xlv. 783; xlv. 331. Mène, *ibid.* l. 731), and in larger quantity in certain mineral waters, especially those of Contrexéville, Antogast, and Châtenois. (Nicklès.)

According to Nicklès, fluoride of calcium occurs in all waters which contain acid carbonate of calcium, and may therefore be found in all calcareous rocks and minerals formed by sedimentary deposition.

Of fluorine in the free state we know but little. Fluorides are decomposed by chlorine and converted into chlorides, and doubtless the fluorine is at the same time set free; but it directly enters into combination with the material of almost every vessel that can be used to receive it, so that its isolation is a matter of great difficulty.

Louyet (Compt. rend. xxii. 960) decomposed fluoride of silver by means of chlorine or iodine in a vessel made of fluor-spar, and obtained a gas which was colourless in thin strata, did not bleach vegetable colours, decomposed water rapidly, and attacked most metals, not however, gold or platinum. Frémy (Compt. rend. xxxviii. 393; xl. 966), by submitting fused fluoride of potassium to the action of the voltaic current, obtained a gas which rapidly attacked platinum, decomposed water, with formation of hydrofluoric acid, and displaced iodine from its combinations with metals. By decomposing fluoride of calcium at a red heat with dry chlorine or oxygen, he likewise obtained a gas which rapidly attacked glass: this gas appeared to be fluorine.

H. Reinsch (N. Jahrb. Pharm. xi. 1), by heating a mixture of cryolite, peroxide of lead, and acid sulphate of potassium, obtained a colourless gas, chiefly consisting of oxygen, but having a pungent odour, like that of nitrous acid, which he attributed to the presence of a small quantity of free fluorine.

Kämmerer (J. pr. Chem. lxxxv. 452), by heating iodine with excess of fluoride of silver in a sealed tube, from which the air had been expelled by iodine-vapour, obtained a colourless gas, which did not attack glass, could be collected over mercury, and was rapidly absorbed by potash, the liquid subsequently not exhibiting a trace of iodine or of silicon.

FLUORINE, DETECTION AND ESTIMATION OF. 1. Reactions.—

Fluorine is usually detected by the evolution of hydrofluoric acid which takes place when its compounds are heated with sulphuric acid. When a fluoride is gently heated with strong sulphuric acid in a leaden cup or platinum crucible; the vessel covered with a plate of glass coated with etching-wax on which lines are traced with a needle, so as to expose the surface of the glass, the plate removed after a while, and the wax scraped off; the lines are found to be bitten in, and appear particularly distinct when breathed upon.

If the fluorine is in very small quantity, or if silica is likewise present, the substance under examination should be mixed with strong sulphuric acid in a watch-glass, heated till it is dry, and the residue washed off with water; the spot on which the mixture has been evaporated then appears dull. Another method of detecting small quantities of fluorine, is to heat the substance (mixed with silica if that body is not already present) with strong sulphuric acid in a glass vessel; pass the evolved fluoride of silicon into water; supersaturate the resulting hydrofluosilicic acid with ammonia; evaporate to dryness; exhaust the residue with water; again evaporate the filtrate; and test the residue in the ordinary way, by heating it with sulphuric acid in a platinum vessel covered with a waxed glass plate. (G. Wilson, Chem. Soc. Qu. J. v. 151.)

Nicklès (Compt. rend. xlv. 679) points out that in searching for traces of fluorine, error is very apt to arise from the presence of small quantities of hydrofluoric acid in the sulphuric acid used; also from the fact that certain other acids in the state of vapour act upon glass in a similar manner to hydrofluoric acid, though not so powerfully. He states that a surface of rock-crystal completely withstands the action of all acids except hydrofluoric acid, and that by using it instead of glass, the minutest traces of fluorine may be detected with certainty.

Small quantities of fluorine may also be detected by the blow-pipe, especially if the substance examined likewise contains water. A sample is intimately mixed with microcosmic salt, and heated at the end of a glass tube open at both ends, in such a manner that the flame may be partly driven into the tube. If fluorine is present, hydrofluoric acid is given off, and condenses, together with vapour of water, in the upper and cooler part of the tube; on evaporating the water, a dull spot is found where the hydrofluoric acid has acted on the glass.

2. *Quantitative estimation.*—Solid fluorides are decomposed by heating them in a platinum crucible with strong sulphuric acid, containing the heat till all the fluorine is expelled in the form of hydrofluoric acid, and the excess of sulphuric acid is likewise drawn off. The residual sulphate is then weighed, and the quantity of metal in it calculated; this quantity deducted from the original weight of the fluoride gives the quantity of fluorine. Or, supposing no other volatile acid to be present, if the difference in the weight of the fluoride and the sulphate formed from it be d , the quantity of the fluorine may be found by means of the equations,

$$SO^4 - F^2 = d; \quad \frac{SO^4}{F^2} = \frac{48}{19};$$

whence the quantity of fluorine which goes off is

$$F^2 = \frac{19}{48-19} d = \frac{19}{29} d.$$

The second mode of calculation is equally applicable, whether the fluorine be combined with one metal or with several.

Some fluorides, especially the fluoride of aluminium, are somewhat difficult to decompose by sulphuric acid. In this case, the substance must be reduced to extremely fine powder, and heated for some time with very strong sulphuric acid. The decomposition may, however, be more quickly effected by fusion with *acid sulphate of ammonium*. When fluoride of aluminium is thus treated, and the residual sulphate of aluminium calcined with addition of a small quantity of carbonate of ammonium, a residue of pure alumina is obtained; and by calculating the quantity of aluminium contained therein, the amount of fluorine may be determined by difference; if, however, the fluoride contains water, the amount of the water must be previously determined.

In decomposing fluorides by sulphuric acid, it is often desirable to estimate the amount of fluorine directly. For this purpose, the acid vapours evolved are passed into water, and the amount of fluorine is determined by means of oxide of lead, as will be presently explained.

As gaseous fluoride of silicon is more easily separated from solid compounds by the action of strong sulphuric acid than hydrofluoric acid, Wöhler has proposed to determine the fluorine in certain compounds by mixing them with *silica*, and treating them with strong sulphuric acid. The fluorine is then given off as fluoride of silicon, which, when passed into water, is resolved into a precipitate of silica and a solution of hydrofluosilicic acid. The liquid separated from the silica by filtration is mixed with alcohol and with a salt of potassium, sodium, or barium, whereby a precipitate is formed containing the whole of the fluorine in the form of silicofluoride of potassium, sodium, or barium; this precipitate is collected on a weighed filter, washed with a mixture of equal volumes of alcohol and water, dried at 100° C. and weighed, and the amount of fluorine determined from it by calculation.

Estimation of Fluorine in Solutions: a. By means of Oxide of Lead.—In a liquid containing hydrofluoric acid, unmixed with any base, or with any acid except nitric acid, the quantity of fluorine may be determined by adding a weighed quantity of pure calcined oxide of lead, evaporating to dryness in a platinum capsule, and calcining the residue in a small platinum crucible, taking care not to raise the heat high enough to decompose the fluoride of lead. The solution must not contain ammonia or any of its salts. The residue exhibits an increase of weight, arising from the substitution of fluorine for oxygen; and a calculation similar to the above shows, that *this increase is to the quantity of fluorine in the residue, in the same ratio as the difference between the atomic weight of fluorine and half the atomic weight of oxygen is to the atomic weight of fluorine.* Hence if the increase of weight be d , the quantity of fluorine in the residue is

$$f = \frac{19}{19-8} d = \frac{19}{11} d.$$

b. By precipitation as Fluoride of Calcium.—In neutral liquids containing soluble fluorides, the fluorine may be precipitated by chloride of calcium. To facilitate the deposition of the precipitate, the whole must be boiled, and left to itself for the precipitate to settle down; the clear liquid then poured through a filter; the remaining precipitate well boiled with water; the clear liquid again poured off; and these operations repeated several times, the precipitate not being poured upon the filter till it has been well washed by decantation. It is then dried, ignited, and weighed. It contains 48.32 per cent. of fluorine.

If the solution is acid, it is best to supersaturate it with carbonate of sodium, and add a solution of chloride or nitrate of calcium, which throws down a mixture of fluoride and carbonate of calcium, much easier to filter and wash than the fluoride alone. It is dried and ignited, the filter being burnt in the ordinary way, and digested in a platinum capsule with acetic acid, which decomposes and dissolves

the carbonate of calcium, but leaves the fluoride untouched. The whole is evaporated to dryness over the water-bath, till the residue no longer smells of acetic acid; and this residue is tested with hot water, which dissolves the acetate of calcium, leaving the fluoride, which may be washed, dried, and weighed as above. If the precipitate were not calcined before being treated with acetic acid, it would stop up the pores of the filter during washing.

If the solution of a fluoride contains ammoniacal salts, they must be decomposed by boiling with carbonate of sodium before precipitation, inasmuch as fluoride of calcium is somewhat soluble in ammonia-salts.

Fluorine may also be precipitated as *fluoride of barium*, or of *lead*; but these modes of estimation are less exact than that which is based on the precipitation by calcium salts as just described.

Estimation of Fluorine in insoluble compounds.—When the quantity of fluorine in an insoluble compound is somewhat considerable, the method of estimation by decomposition with sulphuric acid (p. 674) is the simplest and most accurate that can be employed; but very small quantities of fluorine cannot be exactly estimated in this manner. The best mode of proceeding in such cases, is to convert the insoluble fluoride into a soluble fluoride by fusion with an *alkaline carbonate*, treat the fused mass with water, and precipitate the filtered solution with chloride or nitrate of calcium in the manner already described. Some of the earthy fluorides, however, especially fluoride of calcium, which is of frequent occurrence as a natural mineral, cannot be completely decomposed by this process. In all cases, however, complete decomposition may be effected by fusing the fluoride with a mixture of *alkaline carbonate and silica*; fluoride of calcium thus treated yields a mixture of alkaline fluoride and silicate, with carbonate and silicate of calcium. On treating the fused mass with water, a solution is obtained containing a fluoride of the alkali-metal, together with carbonate and a small quantity of silicate. The silica may be precipitated as silicate of zinc, by adding to the alkaline liquid a solution of zinc in ammonia; and from the filtrate, which contains fluoride and carbonate of the alkali-metal, the fluorine may be precipitated by a calcium-salt, and the estimation completed in the manner already described.

Estimation of free Hydrofluoric acid in presence of Fluorides.—In compounds of metallic fluorides with hydrofluoric acid, the amount of the latter may often be estimated by simple calcination in a platinum crucible. In some cases, however, the residual metallic fluoride is partly decomposed by contact with the air. To avoid the source of error thence arising, Berzelius mixed the compound with six times its weight of oxide of lead, and calcined the whole in a small retort. The free hydrofluoric acid is then decomposed, yielding fluoride of lead and water, which escapes and may be estimated by loss, and the equivalent quantity of hydrofluoric acid thence determined. Another portion of the compound is decomposed by sulphuric acid (p. 674); the quantity of fluorine existing in the compound as metallic fluoride is determined from the amount of sulphate thus obtained; and this, added to the quantity present as hydrofluoric acid, gives the total quantity of fluorine in the compound.

If the compound likewise contains water of crystallisation, the loss of weight resulting from calcination with oxide of lead represents the sum of this water of crystallisation, and the water which is formed by combination of the hydrogen of the hydrofluoric acid with the oxygen of the lead-oxide. The total quantity of fluorine originally in combination with the metal, may then be determined by heating the calcined residue with sulphuric acid; and this diminished by the quantity originally in combination with the metal,—which may be determined by heating a separate portion of the original substance with sulphuric acid, as above,—gives the quantity present as hydrofluoric acid. The amount of water equivalent to this latter quantity may then be calculated, and this deducted from the loss of weight resulting from calcination with lead-oxide, gives the amount of water of crystallisation.

3. *Separation of Fluorine from other elements.*—1. *From Metals.* Fluorides soluble in water or in acids may, in many cases, be decomposed by precipitating the metal as sulphide with sulphuric acid. The filtered liquid is then saturated with carbonate of sodium, and the fluorine precipitated by chloride of calcium. If the solution is acid, the precipitation of the metal must be performed in a platinum vessel (since free hydrofluoric acid attacks glass), and the liquid filtered on a platinum funnel; or the solution may be supersaturated with the alkaline carbonate; the precipitate decomposed, without previous filtration, by sulphuric acid: the liquid then filtered, and the fluorine precipitated by chloride of calcium: by proceeding in this manner, the whole process may be performed in glass vessels.

Compounds of fluorine with metals which are not precipitated by sulphydric acid as sulphides, viz. the fluorides of the earth-metals, cannot be decomposed in this manner, but must be treated either with sulphuric acid (p. 674), or by fusion with carbonate of sodium and silica.

From Chromic acid.—When a solution containing hydrofluoric and chromic acids, is treated with chloride of calcium, a small quantity of chromic acid is always precipitated together with the fluoride of calcium, and consequently exhibits a green colour after calcination, the chromic acid having been partly reduced to sesquioxide by the combustion of the filter. To separate this small quantity of chromium, the calcined precipitate is moistened with sulphuric acid, which decomposes it completely, and the decomposed mass is heated with alcohol diluted with half its bulk of water, and the resulting sulphate of calcium is washed with alcohol. The filtered solution, which contains all the chromium in the form of chromic sulphate, is treated with ammonia, which precipitates the chromium in the form of sesquioxide.

The liquid filtered from the original precipitate of fluoride of calcium contains the greater part of the chromium in the form of chromate of calcium. The chromic acid is reduced to sesquioxide by means of hydrochloric acid and sulphydric acid or alcohol, and the chromium precipitated by ammonia from the filtrate as sesquioxide. From this quantity, added to the small quantity previously determined, the amount of chromic acid or metallic chromium in the compound may be found by calculation.

The quantity of chromate of calcium equivalent to the sesquioxide of chromium separated from the fluoride of calcium, must also be determined; and this deducted from the total weight of the calcined precipitate, gives the exact quantity of the fluoride of calcium. This method may serve for the analysis of fluoride of chromium (i. 946).

For the separation of fluorine from *Boron* see i. 631.

Separation of Fluorides from Phosphates.—Fluorides frequently occur in nature in conjunction with phosphates, as in apatite and in bones. To analyse such a compound, it is first heated with sulphuric acid, to expel the fluorine; the residue digested with alcohol to dissolve the phosphoric acid which has been set free; the quantity of that acid determined by precipitation with ammonia and sulphate of magnesium; and the metals, now remaining in the form of sulphates, determined by the usual methods. Lastly, the total weight of these metals, together with that of the phosphoric acid, or rather of the corresponding salt-radicle (PO_4 , if the phosphates are tribasic) is deducted from the original weight of the mineral; and the difference gives the quantity of fluorine.

For the separation of fluorides from *silicates*, see SILICON, ESTIMATION OF.

Separation of Fluorides from Sulphates.—Some fluorides occur in nature mixed with insoluble sulphates; fluor-spar with sulphate of barium for example. Such a mixture cannot be completely decomposed, either by hydrochloric acid, or by alkaline carbonates: for hydrochloric acid, besides dissolving a small quantity of the sulphate, leaves a portion of the fluoride of calcium mixed with the undissolved sulphate; and fusion with alkaline carbonates decomposes the sulphate of barium completely, but not the fluoride of calcium. The only way of effecting the complete decomposition of such a mixture is to fuse it with a mixture of alkaline carbonate and silica; best with six times its weight of a mixture of potassic and sodic carbonates in atomic proportions, and 2 pts. of silica.

The fused mass is treated with water, the whole evaporated to dryness to separate the silica as completely as possible, the alkaline liquid then supersaturated with hydrochloric acid, and precipitated by chloride of barium. Sulphate of barium is thereby precipitated quite free from fluorine: this determines the sulphuric acid.

To determine the fluorine, the alkaline liquid from another portion must be supersaturated with nitric acid, the sulphuric acid precipitated by nitrate of barium, the filtrate exactly saturated with carbonate of sodium, and the fluorine precipitated as fluoride of barium by addition of alcohol.

The residue insoluble in water is treated with hydrochloric acid; the whole is evaporated to dryness, the dried mass moistened with hydrochloric acid, and boiled with water to separate silica, and the baryta and lime separated in the filtrate by methods already given (i. 717).

Separation of Fluorine from Chlorine.—In neutral soluble compounds, chlorine may be separated from fluorine by precipitation with nitrate of silver. The excess of silver is then separated by hydrochloric acid, the filtrate saturated with carbonate of sodium, and the fluoride precipitated as fluoride of calcium.

Or the fluorine may be first precipitated by nitrate of calcium, and the chlorine from the filtrate by nitrate of silver. This is the easier method of the two.

To effect the separation of chlorine and fluorine in insoluble compounds, it is in most cases necessary to decompose the compound with a mixture of alkaline carbonate and silica. The fused mass is then treated with water, which dissolves the chloride and fluoride of the alkali-metal, together with the excess of the alkaline carbonate, and a small quantity of silica. The residue is washed with water containing carbonate of ammonia, and the alkaline filtrate is exactly neutralised with nitric acid to separate the dissolved silica, the liquid again filtered, and the chlorine and fluorine separated as above.

Similar methods may be used to separate fluorine from *bromine* and *iodine*.

4. *Atomic weight of Fluorine.*—Berzelius (Pogg. Ann. i. 1; Lehrb. 3^{te} Aufl. iii. 1196) determined the atomic weight of fluorine by converting known weights of fluoride of calcium into sulphate, by decomposing it with pure sulphuric acid, and igniting and weighing the product.

100 pts. of Derbyshire fluor-spar gave, when thus treated, from 173.63 to 173.86 pts. sulphate of calcium. The material used for these experiments was, however, afterwards found to contain phosphoric acid and magnesia, so that the following determinations, made with artificially prepared fluoride of calcium, may be considered more accurate. 100 pts. of the latter material gave—174.9, 175.0, and 175.1, on the average 175.0 pts. sulphate of calcium. Taking Ca = 40, S = 32, and O = 16, these results lead to the number 18.85 for the atomic weight of fluorine. Berzelius, however, considered this number as still only approximately correct.

Louyet (Ann. Ch. Pharm. lxx. 234), on repeating the determination in the same way, got nearly similar results. 100 pts. of almost colourless Derbyshire fluor-spar gave him from 173.5 to 173.6 pts. sulphate of calcium; mean 173.53 pts. Artificial fluoride of calcium gave 173.4, 173.5, and 173.7 pts. sulphate of calcium. The mean of these analyses gives 19.2 as the atomic weight of fluorine.

Louyet observed, however, that the complete decomposition of fluor-spar by sulphuric acid, took place only with great difficulty. Finally, he succeeded in effecting it by pulverising the fluor-spar very finely, treating it in the cold with concentrated sulphuric acid, heating the mixture when the spar was entirely dissolved, and then strongly igniting the residue. Six experiments made in this way gave from 174.2 to 174.5 pts. sulphate from 100 pts. of fluoride of calcium. The atomic weight of fluorine hence deduced is 19.0. Experiments with artificial fluorides of calcium, barium, and lead, confirmed this result (Handwörterb. 2^{te} Aufl. ii. [1] 485). Dumas' experiments on the decomposition of native fluoride of calcium, and of the artificially prepared fluorides of potassium and sodium by sulphuric acid, also gave for fluorine the number 19 (Ann. Ch. Pharm. exiii. 20).

FLUOR-SPAR. CaF_2 . *Fluor. Fluorite. Fluoride of Calcium. Fluats of Lime. Ratoffkite. Chlorophane. Blue John. Liparite. Chaux fluorée. Fluss-spath. Muria phosphorans.*—This mineral crystallises in simple forms of the monometric system; viz. the cube, octahedron, rhombic dodecahedron, tetrakis-hexahedron 30∞ (like fig. 484, which represents 20∞), &c.; also in combinations of the cube and

Fig. 484.

Fig. 485.

Fig. 486.

Fig. 487.

octahedron (figs. 485, 486, 487); also $O \cdot \infty O$ (fig. 488); $\infty O \infty \cdot \infty O$ (fig. 489); $\infty O \infty \cdot 202$ (fig. 490); $\infty O \infty \cdot 30\infty$ (fig. 491) and $\infty O \infty \cdot 204$ (fig. 492).

Twin-crystals occur formed by the intersection of two equal cubes (fig. 493), having

a diagonal in common, and one turned round 180° from the position of the other; more frequently, however, the intersection is not quite so regular, the cubes either being of different sizes, or having their diagonals parallel, but not exactly coincident. Cleavage, octahedral perfect (*Kopp's Krystallographie*, p. 122).—Fluor-spar also occurs columnar, though rarely; often granular, coarse or fine.

Hardness = 4. Specific gravity 3.14 — 3.19, or according to Kennigott, from examination of 48 specimens, 3.1800 — 3.1889, mean 3.183.

Fluor-spar is transparent to subtranslucent, and has a glassy, sometimes splendid lustre. It is sometimes perfectly colourless and transparent, but much more frequently

Fig. 488.

Fig. 489.

Fig. 490.

Fig. 491.

Fig. 492.

Fig. 493.

coloured, exhibiting very pure and bright tints of yellow, green, blue, and red, of the most various shades. These colours do not arise from the presence of mineral pigments, for they nearly all disappear when the mineral is heated to redness. On the other hand, it is by no means probable that they are due to the presence of organic matter; they appear rather to depend upon the molecular structure of the mineral, and to be connected with its property of exhibiting phosphorescence when heated (*Handw. d. Chem.* iii. 171). Streak white. Brittle. Fracture of fine massive varieties, flat conchoidal, and splintery.

Nearly all varieties of fluor-spar, especially in the state of powder, when heated to a temperature somewhat below redness, exhibit vivid phosphorescence, the light emitted being of various colours, and independent of the external colour. This effect may be produced several times successively with the same specimen of fluor-spar, provided the temperature be not raised above a certain limit; but above this limit the mineral completely loses its phosphorescent power, and likewise becomes colourless, a coincidence

which seems to indicate that the conditions which produce the colour and the phosphorescence are the same, or at least closely related. The phosphorescent power which has been lost by exposure to a high temperature, may be partially restored by an electric discharge.

Before the blowpipe, fluor-spar decrepitates and ultimately melts to an enamel. If the flame be continued, the fluorine is partly expelled, and the specimen assumes a cauliflower-like appearance. Easily decomposed by heating with strong sulphuric acid (p. 669).

Pure fluor-spar contains 48·7 per cent. fluorine and 51·3 calcium. The mineral generally, however, contains small quantities of phosphate of calcium, and sometimes sulphate of barium. Berzelius found 0·5 per cent. phosphate of calcium in the fluor-spar of Derbyshire. Kersten, in a fluor-spar from Marienberg and Freiberg, detected a small quantity of chlorine. The blue granular or earthy variety called Ratoffkite, from Ratoffka in Russia, is mixed with clay.

Fluor-spar is a mineral of very frequent occurrence, especially in association with metalliferous veins; as with silver, copper, tin, lead, and cobalt ores. It sometimes occurs as an unessential constituent of certain rocks, especially of some varieties of granite and porphyry, and most frequently where these rocks border on others. It occurs, however, also in distinct veins, as in the neighbourhood of Freiberg and in the Harz. In the latter district, near Stolberg, there is a very extensive vein of compact fluor-spar, which has for years supplied the Mansfeld copper works with the fluoride of calcium which they require as a flux.

In the North of England, fluor-spar forms the gangue of the lead-veins which intersect the coal-formations of Northumberland, Cumberland, Durham, and Yorkshire; the Cumberland fluor, especially the green variety, often contains drops of liquid. It is abundant in Derbyshire, and also in Cornwall, where the veins intersect much older rocks. Professor Rogers has detected it in cannel coal.

Fluor-spar is also found abundantly in many parts of North America. A remarkable locality, now exhausted, was discovered on the borders of Muscalonge Lake, in Jefferson county, New York, where cubical crystals, some of them more than a foot through, and having a greenish tinge, were found in granular limestone. *Chlorophane* forms two veins in gneiss about 18 inches wide in the town of Trumbull, Connecticut, together with topaz and magnetic pyrites.

Fluor-spar is much used as a source of hydrofluoric acid (ii. 669), and as a flux in metallurgical operations, for instance, in Deville's method of preparing aluminium (i. 150).

Altered forms.—Fluor-spar is slightly soluble in water containing acid carbonate of calcium. The alkaline carbonates decompose it, producing carbonate of calcium or calespar, and a subsequent change of the calespar may produce other pseudomorphs. Fluor-spar occurs changed to quartz by substitution, also to limonite, hematite, lithomarge, psilomelane, calamine, smithsonite, and cerusite. (Dana, ii. 95.)

FLUOSILICANILIDE. A product of the decomposition of phenylamine by fluoride of silicon. (See PHENYLAMINE, DECOMPOSITIONS.)

FLUOTANTALATES.

FLUOTITANATES.

} See FLUORIDES, also SILICON, TANTALUM, and TITANIUM.

FLUX. A general term for any substance or mixture added to assist the fusion of minerals. In the large way, limestone and fluor-spar are used as fluxes. The fluxes used in assays or blowpipe experiments consist usually of alkalis, which render the earthy mixtures fusible by converting them into glass, or else glass itself in powder.

Alkaline fluxes are either the *crude flux*, the *white flux*, or the *black flux*. Crude flux is a mixture of nitre and tartar, which is put into the crucible with the mineral intended to be fused. The detonation of the nitre with the inflammable matter of the tartar is of service in some operations, though generally it is attended with inconvenience, on account of the swelling of the materials, which may throw them out of the vessel, if proper care be not taken either to throw in only a little of the mixture at a time, or to provide a large vessel.

White flux is formed by projecting equal parts of a mixture of nitre and tartar, by moderate portions at a time, into an ignited crucible. The mass thus obtained is white, because, in this proportion, the oxygen of the nitre is more than sufficient for the combustion of the carbon in the tartar; but for that very reason the residue contains a considerable quantity of nitrite of potassium, and likewise some nitrate.

Black flux differs from the preceding in the proportion of its ingredients. In this, the weight of the tartar is double that of the nitre; on which account the combustion is incomplete, and a considerable portion of the tartaric acid is decomposed by the mere heat, and leaves a quantity of coal behind, on which the black colour depends.

It is used where metallic ores are intended to be reduced, and effects this purpose by combining with the oxygen of the oxide.

Morveau's reducing flux is made of eight parts of pulverised glass, one of calcined borax, and half a part of charcoal powder. Care must be taken to use a glass which contains no lead. The white glasses contain in general a large proportion, and the green bottle glasses are not entirely free from it.

Cyanide of potassium is much used as a fusing and reducing agent; when ignited with metallic oxides, it is converted into cyanate of potassium, reducing some oxides, as oxide of lead, to the metallic state; others, as peroxide of manganese, to a lower degree of oxidation (see BLOWPIPE).

FLY-POWDER. This term is applied to various preparations of arsenic, used for poisoning flies. (See *Ure's Dictionary of Arts, &c.*, ii. 280.)

FODDER. The following analyses of the ash of various fodder-plants have been made by Way and Ogston (*Roy. Agr. Soc. J.* xi. [2] 536; *Jahresber. f. Chem.* 1850, No. 76—84 of Table B, p. 661).

Composition and nutritive value of Fodder (Völeker, *Highland Agric. Soc. J.* July, 1853, p. 36.—Way, *Roy. Agr. Soc. J.* 1853, p. 561; *Jahresber.* 1853, p. 759).

The acid salt is the more advantageous of the two for the preparation of naphthylformamide, as it yields this product in larger proportion. It melts at about 200°C . giving off carbonic oxide and carbonic anhydride, together with a large quantity of water, and leaves a residue amounting to two-thirds of the salt, which solidifies in a radio-crystalline mass on cooling. Hot alcohol dissolves out the naphthylformamide, leaving the dinaphthylloxamide, and on cooling deposits it in long white needles. The compound is very soluble in water, turns red when exposed to damp air, melts at 102°C . and distils without decomposition. By the action of *acids* or *alkalis* at the boiling heat, it is easily resolved into naphthylamine and formic acid.

Phenylformamide. Formanilide. $\text{C}^6\text{H}^5\text{NO} = \text{N} \left\{ \begin{array}{l} \text{CHO} \\ \text{C}^6\text{H}^5 \\ \text{H} \end{array} \right\}$ (Gerhardt, J. Pharm.

[3] ix. 409; *Traité*, i. 237).—Prepared by heating oxalate of phenylamine, the decomposition being precisely analogous to that of oxalate of naphthylamine. The residue is exhausted with cold alcohol; the solution heated till the greater part of the alcohol is driven off, then boiled with water, and the solution filtered to separate a small quantity of red or brown matter. The filtrate, if further evaporated by heat, deposits the phenyl-formamide in oily drops which do not solidify; but if the heating be discontinued as soon as the oily drops begin to separate, and the solution then left to evaporate spontaneously, the amide is gradually deposited in very flattened, acuminate rectangular prisms, usually very long and interlaced.

Phenylformamide is moderately soluble in cold, more freely in hot water, still more in alcohol; the aqueous solution is slightly bitter and neutral to test paper. In the dry state it melts at 46°C ., and may then be cooled several degrees below this temperature without solidifying, but if agitated with a glass rod, it solidifies immediately. Under water it melts more easily and remains liquid after cooling. It likewise retains its fluidity after being distilled. It begins to give off vapours, even at the heat of the water-bath. *Acids* and *alkalis* decompose it slowly in the cold, more quickly at the boiling heat, into formic acid and phenylamine. When heated with strong *sulphuric acid*, it gives off carbonic oxide without blackening, and is converted into phenyl-sulphuric acid.

FORMANILIDE. See the last article.

FORMENE, TRINITRATED. Syn. with NITROFORM (*q. v.*)

FORMIC ACID. $\text{CH}^2\text{O}^2 = \begin{array}{l} \text{CHO} \\ \text{H} \end{array} \text{O}$. *Acidum formicum. Ameisensäure* (Gm. vii. 268; Gerh. i. 255; Handw. d. Chem. 2 Aufl. i. 668.)—This acid, which the first term of the adipic series $\text{C}^2\text{H}^2\text{O}^2$, derives its name from the ant (*formica* from which it was first obtained. The acid nature of these insects has long been known. Samuel Fischer first subjected them to distillation, and obtained an acid liquid; Marggraf, Arvidson and Oehrn, Hermbstädt, and Richter examined the acid more minutely. Fourcroy and Vauquelin pronounced it to be a mixture of acetic and malic acids, a statement which was afterwards completely refuted by Süersen and Gehlen. Berzelius, Göbel, Döbereiner, Liebig, and Pelouze examined the most important relations of formic acid. Its formation from inorganic materials was first effected by Bertholot.

Occurrence.—1. *In the animal kingdom.* In ants, especially the red ant (*Formica rufa*), these insects projecting it from their bodies as a defence against their enemies. According to Fr. Will (Jahresber. f. Chem. 1847–8, p. 546), the corrosive substance in caterpillars, especially in *Bombyx processionea*, likewise consists of formic acid. It exists in the free concentrated state in all parts of the caterpillar, but especially in its faeces, in the yellowish green juice which exudes on making an incision into the sect, and lastly, in the hollow, very brittle hairs. The acid occurs also in several secretions of the human body, viz. in the blood, in the urine (Campbell, Chem. Gaz. 1863, p. 310), in the fluid of the spleen, in the flesh juice (Scheerer, Ann.

Pharm. lxi. 196), and in the perspiration (Schottin, Jahresber. f. Chem. 1852, p. 704). Small quantities of it have been found in guano (Lucius, Ann. Ch. Pharm. ciii. 105).

2. *In the vegetable kingdom*, partly perhaps as a product of decomposition. It is found in commercial oil of turpentine, whence it may be extracted by agitation with water (Wiggers, Ann. Ch. Pharm. xxxiv. 235); being doubtless formed by oxidation in the air; it imparts an acid reaction to the oil, and passes over as an aqueous acid when the oil is distilled with water (Weppen, Ann. Ch. Pharm. xli. 294). When oil of turpentine is kept in leaden vessels, crystals of formate of lead are sometimes produced (Laurent, J. pr. Chem. xxvii. 316). Fr. Müller (Arch. Pharm. [2] 149) states, though not positively, that formic acid is sometimes produced in a similar manner from oil of lemons. It occurs in the needles of *Pinus Abies*, somewhat more abundantly in those which fall off, than in those which are dried while fresh and green (Aschoff, N. Br. Arch. xl. 274), being probably formed therein by oxidation of oil of turpentine. In pine-needles, which had been used for litter, and had stood for several months made up into a heap and exposed to the air, the acid was formed so abundantly that on opening the heap a very sour smell of ants was emitted (Redtenbacher, Ann. Ch. Pharm. xlvii. 148). The juice of houseleek (*Sempervivum tectorum*), when distilled, yields an acid which reduces the noble metals like formic acid, but forms with mercurous nitrate a white precipitate, from which the metal is not reduced till the mixture is heated (Döbereiner, Schw. J. lxiii. 368). According to Gorup-Besanez (Ann. Ch. Pharm. lxi. 369), the fruit of the soap-tree (*Sapindus saponaria*) distilled with water and sulphuric acid yields a distillate containing formic and butyric acids. Tamarinds similarly treated yield formic and acetic acids, and emit an odour of butyric acid. Gorup-Besanez considers it not improbable that these acids may be formed by oxidation from the tartaric acid originally contained in the fruits. Formic acid is also found in the juice of the stinging nettle. (Gorup-Besanez, Ann. Ch. Pharm. lxii. 267.)

3. *In mineral waters*.—In the water of Prinzhofen, near Straubing (Pettenkofer, Kastn. Arch. vii. 104); in that of Brückenau, together with acetic, propionic, and butyric acids, the formic acid constituting 85 per cent. of the entire amount of volatile fatty acids (Scheerer, Ann. Ch. Pharm. xcix. 257), and in the deposit from the waters of Marienbad. (Lehmann.)

Formation.—a. *From Inorganic materials*.—1. By the action of carbonic oxide at a high temperature on moist hydrate of potassium, the bodies simply uniting and yielding formate of potassium (Berthelot, Ann. Ch. Pharm. xcvii. 125):

The absorption of the gas and production of formic acid take place more quickly when a considerable quantity of water is present, than when the potash is merely moistened; alcohol and wood-spirit accelerate it still further, and ether most of all; glycerin, on account of its viscosity, has but little effect, and acetic ether none at all; in short, the effect of any liquid in accelerating the action appears to be proportional to its power of dissolving the carbonic oxide. Similar results are obtained when caustic soda, baryta, or lime is used in place of potash. (Berthelot, Ann. Ch. Phys. [3] lxi. 463.)

2. Potassium spread on the inner surface of a vessel filled with carbonic anhydride, and standing over lukewarm water, is converted in 24 hours into a mixture of formate and acid carbonate of potassium (Kolbe and R. Schmidt, Ann. Ch. Pharm. cxix. 251):

b. *From Organic materials*, chiefly by oxidation, formic acid being, with the exception of oxalic acid and carbonic anhydride, the most highly oxidised of all carbon-compounds.

1. In the oxidation of wood-spirit by the air in presence of platinum, or by nitric acid (Dumas and Peligot).—2. By heating wood-spirit with a mixture of lime and hydrate of potassium (Dumas and Stas).—3. In the decomposition of chloroform, bromoform, or iodoform, by potash.—4. In the decomposition of hydrocyanic acid by potash, or by the stronger mineral acids (Pelouze, Ann. Ch. Phys. xlviii. 395; Geiger, Ann. Ch. Pharm. i. 44).—5. In the decomposition of oxalic acid by heat (Gay-Lussac, Ann. Ch. Phys. xli. 218). When the oxalic acid is heated alone, the quantity of formic acid obtained is very small, but it is greatly increased by distilling oxalic acid with glycerin or mannite (Berthelot, p. 684).—6. By the combustion of alcohol or ether in the glow lamp (A. Connell, Phil. Mag. [3] xi. 512).—7. In the preparation of iodoform from alcohol, iodine, and potassium (Bouchardat).—8. By the action of the air on an alcoholic solution of potash (A. Connell, N. Ed. Phil. J. xiv. 231).—9. By heating alcohol with nitric acid (Gaultier de Claubry, J. Pharm. xxv. 764; Dalpiaz, J. Pharm. [3] v. 239).—10. In the decomposition of

chloral or bromal by aqueous potash (Liebig).—11. By boiling chloracetic acid with excess of potash (Dumas).—12. By heating gelatin with aqueous chromic acid (Schlieper, *Ann. Ch. Pharm.* lix. 1).—13. By exposing oil of turpentine to the air, or heating it with aqueous chromic acid (Weppen, *Ann. Ch. Pharm.* xli. 294).—14. By distilling aqueous tartaric acid with peroxide of manganese (Döbereiner, *Gilb. Ann.* lxxi. 107).—15. By distilling the following substances with peroxide of manganese and dilute sulphuric acid: tartaric acid or cane-sugar (Döbereiner, *Ann. Ch. Pharm.* iii. 144); starch (Wohler, *Pogg. Ann.* xv. 307); mucic acid, milk-sugar, starch, woody fibre, marsh-mallow root, fibrin (C. G. Gmelin, *ibid.* xvi. 55); alcohol (C. G. Gmelin; Connell, *N. Ed. Phil. J.* xiv. 240; L. Gmelin, *Pogg. Ann.* xxviii. 508); suberic acid (Brandes, *N. Br. Arch.* xxi. 319); glucose, which likewise yields formic acid when treated with sulphuric acid and chromic acid or ferric oxide (Hünefeld, *J. pr. Chem.* vii. 44);—albumin, fibrin, casein, and gelatin, which likewise yield formic acid with acid chromate of potassium and sulphuric acid; in both cases the formic acid is accompanied by other acids of the series $C^mH^nO^2$, and a variety of other products (Guckelberger, *Ann. Ch. Pharm.* lxiv. 39; *Jahresber.* 1847–8, pp. 847–854). When some of these compounds—starch, for example—are thus treated, there is given off, together with the formic acid, a strong smelling volatile oil (furfural), which, if the distillate be saturated with a fixed alkali, imparts a yellow colour to the liquid, but passes off, or is decomposed when the solution is evaporated. In this impure distillate, and in another obtained from starch, oxide of manganese, and hydrochloric acid. Tünnermann (*Pogg. Ann.* xv. 307) thought that he had discovered two peculiar acids, to which he gave the names of *pyrogenic* and *amylenic* acids. When alcohol is treated with sulphuric acid and oxide of manganese, no oil like furfural passes over, but a large quantity of acetic acid.—16. Sugar, starch, gum, woody fibre, cereal grains, and other organic substances, yield much more formic acid when distilled with strong sulphuric acid, or a mixture of that substance with an equal bulk of water, than when treated with sulphuric acid and peroxide of manganese: for the latter converts a considerable quantity of the formic acid into carbonic acid and water. Before carbonisation, a volatile oil passes over; but as soon as carbonisation takes place, the distillate consists of colourless formic acid. Phosphoric acid, stannic chloride, and other dehydrating substances, act like sulphuric acid (Emmet, *Sill. Am. J.* xxxii. 140; also *J. pr. Chem.* xii. 120). These statements have been verified by Erdmann (*J. pr. Chem.* xii. 124) and Stenhouse (*Phil. Mag.* [3] xviii. 122; also *Ann. Ch. Pharm.* xxxv. 301).—17. A solution of tartaric acid containing a little sulphuric acid heated with permanganate of potassium yields formic and carbonic acids, $C^mH^nO^6 + O^2 = 2CH^mO^2 + 2C^mO^2 + H^2O$; but if the solution is neutralised by an alkali, the whole of the formic acid is oxidised to carbonic acid (Péan de St. Gilles, *Ann. Ch. Phys.* [3] lv. 374).—18. When linseed-oil is heated with sulphuric acid, a large quantity of formic acid passes over, together with sulphurous acid (Sacc, *Ann. Ch. Pharm.* li. 214).—19. Sugar, starch, cotton, &c., treated with chloride of lime containing free lime, yield formate of calcium; if no free lime be present, carbonic acid is produced instead of formic acid: or a solution of sugar the action is very violent. Chloride of lime containing free lime forms, with a solution of gelatin, formate of calcium and ammonia (Bastick, *Pharm. J. Trans.* vii. 467; *Jahresber. f. Chem.* 1847–8, 381).—20. By treating crude oil of asafetida with caustic soda, acetic acid being likewise formed, and sulphuretted hydrogen given off. The gummy portion of asafetida, when subjected to dry distillation, yields formic acid, with a small quantity of acetic acid.—21. Oil of mustard and oil of garlic treated with nitric acid yield formic acid, together with oxalic (Hlasiwetz, *J. pr. Chem.* li. 355).—22. An aqueous solution of acetone containing sulphuric acid yields, by electrolysis, acetic and formic acids, together with oxygen, hydrogen, and carbonic anhydride. The formic acid is, perhaps, produced by the oxidation of the methyl contained in the acetone (i. 26). (Friedel, *Ann. Ch. Pharm.* cxii. 376.)

Formic acid has been found among the products of the destructive distillation of peat (Sullivan, *Atlantis*, i. 185; *Jahresber. f. Chem.* 1858, p. 280).

By distilling aloes with very dilute sulphuric acid, Ed. Simon (*N. Br. Arch.* xxix. 186) obtained a distillate which reduced silver-salts like formic acid; but yielded crystals with oxide of lead different from those of formate of lead. In the weathering of brown coal containing iron pyrites, a strong odour of formic acid is often evolved (Anthon, *Repert.* lxxxviii. 105). When 4 at. of iron-filings are distilled with $\frac{1}{2}$ at. tartaric acid ($C^4H^6O^6$), the water in the receiver acquires an odour of ants, and the property of reducing metallic oxides (Artus, *J. pr. Chem.* xii. 251). According to Göbel (*N. Tr.* x. 1, 34), formic acid is produced in the dry distillation of argol. This, however, has not been satisfactorily proved.

Klinger (*Ann. Ch. Pharm.* cvi. 13) found small quantities of formic and propionic acids, together with large quantities of acetic and butyric acids, in the products of the fermentation of diabetic urine; other observers, however, have found only acetic and butyric acids (*Jahresber.* 1858, p. 571.)

According to Genther (*Ann. Ch. Pharm.* cix. 73) and Lieben (*ibid.* cxii. 326), formic acid is produced by the action of carbonic oxide on ethylate of sodium. Lieben, however, and Wanklyn (*Phil. Mag.* [4] xviii. 391) attribute this result to the presence of hydrate of sodium in the ethylate (p. 682).

Preparation.—*a. Of the aqueous acid.*—1. *From Ants.*—Red ants previously mashed, or their expressed juices, are distilled; the distillate is saturated with potash, soda, oxide of lead, or oxide of copper; the solution evaporated, whereupon the volatile oil of ants passes off together with the water; and the residue, or the formate purified by recrystallisation, is distilled with dilute sulphuric acid.

The very dilute acid thus obtained is saturated with carbonate of potassium (Richter, Süersen), sodium (Lowitz, Gehlen), or copper (Gehlen); and the dried residue, or, when oxide of copper is used, the crystals purified by repeated crystallisation are distilled with oil of vitriol (Richter, Gehlen), or with a mixture of 1 pt. oil of vitriol and $\frac{1}{2}$ water (Süersen), or with pulverised acid sulphate of potassium (Lowitz). If the quantity of water present is too small, a large proportion of the formic acid is decomposed; hence strong sulphuric acid cannot be used for the distillation. Any sulphurous acid that may be present is removed by continued digestion with red lead; also hydrochloric acid (proceeding from the carbonate of potassium) by red lead, or better by oxide of silver. (Göbel.)

The residue left in the preparation of oil of ants (a pharmaceutical product obtained by distilling 2 pts. of red ants with 4 pts. rectified spirit of 60 per cent., and an equal quantity of water) contains a considerable quantity of formic acid, and may be used for its preparation. The residue is pressed; the expressed liquid left to itself for a while; the fatty oil which collects on the surface removed; the subjacent liquid neutralised with an alkali, filtered and evaporated; and the residual salt mixed with half its weight of strong sulphuric acid diluted with an equal quantity of water, and distilled till the liquid begins to pass over turbid. This first distillate consists of tolerably pure formic acid. The turbid liquid which follows still contains formic acid; it may be neutralised with carbonate of barium, and used for the preparation of pure barytic formate. (Handw. 2^e Aufl. i. 688.)

2. *From Tartaric acid.*—10 pts. of tartaric acid are mixed with 14 pts. of oxide of manganese and from 30 to 45 pts. of water, and distilled in a capacious retort. (Döbereiner.)

3. *From Sugar or Starch with Peroxide of Manganese and Sulphuric acid.*—A solution of 1 pt. sugar in 2 pts. water is heated to 60° C., with 2½ or 3 pts. of finely pounded manganese in a copper still, which, as the liquid is very apt to froth up, must have at least 15 times the bulk of the mixture; a third part of a mixture of 3 pts. oil of vitriol and 3 pts. water is then gradually added, whereupon carbonic acid gas loaded with vapour of formic acid immediately escapes with violence. The head and condensing tube must now be quickly put on, and when the violent action has subsided, the other two-thirds of the dilute sulphuric acid added, the mixture being stirred all the while; after which the liquid is gradually distilled almost to dryness. The distillate, which is transparent and colourless, and still contains volatile oil (furfural), is saturated with chalk (the distillate from 100 pts. of sugar saturates from 31 to 38 pts. of chalk); and the filtrate evaporated to the crystallising point; or, if it be desired to obtain the acid, the distillate is saturated with carbonate of sodium, evaporated, and 7 pts. of the dry residue distilled with a mixture of 70 pts. oil of vitriol and 4 pts. water (Döbereiner, *Ann. Ch. Pharm.* iii. 144). This process is a very good one; but the formic acid which it yields is slightly contaminated with acetic acid. To remove this impurity, the distillate should be saturated, while yet warm, not with carbonate of sodium, but with carbonate of lead, and the solution evaporated to the crystallising point; the more soluble acetate of lead remains principally in the mother-liquor; and the formate of lead thus obtained must be distilled with a mixture of equal parts of oil of vitriol and water.

4. 1 pt. of starch is mixed with 4 pts. of finely pounded manganese and 4 pts. of water in a copper still; 4 pts. of oil of vitriol added by small portions, and with constant stirring; the vessel heated by a slow fire till the contents begin to froth up; the head and condensing tube then put on, and the distillation continued till 4½ pts. of the liquid have passed over. This liquid has a density of 1.025 at 10° C., and saturates 10.6 per cent. of dry carbonate of sodium. If the distillation is performed in a retort instead of a still, it is necessary, in order to prevent frothing over, to take only 3.7 pts. of manganese, 3 water, and 3 oil of vitriol to 1 pt. of starch; the retort must have 10 times the bulk of the mixture. The product thus obtained amounts to 3.35 pts. of a distillate of specific gravity 1.042, which neutralises 15 per cent. of dry carbonate of sodium. The distillate obtained either from the retort or from the still is clouded by a white substance; and if the distillation has been carried too far, the liquid also contains sulphurous acid. It must therefore be neutralised with carbonate of calcium: milk of lime added in excess to convert the soluble acid sulphite of calcium into

the neutral insoluble sulphite; the filtrate evaporated to dryness; and 10 pts. of the resulting formate of calcium distilled, either with 8 pts. oil of vitriol and 4 water, whereby 9 pts. of formic acid are obtained, having a density of 1.075, or with 8 pts. oil of vitriol and $1\frac{1}{2}$ water, by which a highly concentrated acid is obtained. The strongest acid that can be prepared in this manner is obtained by distilling 18 pts. of finely pounded formate of lead with 6 pts. oil of vitriol and 1 pt. water in a chloride of calcium bath. The distillate has a density of 1.110 at 10° (Liebig). Cloez ([3] J. Pharm. iv. 306) mixes 500 grm. of starch with 2000 grm. of manganese; places the mixture in a still having a capacity of 25 or 30 litres; adds 1 litre of water, then a mixture of 2 kilogrammes of oil of vitriol with 2 litres of water, stirring the mixture well; and distills, adding hot water in proportion as the liquid passes over: from 12 to 15 litres of a strongly acid liquid may be thus obtained over, containing about 412 grammes of formic acid (CH_2O^2).

4. *From Sugar, Starch, or Woody fibre, with Sulphuric acid.*—One measure of oil of vitriol, 1 measure of water, and 1 measure of rye, wheat, oats, or coarsely bruised maize, are heated together in a glass retort till the liquid boils; one measure of water is added as soon as the mass becomes thoroughly black; the liquid distilled till one measure of distillate has passed over; another measure of water added to the residue; and the distillation repeated with a fresh receiver. The first distillate consists of strong formic acid, generally free from sulphurous acid; the second is very dilute and often contains sulphurous acid; this impurity may be removed by agitating the cold liquid for a short time with peroxide of lead. The organic matter used in this process, being of a granular nature, does not swell up so much: hence the vessels used need not be so large as those required in the preceding processes (Emmet, Sill. Am. J. xxxii. 143). Carbonisation takes place before boiling, so that there is no occasion to wait till the liquid boils. The addition of water causes the hot mass to froth over: hence it is necessary to let the mixture cool before adding fresh water. In all cases frothing and boiling over are very likely to be produced by a slight rise of temperature: hence the retort should hold at least five times as much as the volume of the mixture. The distillate is free from acetic acid, but contains furfural, which may be removed by ether (Erdmann, J. pr. Chem. xii. 124). Stenhouse (Phil. Mag. [3] xviii. 122) proceeds in the same manner as Emmet for the preparation of furfural and formic acid, excepting that he uses wheat-flour, saw-dust, or chaff, instead of grain.

5. *From Oxalic acid.*—An intimate mixture of oxalic acid and very fine sand is distilled in a glass retort, and the distillate freed from oxalic acid by frequent rectification. This process yields very pure formic acid in a highly concentrated state. (Gerhardt, Ann. Ch. Phys. [3] vii. 130.)

A much larger product may be obtained by distilling the oxalic acid with glycerin. Oxalic acid, $\text{C}^2\text{H}^2\text{O}^4$ contains the elements of carbonic anhydride, CO^2 , and formic acid, CH^2O^2 , and is actually resolved into these compounds by heat; but when it is heated alone, or even with sand, the temperature rises so high that the greater part of the formic acid is further resolved into carbonic oxide, CO , and water H^2O ; but the addition of glycerin, which takes no part in the decomposition, enables it to take place at a lower temperature, and the whole of the formic acid is then obtained. When equal weights of commercial oxalic acid and syrupy glycerin (a kilogramme of each) and from 100 to 200 grammes of water, are gently heated (scarcely above 100°C .) in a capacious retort, a brisk evolution of carbonic anhydride soon begins, and after 12 to 16 hours the whole of the oxalic acid is decomposed without any evolution of carbonic oxide. A small quantity of the resulting formic acid distils over with the water; but the larger portion remains in the retort together with the glycerin, and may be separated by distilling the residue with half a litre of water, renewing the water as it distils, till 6 or 7 litres of liquid have passed over. The glycerin which remains may be used for the conversion of fresh quantities of oxalic acid. The decomposition must be conducted slowly, as, if too much heat is applied, the temperature rises to between 190° and 200° , and carbonic oxide is evolved. (Berthelot, Ann. Ch. Phys. [3] xvi. 477.) This is the best of all methods of preparing formic acid.

6. *Preparation of the pure concentrated acid, CH_2O^2 .*—1. Pulverised formate of lead dried by heat is introduced into a long glass tube, from 4 to 6 lines in width, on end of which is drawn out into a narrow neck, turned downwards and inserted into a small receiver; sulphuretted hydrogen dried by chloride of calcium is passed into the tube at the other end, till the lead-salt is completely decomposed; a gentle heat applied to drive the formic acid into the receiver; and the acid repeatedly boiled to free it from sulphuretted hydrogen. If the tube be too strongly heated, the acid becomes contaminated with decomposition-products containing sulphur (Liebig). Bineau (Compt. rend. xix. 769) passes dry carbonic anhydride through the distillate to drive off the sulphuretted hydrogen, and rectifies it, rejecting the first portion, which still smells of sulphuretted hydrogen.

2. By mixing 8 at. of a dry formate, the barium-salt for example, with 8 at. water

gradually adding 3 at. chloride of sulphur, Cl_2S , distilling between 110° and 122° C., and rectifying the distillate over a small quantity of formate of lead :

(Heintz, Pogg. Ann. xlviii. 468.)

Properties.—The most concentrated acid solidifies at -1° C. in shining laminae, which melt at $+1^\circ$. At ordinary temperatures it forms a thin, transparent, and colourless liquid, of specific gravity 1.2353, which boils at 98.6° (bar. $27''$ 10'') (Liebig).—According to Kopp (Jahresber. 1847–8, p. 68), the specific gravity is 1.2227 at 0° , and the boiling point 105.3 (bar. 760 mm.); according to Person (Jahresber. 1847–8, p. 91), the acid boils at 100° ; according to Roscoe (Chem. Soc. J. xv. 271), at 101.1° under a pressure of 758 mm. of mercury. The vapour-density, between the temperatures 111° and 118° , varies from 2.125 to 2.14 (Bineau, Compt. rend. xix. 769; also Pogg. lxx. 424; Compt. rend. xxiii. 416). The strongest acid fumes slightly in the air, has a pungent sour taste, and is so corrosive that a single drop placed upon a soft part of the skin produces intolerable pain, causing the part to swell and turn white, afterwards drawing the skin together and producing a painful ulcer (Liebig). The dilute acid has a peculiar pungent and sour smell, and a purely acid taste.

Formic acid mixes with water in all proportions, with diminution of specific gravity and without rise of temperature. According to Liebig, an aqueous acid containing 1 at. water ($\text{CH}^2\text{O}^2.\text{H}^2\text{O}$), and boiling at the fixed temperature of 106° C., is obtained by distilling 18 pts. formate of lead with 6 pts. oil of vitriol and 1 pt. water. According to Roscoe (Chem. Soc. J. xv. 271), formic acid (like all other acids) possesses no hydrate of constant boiling point at all pressures; but any number of mixtures of formic acid and water can be made, each of which, when distilled under a given pressure, will undergo no change in composition, and therefore will boil at a fixed point, but will undergo decomposition when boiled under any other pressure. Under the ordinary atmospheric pressure (760 mm.), a liquid containing 77.5 pts. acid to 22.5 pts. water undergoes no change by distillation, boiling at the temperature of 107.1° C.; and all mixtures containing more acid or more water than this quantity, when distilled under the above conditions, ultimately attain this same fixed boiling point and constant composition. When distilled under a higher pressure, however, this aqueous acid undergoes a change of composition. Under a pressure of 1.83 met. of mercury, the residual liquid attains a composition of 83.2 per cent. real acid and boils unchanged at 134.6° C. Under a pressure of 1.35 met. of mercury, the aqueous acid boils constantly at 124.1° C., and attains the strength corresponding to 80 per cent. of real acid.

Formic acid dissolves in all proportions in alcohol, being partly converted into formate of ethyl.

Decompositions.—1. The vapour of the boiling concentrated acid may be set on fire in the air, and burns with a dull blue flame (Liebig). Platinum-black, repeatedly moistened in the air with aqueous formic acid, causes slow combustion of the acid, accompanied by evolution of heat and a hissing noise, the products of the combustion being carbonic acid and water. If the platinum-black has been previously charged with oxygen by exposure to the air, it will oxidise small quantities of the acid, even out of contact of air. Spongy platinum, slightly moistened in the air with formic acid containing not more than $1\frac{1}{2}$ at. water, becomes almost instantly red-hot, producing water and carbonic acid (Döbereiner). 2. Chlorine decomposes the acid and its salts completely, converting them after a while into carbonic and hydrochloric acids. (Cloeze, Ann. Ch. Phys. [3] xvii. 297):

3. Nitric acid decomposes formic acid. (Arfvedson.)

4. Aqueous iodic or periodic acid acts violently on formic acid at a boiling heat, evolving carbonic anhydride and iodine (Benckiser, Ann. Ch. Pharm. xvii. 258). At a temperature near 100° C. aqueous iodic acid completely converts formic acid, in the course of twenty minutes, into water and carbonic anhydride; but a trace of hydrocyanic acid prevents the decomposition, even at a boiling heat. (Millon, Compt. rend. xix. 271.)

5. Strong sulphuric acid, at a gentle heat, decomposes formic acid and its salts, converting them into water and carbonic oxide, with strong effervescence, but without blackening: $\text{CH}^2\text{O}^2 = \text{H}^2\text{O} + \text{CO}$. (Döbereiner.)

6. Formic acid reduces the oxides of the noble metals, yielding water and carbonic anhydride. It reduces mercuric oxide with effervescence when heated. From mercurous or mercuric nitrate, it throws down metallic mercury at a boiling heat; boiled with a solution of mercuric chloride, it throws down calomel (Göbel, Döbereiner). A hot aqueous solution of mercuric chloride mixed with formate of

potassium or sodium, and kept for two or three hours — at temperature between 70° and 80° C., deposits all the mercury in the form of calomel; but if kept constantly at a boiling heat, it yields the mercury in the metallic state (Bonsdorff, Pogg. Ann. xxxiii. 73). This reducing action is, however, prevented by the presence of chloride of potassium, sodium, or ammonium, and even by adding acetic acid to the solution of mercuric chloride (H. Rose, Pogg. Ann. cvi. 500). Silver-oxide and those of its salts which are soluble in water are reduced by formic acid with the aid of heat; the salts are more quickly reduced by formate of sodium (Göbel, Döbereiner). Solutions of gold, platinum, and palladium are not reduced by continued boiling with free formic acid, because the acid gradually volatilises; but they are completely reduced by formate of sodium, which in some cases throws down spangles, in others, as with platinum, precipitates a black possessing great power of inducing combustion (Göbel). The aqueous acid converts platinous oxide and platinate of sodium into platinum-black, with brisk evolution of carbonic acid (Döbereiner, Pogg. xxviii. 180; Schw. lvi. 289). At a boiling heat, it reduces protochloride of platinum to the metallic state. (Berzelius, Pogg. xxxvi. 8.)

7. Peroxides with dilute sulphuric acid convert formic acid into carbonic anhydride and water. (Liebig.)

8. Formate of potassium, moderately heated with excess of hydrate of potassium, gives off hydrogen, and is converted into oxalate, $2\text{CHKO}^2 = \text{C}^2\text{K}^2\text{O}^4 + \text{H}^2$. (Pelliot, Ann. Ch. Phys. lxxiii. 220; Dumas and Stas, *ibid.* lxxiii. 123.)

Formates.—The affinity of formic acid for bases is, according to Arfvedson, greater than that of acetic acid. It is monobasic, the formulae of its salts being CHMO^2 and $\text{C}^2\text{H}^2\text{M}^2\text{O}^4$. There are, however, a few double and acid formates produced by the union of two metallic formates or of a metallic formate with formic acid, analogous in fact to the double chlorides, acid acetate of potassium, &c., not to the double salts of dibasic acids. They are obtained by dissolving the bases or their carbonates in the aqueous acid, and evaporating. The formates of the fixed alkali-metals ignited out of contact of air, leave alkaline carbonates slightly blackened by charcoal, a combustible gas, probably carbonic oxide and hydrogen, being also evolved:

Formate of barium yields the products just mentioned, together with gaseous hydrocarbons, viz. marsh-gas, ethylene, and tritylene. (Berthelot, Ann. Ch. Phys. [3] liii. 69; Jahresber. f. Chem. 1858, p. 216.)

The formates of uranium, bismuth, zinc, cadmium, lead, cobalt, nickel, and copper, when heated to redness, leave a regulus of metal, which at a stronger heat assumes the metallic lustre (Göbel). In these decompositions, water, carbonic anhydride, and carbonic oxide are doubtless evolved:

Sulphuric acid heated with the formates decomposes them, forming a sulphate, water, and carbonic oxide gas, which escapes:

Platinum-black, moistened with the solution of an alkaline formate, converts it into carbonate (Döbereiner, Ann. Ch. Pharm. xiv. 14). The aqueous solutions of formates, heated with solutions of the noble metals, e.g. mercury and silver, in acids, reduce the metals, with evolution of carbonic anhydride.

All formates are soluble in water: their aqueous solutions form dark red mixtures with ferric salts.

Formate of Aluminium may be obtained by precipitating formate of barium with sulphate of aluminium in equivalent proportion, and evaporating the filtrate. It crystallises with difficulty (Liebig). It tastes sweet and rough; reddens litmus slightly; becomes moist in the air; forms a clear solution in cold water; dissolves likewise in hot water, but with instant precipitation of all the alumina (Göbel). The solution of the pure salt does not become turbid when heated; but if sulphate of potassium is present, it forms a precipitate which redissolves as the liquid cools. (Liebig.)

Formate of Ammonium, $\text{CH}(\text{NH}^4)\text{O}^2$, forms monoclinic crystals, exhibiting the combination $\infty\text{P} \cdot \infty\text{P} \cdot +\text{P} \cdot +\text{P} \cdot [\text{P} \cdot]$. Ratio of axes, $a : b : c = 0.884 : 1 : 1.280$. Angle of inclined axes = $87^\circ 28'$; $\infty\text{P} \cdot : +\text{P} \cdot = 140^\circ 38'$; $\infty\text{P} : [\text{P} \cdot] = 124^\circ 54'$. Cleavage parallel to ∞P (Grallich and Lang, Wien. Akad. Ber. xxvii. 178). It has a fresh pungent flavour, and is not poisonous (Pelouze). When suddenly heated in a retort, it is resolved into water and hydrocyanic acid (Döbereiner, Repert. xv. 425):

- When gradually heated it fuses at 120°C . without giving off water, but evolves a

small quantity of ammonia at 140° and at 180° , it is for the most part resolved into hydrocyanic acid and water, a small portion only volatilising undecomposed (Pelouze, Ann. Ch. Phys. xliii. 399; also Ann. Pharm. ii. 87). To make the decomposition complete, the salt must be heated at the closed end of a bent tube, and the vapour passed over a part of the tube kept at a stronger heat (Liebig). The aqueous solution exposed to light in a stoppered bottle for half a year deposits a large quantity of flakes and becomes alkaline (Horst, Br. Arch. iv. 257). The salt dissolves readily in water.

Formate of Amyl. See FORMIC ETHERS.

Formate of Barium, $C^2H^2Ba^2O^4$.—Crystallises in shining transparent rhombic prisms; $a : b : c = 0.7554 : 1 : 0.8842$. Inclination of ∞P : ∞P , in the macrodiagonal principal section = $75^{\circ} 35'$; of $P\infty : P\infty$ in the basal principal section = $97^{\circ} 30'$. Ordinary combination $\infty P . P\infty$ (fig. 494; Kopp's *Krystallographie*, p. 265); also with the faces $P\infty$, $2P\infty$, and $\infty P\infty$, more rarely $\infty P\infty$ (Heusser, Pogg. Ann. lxxxiii. 37). The crystals are permanent in the air, have a bitter taste, dissolve in 4 pts. of cold water, but are insoluble in alcohol and in ether. The salt decomposes when heated, emitting the odour of burnt sugar.

Fig. 494.

Formate of Bismuth.—Soluble in water; crystallises on evaporation.

Formate of Butyl.—See FORMIC ETHERS.

Formate of Cadmium, $C^2H^2Cd^2O^4 + 2H^2O$.—Crystallises in cubes and rhombic dodecahedrons (Göbel); in monoclinic prisms isomorphous with the zinc-salt (Heusser). $a : b : c = 0.7546 : 1 : 0.924$. Angle of inclined axes = $82^{\circ} 55'$; $\infty P : \infty P$ in the orthodiagonal principal section = $105^{\circ} 30'$; $\infty P : \infty P = 85^{\circ} 43'$; $+ 2P\infty$: the principal axis = $29^{\circ} 55'$. The crystals have the faces ∞P and ∞P predominant, or they form short prisms with the faces $+P$, $+2P\infty$, $-P$, and $\infty P\infty$; or they are tabular from predominance of ∞P , with $-P$ and $+2P\infty$, which latter often predominates to the obliteration of $\infty P\infty$ (Kopp's *Krystallographie*, p. 310). The salt has a sweetish, but somewhat metallic taste, and dissolves easily in water. The crystals when heated give off their water with difficulty, and undergo sudden decomposition at a higher temperature.

Formate of Cadmium and Barium, $C^2Ba^2Cd^2O^4$.—Crystallises in rhombic prisms, whose predominant faces are ∞P , $\infty P\infty$, and $P\infty$. Inclination of $\infty P : \infty P$ in the macrodiagonal principal section = $84^{\circ} 10'$; $P\infty : P\infty$ over the principal axis = $118^{\circ} 50'$. (Handl, Wien. Akad. Ber. xxxii. 252.)

Formate of Calcium, $C^2H^2Ca^2O^4$.—Obtained by spontaneous evaporation in rhombic crystals, exhibiting the faces P , $\infty P2$, $\infty P\infty$, $\infty P\infty$, $2P$. Ratio of axes $a : b : c = 0.75988 : 1 : 0.46713$. $P : P$ in the terminal edges = $136^{\circ} 36'$ and $121^{\circ} 46'$; $\infty P2 : \infty P2$ in the brachydiagonal principal section = 67° (Heusser, Pogg. Ann. lxxxiii. 37). Usually, however, it separates in crystalline crusts made up of small shining six-sided crystals. It has a sharp saline taste, dissolves in 8 to 10 pts. of cold water, scarcely more in warm water, insoluble in alcohol.

Göbel obtained a salt containing crystallisation-water, which crystallised in octahedrons and dodecahedrons, but gave up its water with efflorescence, even at common temperatures.

Formate of Cerium, $C^2H^2Ce^2O^4$.—Formed by precipitating a hot concentrated solution of cerous chloride with formate of sodium, and separates on cooling as a faintly rose-coloured granulo-crystalline powder. It is very sparingly soluble. It contains water of crystallisation, which, however, it gives off completely at 120° C. (Liebig). According to Beringer, it still retains $\frac{1}{2}$ at. water at 250° . At 200° it intumesces without melting, gives off carbonic anhydride and hydrocarbons, and is converted, without blackening, into cerous carbonate, which when more strongly heated leaves ceroso-ceric oxide. (Liebig.)

Chromic Formate is a green soluble salt.

Formate of Cobalt forms rose-red indistinct crystals, sparingly soluble in water, insoluble in alcohol; when heated, they give off water and turn blue.

Formate of Copper, $C^2H^2Cu^2O^4 + 4H^2O$.—Crystallises in monoclinic prisms or tables. $a : b : c = 0.983 : 1 : 0.766$. Angle of inclined axes = $79^{\circ} 20'$. Inclination of $\infty P : \infty P$ in the clinodiagonal principal section = 90° ; of $+P : +P$ in the same = $112^{\circ} 18'$; of $\infty P : \infty P = 82^{\circ} 30'$. Ordinary combination $\infty P . \infty P . +P$ (fig. 495;

Kopp's Krystallographie, p. 310). According to Heusser, whose measurements agree very nearly with those of Kopp, the crystals likewise exhibit the faces $-P$ and

Fig. 495.

[$\infty P\infty$], and often form twins, with the face of combination parallel to oP . Cleavage parallel to oP . The crystals are transparent and of a pale blue or greenish yellow colour. Specific gravity 1.81. Soluble with blue colour in 7 or 8 pts. water, and in 400 pts. alcohol of 80 per cent. They effloresce in warm air, and when heated give off inflammable products which burn with a green flame. The salt when subjected to dry distillation, leaves metallic copper, and gives off a mixture of carbonic oxide, carbonic anhydride, and hydrogen gases.

Formate of Copper and Hydrogen; Acid Formate of Copper, $C^2H^2Cu^2O^4.2CH^2O^2 + 3H^2O$.—Separates, together with formate of copper and strontium, from a strongly acid solution of 2 at. formate of strontium

and 1 at. formate of copper, in monoclinic crystals, which, according to Zepharovich, exhibit the combination $oP. + 2P\infty. \infty P. \infty P\infty. -P. + P$. Ratio of axes $a : b : c = 1 : 1.3238 : 1.1765$. Angle of inclined axes $= 82^\circ 31'$. Inclination of $\infty P : \infty P\infty = 127^\circ 15'$; $+P : +P = 94^\circ 18'$; $-P : -P = 100^\circ 44'$, both in the clinodiagonal terminal edge; $oP : + 2P\infty = 114^\circ 21'$. Cleavage parallel to $\infty P\infty$. (K. v. Hauer, Wien. Akad. Ber. xliii. [2] 548.)

Formates of Copper and Barium.—Heusser obtained two of these salts from mixed solutions of the simple salts, viz. bluish green crystals having the composition $C^2H^2(Ba; Cu)^2O^4 + 4H^2O$; that is to say, formate of copper in which part of the copper is isomorphously replaced by barium; and light blue crystals, whose composition he represents by the formula $C^2H^2Cu^2O^4.4H^2O + 2C^2H^2Ba^2O^4$. Both are isomorphous with neutral formate of copper.

Formate of Copper and Strontium, $(C^2H^2Cu^2O^4.4H^2O) + 2(C^2H^2Sr^2O^4.2H^2O)$.—Obtained like the cupro-barytic salt. According to Heusser, it is likewise isomorphous with neutral formate of copper; but according to Zepharovich (Wien. Akad. Ber. xliii. [2] 545), it does not even crystallise in the same system, the crystals being not mono- but tri-clinic, and exhibiting the combination $oP. \infty P\infty. \infty P\infty. \infty P'. \infty P. P\infty. \frac{1}{2}P\infty. P\infty. P\infty. P. \frac{1}{2}P$. Ratio of brachydiagonal a , macrodiagonal b , and principal axis $c = 0.7436 : 1 : 1.0103$. Angle $b : c$ in the left upper octant $= 104^\circ 43'$; $a : c = 96^\circ 52'$; $a : b = 88^\circ 18'$. Inclination of $oP : \infty P\infty = 104^\circ 38'$; $oP : \infty P\infty = 95^\circ 37'$; $\infty P\infty : \infty P\infty = 89^\circ 47'$; $\infty P\infty : \infty P = 142^\circ 31'$; $\infty P\infty : P\infty = 127^\circ 59'$. Cleavage perfect parallel to $\infty P\infty$; less perfect parallel to $\infty P\infty$.

Formate of Ethyl.—See FORMIC ETHERS.

Formates of Iron.—The ferrous salt is obtained by dissolving ferrous hydrate in formic acid, or more easily by decomposing the barium-salt with ferrous sulphate. The colourless solution when evaporated in an open vessel deposits a basic ferric salt.

Neutral ferric formate, $C^2H^2(Fe^2)^2O^{12}$, is obtained by digesting moist ferric hydrate for several days in aqueous formic acid, evaporating the red-brown acid solution at about $70^\circ C$, and drying the residue at 40° . It is a light, loosely coherent powder, of the colour of levigated litharge, easily soluble in water, having an astringent taste, and acid reaction; it does not reduce nitrate of silver even at the boiling heat. (Ludwig, Arch. Pharm. [2] cvii. 1.)

Döbereiner obtained a basic ferric formate, probably $6Fe^2O^3.C^2H^2(Fe^2)^2O^4$, by boiling the solution of a ferrous salt with formate of sodium.

Formate of Lead, $C^2H^2Pb^2O^4$, forms anhydrous shining rhombic crystals isomorphous with the barium-salt (Heusser), having a sweet, metallic, astringent taste, like that of the acetate, soluble in 36 to 40 pts. of water, but insoluble in alcohol; this last character affords a means of separating formate of lead from the acetate. Specific gravity 4.56 (Böttger and Giesecke, Jahresber. f. Chem. 1860, p. 17). It decomposes when heated, giving off a watery liquid having a disagreeable odour, but no acid reaction. Göbel obtained a formate of lead containing 1 at. water ($C^2H^2Pb^2O^4 + H^2O$), which it gave off at $100^\circ C$.

Formonitrate of Lead, $3C^2H^2Pb^2O^4.Pb^2N^2O^4 + 2H^2O$.—Obtained by dissolving formate of lead in a hot nearly saturated solution of the nitrate, and cooling slowly, in large rhombic crystals, permanent in the air, and sparingly soluble in cold water. (Lucius, Ann. Ch. Pharm. ciii. 113.)

Formate of Lithium, $CHLiO^2$.—Rhombic crystals, having the faces $\infty P. \infty P\infty. P. P\infty. 2P\infty$. Inclination of $\infty P : \infty P = 113^\circ 52'$; $P\infty : P\infty$ over the principal

axis = $106^{\circ} 42'$; $2P_{\infty} : 2P_{\infty}$ over the principal axis = $91^{\circ} 48'$. (Handl, Wien. Akad. Ber. xxxii. 262.)

Formate of Magnesium, $C^2H^2Mg^2O^4 + 2H^2O$.—Crystallises in microscopic rhombic prisms and octahedrons, efflorescing in the air, soluble in 13 pts. water, insoluble in alcohol and ether; gives off its water at 100° C. (Souclay and Groll, J. pr. Chem. lxxvi. 470.)

Formate of Manganese, $C^2H^2Mn^2O^4 + 2H^2O$.—Reddish monoclinic crystals, isomorphous with the following salt, and exhibiting the same faces. Soluble in 15 pts. cold water, insoluble in alcohol. When heated, they give off water and crumble to a white powder.

Formate of Manganese and Barium, $C^2H^2 + 2H^2O$.—This salt, which has the composition of the preceding with an indefinite portion of the manganese (Mn ; Ba) O^4 replaced by barium, crystallises, on evaporating the mixed solutions of its component salts, in monoclinic crystals exhibiting the combination $\infty P . \infty P . \infty P_{\infty} . [\infty P_{\infty}] . + P . - P . + 2P_{\infty}$. Ratio of axes $a : b : c = 0.7598 : 1 : 0.9175$. Angle $b : c = 82^{\circ} 28'$; $\infty P : \infty P$ in the orthodiagonal principal section = $105^{\circ} 4'$; $\infty P : + P = 120^{\circ} 20'$; $\infty P : \infty P = 94^{\circ} 33'$; $\infty P : + 2P_{\infty} = 112^{\circ} 39'$; $+ P : + P = 93^{\circ} 11'$; $+ P : - P = 109^{\circ} 39'$. Cleavage distinct parallel to ∞P . (Heusser, Pogg. Ann. lxxiii. 37.)

Formates of Mercury.—1. *Mercurous Formate*. $C^2H^2(Hg^2)^2O^4$.—When mercuric oxide is dissolved in cold aqueous formic acid, containing 10 per cent. of the acid (CH^2O^2), and a gentle heat applied, the solution suddenly solidifies, with intumescence and escape of carbonic anhydride, yielding a micaceous mass; this effect is due to the separation of the mercurous salt formed by the action of the formic acid on the mercuric oxide. At first, a solution of mercuric formate is produced, but on the application of heat, 2 at. of this salt are resolved into 2 at. mercurous formate, 1 at. free formic acid, and 1 at. carbonic anhydride:

As formic acid is set free in this process, the liquid separated from the crystals of the mercurous salt may be again saturated in the cold with mercuric oxide, and then, if gently heated, it will yield another crop of crystals of the mercurous salt. If the mercuric solution be too strongly heated, the crystals turn grey from admixture of mercury, and if a still stronger heat be applied, nothing but metallic mercury is precipitated. The crystals must be dried between bibulous paper at a temperature between 30° and 40° C. They are delicate microscopic four and six-sided tables, snow-white with a pearly lustre, and greasy to the touch; their taste is saline at first, but afterwards metallic and astringent. They blacken when exposed to light, especially if moist, and likewise, though more slowly, in the dark. They are decomposed by pressure, or by a heat of 100° , into mercury, carbonic anhydride, and formic acid:

When heated in a spoon, they are suddenly decomposed, with a hissing noise, and leave metallic mercury. Their aqueous solution, when continuously heated, gives off carbonic anhydride, and deposits all the mercury in the metallic state, the liquid being converted into a solution of pure formic acid (as shown by the preceding equation). The crystals dissolve in 520 pts. of water at 17° C.; more abundantly, but with incipient decomposition, in warm water; and are insoluble in alcohol and ether. (Göbel, N. Tr. vi. 1, 190; Liebig, Pogg. Ann. iii. 207.)

2. *Mercuric Formate*.—The solution of mercuric oxide in cold dilute formic acid yields, with potash, a precipitate which is yellow at first, and with ammonia a white precipitate; but even if kept cold, it likewise, after a few minutes, deposits crystals of the mercurous salt (Göbel). The finely pulverised oxide dissolves in the cold concentrated acid, forming a syrupy solution, which, if left in vacuo over oil of vitriol, dries up to a white crystallo-granular mass, soluble in water. This mass is likewise converted, by the slightest rise of temperature, into white, acicular mercurous formate, carbonic anhydride being at the same time evolved and formic acid set free. (Liebig.)

Formate of Methyl.—See FORMIC ETHERS.

Formate of Nickel crystallises in hydrated green needles grouped in tufts; they are very soluble in water, and turn yellow in drying.

Formates of Potassium.—1. The *neutral salt*, $CHKO^2$, crystallises with difficulty in white transparent cubes, having a saline bitter taste. They are anhydrous, deliquescent, and very soluble in water. They decrepitate when heated, and at a higher temperature melt to a liquid which solidifies on cooling.

2. *Acid salt*.—A solution of neutral formate of potassium in hot concentrated formic acid, yields, according to Bineau (Ann. Ch. Phys. [3] xix. 291, and xxi. 183), crystalline needles as it cools. The mother-liquor evaporated in vacuo over sulphuric

acid and caustic potash yielded a crystalline mass, part of which was left in *vacuo*, as long as it emitted any odour of formic acid; another portion was dissolved in alcohol and evaporated to dryness in *vacuo*. These three preparations contained formic acid and potash in the proportion indicated by the formula, $\text{CHKO}^2\cdot\text{CH}^2\text{O}^2$, but the first also contained 2.6 per cent. of water, the second 7.6, and the third 11.0 per cent. The salt has a strongly acid taste, and is highly deliquescent. By solution in a large quantity of water and evaporation, it is, for the most part, converted into the neutral salt. When kept for some time in *vacuo*, it gives off part of its acid.

Formate of Silver, CHAgO^2 .—Oxide of silver is instantly reduced by heated formic acid, but the cold acid dissolves it without decomposition; by evaporating the solution, the salt is deposited in transparent rhombohedral crystals. It likewise separates, on mixing moderately strong solutions of nitrate of silver and formate of sodium, in small shining white crystals, which under the microscope exhibit the form of four or six-sided plates. From very strong solutions the salt separates as a curdy precipitate.

Formate of silver quickly turns black even in the dark, especially if moist. When heated it is immediately resolved into carbonic anhydride, metallic silver, and formic acid. Potash decomposes it immediately, with evolution of heat. (Liebig.)

Formates of Sodium.—1. The *anhydrous neutral salt*, CHNaO^2 , crystallises in rhombic prisms with bevelled lateral faces, which melt at 200°C , are moderately soluble in water, less in alcohol, insoluble in ether (Souhay and Groll, J. pr. Chem. lxxvi. 470). A hydrated salt, $\text{CHNaO}^2 + \text{H}^2\text{O}$, was obtained by Göbel, and likewise by Souhay and Groll, in rhombic tables with bevelled lateral faces, or flat four-sided prisms, melting in their water of crystallisation, then giving it off with strong intumescence, and afterwards solidifying to a pearly anhydrous mass. These hydrated crystals are deliquescent and soluble in 2 pts. water. Formate of sodium does not yield any acid distillate when strongly heated.

The solution of this salt is used by Döbereiner to precipitate mercury, silver, gold, palladium, and platinum from their solutions in the metallic state, and thus to separate them from other metals. The dry salt may be used as a reducing agent in blowpipe experiments.

2. The *acid salt*, obtained by dissolving the neutral salt in strong aqueous formic acid, and evaporating in *vacuo*, forms ill-defined crystals, containing acid and base in the proportion represented by the formula $\text{CHNaO}^2\cdot\text{CH}^2\text{O}^2$; they also contain 7 per cent. of water. The properties of this salt are similar to those of the corresponding potassium-salt. (Bineau.)

Formate of Strontium, $\text{C}^2\text{H}^2\text{Sr}^2\text{O}^4 + 2\text{H}^2\text{O}$.—The statements of different observers respecting the crystalline form of this salt do not quite agree. According to Kopp (*Krystallographie*, p. 164), it forms crystals belonging to the dimetric or quadratic system, for which $c = 1.177$; $P : P$ in the terminal edges = $105^\circ 23'$; in the lateral edges = $118^\circ 30'$; $P\infty : P\infty$ in the terminal edges = $98^\circ 48'$; in the lateral edges $133^\circ 58'$. Ordinary combination $P. \infty P$ with $2P\infty$ subordinate; or P with $P\infty$, which then occurs hemihedrally, and often as the dominant form. According to Heusser, on the other hand, the salt crystallises in transparent six-sided prisms be-

longing to the trimetric or rhombic system, with the faces $\infty P, P, \infty P, \frac{P}{2}, \frac{2P}{2}$, and $\frac{2P}{2}$, the two hemihedral forms occurring on opposite sides of the crystal ($+ \frac{P}{2}$ with $-\frac{2P}{2}$, and $-\frac{P}{2}$ with $+\frac{2P}{2}$), but not being invariably attached to either side.

Ratio of axes $a : b : c = 0.60761 : 1 : 0.59494$.* Inclination of $\infty P : \infty P = 117^\circ 28'$; $P\infty : P\infty$ over the principal axis = $118^\circ 30'$. According to Pasteur (*Ann. Ch. Phys.* [3] xcxi. 67), this salt, though it exhibits non-superposable hemihedral forms (which may be distinguished as *right* and *left*), differs from other salts which exhibit this peculiarity (the dextro- and lævo-tartrates for example) in two respects: first, its solution does not deflect the plane of polarisation of a ray of light; and secondly, on recrystallising either the right or the left variety of the salt, crystals of the opposite kind are always obtained mixed with those of the original variety. But according to E. Jacobsen (*Pogg. Ann.* cxiii. 493), the development of the hemihedral faces depends altogether on the presence of foreign substances in the solution; a small quantity of free formic acid favours their development, and on recrystallising the salt several times from pure water, they gradually disappear. Jacobsen finds also that carefully selected hemihedral crystals of either variety never yield the opposite variety on recrystallisation. Crystals of the salt prepared with formic acid obtained by the

* As two of these axes differ but slightly in length, the form is very nearly quadratic.

oxidation of starch, when placed so that an obtuse edge of the prism ∞P is turned to the observer, exhibit for the most part the face $\frac{P}{2}$ to the left point above (of the observer), whereas crystals of the same salt prepared with formic acid obtained from oxalic acid and glycerin exhibit, for the most part, the face $\frac{P}{2}$ to the right point above. (Jacobsen.)

Formate of strontium is soluble in water, permanent in the air, and crumbles to a white anhydrous powder when heated.

Formate of Tetryl.—See FORMIC ETHERS.

Formate of Thorium.—A solution of hydrate of thorium in aqueous formic acid yields, by spontaneous evaporation, crystals which form a clear solution in boiling water, but when digested in cold water form an acid solution and leave a basic salt. Alcohol dissolves them but sparingly. (Berzelius.)

Formates of Tin.—*Stannous Formate* is sometimes a white insoluble powder, which turns black at first when ignited; sometimes a gelatinous mass which is difficult to dry, and from which alcohol precipitates a white powder. (Arfvedson.)

Stannic Formate.—Aqueous tetrachloride of tin mixed with formate of sodium does not become turbid till the mixture is heated; it then becomes white and gelatinous, and after a while the precipitate assumes a crystalline character (Liebig). The acid does not dissolve stannic oxide, even when heated.

Formates of Uranium.—1. *Uranous formate.*—Protochloride of uranium yields, with formate of sodium, a green precipitate, which dissolves, with green colour, in excess of the sodium-salt, and does not reappear on further addition of chloride of uranium. But on heating the mixture, it becomes turbid, and deposits a greyish green body containing uranous oxide and formic acid. The colourless liquid filtered from this substance contains a large quantity of formic acid and but little uranium. (Rammelsberg, Pogg. Ann. lix. 34.)

Uranic Formate.—Uncrystallisable, glutinous mass, which becomes moist on exposure to the air. (Richter.)

Formate of Vanadium.—Hydrated vanadic oxide dissolves in aqueous formic acid, yielding a blue solution, which on evaporation leaves a blue, opaque, saline mass, easily soluble in water. The aqueous solution remains blue if it contains a slight excess of acid; but as this acid evaporates in the air, the solution turns green. (Berzelius.)

Formate of Zinc, $C^2H^2Zn^2O^4 + 2H^2O$.—Crystallises by evaporation in monoclinic prisms, isomorphous with the manganese and cadmium salts, and exhibiting the faces ∞P , oP , $+P$, $+2P$, ∞P . Ratio of axes $a : b : c = 0.76527 : 1 : 0.93430$. Angle of inclined axes $= 82^\circ 41'$; $\infty P : \infty P = 104^\circ 32'$; $oP : +P = 120^\circ 4'$; $oP : \infty P = 94^\circ 28'$; $oP : +2P = 112^\circ 14'$; $+P : +P = 93^\circ 17'$ (Heusser). The crystals are permanent in the air, soluble in 24 pts. water at $19^\circ C$, insoluble in alcohol. By dry distillation they give off pungent inflammable gas, and leave zinc-oxide containing charcoal.

Formate of Zinc and Barium, $C^2H^2(Ba; Zn)^2O^4$, forms crystals belonging to the triclinic system. (Heusser.)

FORMIC ETHERS. Compounds derived from formic acid by the substitution of an alcohol-radicle for the basic hydrogen. Four of them are known, all derived from alcohols of the series $C^2H^{2n+2}O$, viz. the formates of methyl, ethyl, tetryl, and amyl.

Formate of Amyl, $C^2H^{12}O^2 = CH(C^2H^{11})O^2$.—This compound, isomeric with capric acid, and with valerate of methyl, butyrate of ethyl, ethylate of tetryl, and propionate of trityl, is obtained by distilling 6 pts. anhydrous formate of sodium, 6 pts. strong sulphuric acid, and 7 pts. amyl alcohol; mixing the distillate with water; washing the separated liquid with solution of carbonate of sodium, then with water; drying over chloride of calcium, and rectifying. It is a colourless mobile liquid, having an agreeable odour, like that of ripe fruits. Specific gravity 0.8743 at $21^\circ C$. (Kopp); 0.8809 at 15° , referred to water at 4° as unity (Mendelejeff, Compt. rend. l. 52). Boiling point about 116° . Slightly soluble in water; when kept in vessels containing air it quickly turns acid. (H. Kopp, Ann. Ch. Pharm. lv. 183.)

Chloramyl Formate, $C^2H^{11}ClO^2$. Syn. with CHLOROCARBONATE OF AMYL (l. 916).

Formate of Butyl.—See FORMATE OF TETRIL.

Formate of Ethyl, $C^2H^4O^2 = CH(C^2H^3)O^2$. *Ethylic formate.* *Formic ether.* *Ameisensäther.* *Ameisennaphtha.* (Gm. viii. 482; Gerh. i. 234.)—This ether, isomeric

with propionic acid and acetate of methyl, was discovered by Afzelius of Upsal, in 1777; examined soon afterwards by Bucholz, and by Gehlen, and more exactly by Döbereiner, Liebig, Marchand, Löwig and Weidmann, and H. Kopp. It is obtained by distilling alcohol with strong formic acid, or formate of sodium and sulphuric acid, and by the decomposition of oxalic ether.

Preparation.—1. By distilling 7 pts. of dry formate of sodium with a mixture of 6 pts. of highly rectified spirit, and 10 pts. strong sulphuric acid; agitating the distillate, if acid, with magnesia; separating it from alcohol by agitation with water, then decanting the ether and rectifying it over chloride of calcium (Döbereiner). On mixing the three ingredients, heat is evolved sufficient to distil over all the formic ether. The distillate is agitated with an equal volume of milk of lime, and the formic ether evolved as above is dehydrated by chloride of calcium, after separation from the lower stratum, the chloride of calcium being renewed as often as it becomes moist, after which the ether is simply decanted off (Liebig). H. Kopp uses 8 pts. of formate of sodium to 7 pts. alcohol of 88 per cent., and 11 pts. sulphuric acid, conducting the process in other respects in the same manner as Liebig.—2. A mixture of 30 pts. sulphuric acid, 15 pts. water, and 15 pts. highly rectified spirit is poured upon an intimate mixture of 10 pts. starch and 37 pts. very finely pounded manganese, and the whole distilled with gentle ebullition as long as formic ether continues to pass over. A large quantity of chloride of calcium is then dissolved in the distillate, whereby, in the following distillation over the water-bath, the greater part of the water and alcohol is retained, and the liquid which passes over is again rectified with chloride of calcium.

3. Acid oxalate of ethyl distilled with glycerin at 100° C. decomposes similarly to oxalic acid when similarly treated (p. 686), yielding formate of ethyl. The impure ether obtained by prolonged digestion of oxalic acid with alcohol may be used for the purpose. (Church, Phil. Mag. [4] xi. 75.)

4. Formic ether is obtained as a secondary product in the preparation of neutral oxalate of ethyl. When 700 grms. dehydrated oxalic acid (obtained by gently heating a kilogramme of the crystallised acid) are mixed with 750–800 grms. absolute alcohol, or spirit of 97 to 98 per cent., and the mixture distilled in a sand-bath, there is obtained between 145° and 186° C. a distillate containing formate and oxalate of ethyl, together with small quantities of carbonate of ethyl and alcohol, and above 186° pure oxalate of ethyl. The mixture just mentioned may be separated by fractional distillation, the formate of ethyl passing over between 55° and 75°. (Löwig, Ann. Ch. Phys. [3] lxi. 464; Jahresber. f. Chem. 1861, p. 597.)

Properties.—Formic ether is a thin, transparent and colourless liquid, having a strong agreeable odour, like that of peach-kernels, and a strongly aromatic taste; of specific gravity 0.9167 at 18° C. (Gehlen); 0.9188 at 17°; 0.9984 at 0° (H. Kopp); 0.9677 at 0° (Pierre). Boils at 54° (R. Marchand); at 56°, under a pressure of 27.7" (Döbereiner); at 54.9° with platinum wire immersed in it (H. Kopp); at 52.9° under a pressure of 752 mm. (Pierre); at 54.3 under a pressure of 762 mm. (Andrews). Tension of vapour at 230 = 8.2 inches of mercury (Döbereiner). Vapour-density = 2.593 (Liebig); by calculation (2 vol.) = 2.565. It burns with a blue flame yellow at the edges. It dissolves in 9 pts. water at 18° C., absorbs moisture quickly from the air, and is slowly decomposed thereby into alcohol and formic acid; it must therefore be kept over chloride of calcium. In presence of alkalis the decomposition takes place more quickly. Formic ether mixes in all proportions with alcohol, ether, and wood-spirit, and with many oils, both fixed and volatile. Heated with dry ammonia in sealed tubes, it is converted into formamide (Hofmann, p. 681). With chlorine it yields substitution products (*vid. inf.*).

Chlorethyllic Formate, $C^2H^3ClO^2$.—Identical with chlorocarbonate of ethyl (i. 916).

Dichlorethyllic formate, $C^2H^2Cl^2O^2 = \left. \begin{matrix} CHO \\ C^2H^2Cl^2 \end{matrix} \right\} O$.—Chlorine rapidly attacks formic ether, producing hydrochloric acid and dichlorethyllic formate:

together with formic acid and chloride of ethyl, resulting from the action of the hydrochloric acid on the formic ether. The product is distilled slowly, the temperature not being allowed to exceed 90° C.; at 106° the mixture would turn brown. The residue is poured into water, and the oil which rises to the surface is dried in vacuo. It is soluble in alcohol and ether, but is decomposed by water. Specific gravity = 1.261 at 16° C. It cannot be boiled without decomposition. Aqueous potash attacks it readily, producing chloride, acetate, and formate of potassium:

Perchlorethyllic formate, $C^2Cl^4O^2 = \left. \begin{matrix} CClO \\ C^2Cl^3 \end{matrix} \right\} O$.—This compound, produced by the

action of chlorine on formic ether in sunshine, has exactly the same composition, properties, and reactions as perchloromethylic acetate obtained in like manner by the action of chlorine on acetate of methyl (i. 24); in fact the two compounds appear to be identical.

Formate of Methyl, $C^2H^4O^2 = \begin{matrix} CHO \\ CH^3 \end{matrix} \} O$. *Methylic formate*.—This compound, isomeric with acetic acid, was first obtained in 1835 by Dumas and Peligot (Ann. Ch. Phys. [2] lviii. 48). To prepare it, equal parts of sulphate of methyl and formate of sodium are gently heated in a distillatory apparatus. As soon as the action begins, the mass becomes spontaneously heated, and methylic formate passes over in a nearly pure state into the receiver, which should be well cooled. The methylic formate, which afterwards passes over at a higher temperature, is contaminated with a little methylic sulphate. The distillate thus obtained is rectified over formate of sodium, and then once by itself in a dry retort. In this manner, a perfectly pure product is obtained. This compound is not obtained by distilling wood-spirit and formate of sodium with sulphuric acid.

Formate of methyl is a transparent and colourless liquid, lighter than water, very volatile, and having an ethereal but very pleasant odour. Vapour-density = 2.084 (Dumas and Peligot); by calculation (2 vol.) = 2.08. Boils between 36° and 38° C.; smells like formic ether. (Liebig.)

Chloromethylic formate, CH^3ClO^2 .—Identical with chlorocarbonate of methyl (i. 916).

Perchloromethylic formate, $C^2Cl^4O^2 = \begin{matrix} CHO \\ CCl^3 \end{matrix} \} O$.—To prepare it, perfectly anhydrous methylic formate is placed in a bottle filled with dry chlorine gas, and exposed for some days to the sun (the action, though violent at first, soon diminishes in intensity), till after about fourteen days the colour of the chlorine no longer diminishes. The liquid, which is coloured by free chlorine, is then distilled, the portion which distils over below 190° C. collected apart, and rectified several times, the more volatile portion being each time collected.

It is a transparent, colourless, very thin liquid, of specific gravity 1.724 at 10° C., boiling at 180° to 181° , and having a strong pungent odour, like that of phosgene. When passed in the state of vapour through a tube heated to 340° – 350° , it is converted almost wholly into phosgene gas, with which indeed it is polymeric. Aqueous ammonia acts violently upon it, forming white nacreous trichloracetamide and sal-ammoniac, and probably a third product. Potash, even when hot and concentrated, exerts scarcely any decomposing action. Alcohol decomposes it, with formation of chlorocarbonate of ethyl; methylic and amylic alcohols form similar products. (Cahours.)

Formate of Tetryl, $C^2H^4O^2 = \begin{matrix} CHO \\ C^4H^3 \end{matrix} \} O$.—Discovered by Wurtz (Ann. Ch. Pharm. xiii. 121). Isomeric with valeric acid, with butyrate of methyl, propionate of ethyl, and acetate of trityl. It is prepared by heating formate of silver with somewhat less than an equivalent quantity of iodide of tetryl in a sealed tube in the water-bath for several hours, then distilling off the volatile product, washing with sodic carbonate, drying over chloride of calcium, and rectifying. It is a fragrant liquid, boiling at about 100° C.

FORMOMETHYLAL. See METHYLAL.

FORMONAPHTHALIDE. Syn. with NAPHTHYL-FORMAMIDE (p. 681).

FORMONETIN. $C^{30}H^{40}O^{12}$? (Hlasiwetz, Wien. Akad. Ber. xv. 142).—A substance obtained, together with glucose, by the action of hot hydrochloric or boiling dilute sulphuric acid on ononin, $C^{32}H^{40}O^{27}$ (q. v.):

It may be purified and obtained quite white by crystallisation from strong alcohol, or by solution in ammonia and partial precipitation with hydrochloric acid. From the hot alcoholic solution it separates in small crystals. It is nearly insoluble in water and in ether, does not precipitate metallic salts, or colour ferric chloride. Fixed alkalis dissolve it and decompose it at the boiling heat. By sulphuric acid and peroxide of manganese it is coloured violet. By boiling with baryta-water it is resolved into formic acid and ononetin, $C^{46}H^{44}O^{13}$:

FORMONITRILE. Syn. with HYDROCYANIC ACID (p. 214.)

FORMULÆ, RATIONAL.—Chemists are accustomed to distinguish between two different kinds of formulæ; namely, *empirical formulæ* and *rational formulæ*. These terms were first introduced by Berzelius (Jahresber. [1833] xiii. 189; Pogg.

Ann. xxviii. 617; Ann. Ch. Phys. liv. 5; abstr. Ann. Ch. Pharm. vi. 173); the former to denote formulæ which "result immediately from an exact analysis and are invariable;" the latter to denote formulæ which "are designed to give an idea of the two electro-chemically opposite bodies of which the compound is regarded as constituted; that is to say, to render evident the electro-chemical division of the body submitted to analysis." The meaning now attached to these expressions is only so far different from their original meaning as here defined, that, with the growth of new theories of chemical constitution, the signification of rational formulæ has been widened so as no longer to denote the representation of substances on the electro-chemical theory only, but so that a formula which expresses any view whatever respecting the constitution or nature of a substance, beyond what results directly from its analysis, is now called a rational formula.

Empirical formulæ being merely expressions of the results of analysis in terms of the atomic weights of the elements (or more strictly speaking, in terms of the values represented by the elementary symbols: which, however, are always taken in this work as standing for atomic weights), all that is required, in order to fix the empirical formula of any substance, is that the atomic weights of the elements should have been determined, and that the substance itself should have been accurately analysed. Such formulæ, therefore, can never become the subjects of discussion, or of differences of opinion; except, indeed, in cases where the experimental data are incomplete. With rational formulæ, on the other hand, it is very different. A perfect rational formula would amount to a complete statement of the chemical constitution, analogies, and relations of the body which it represents, while the simplest of such formulæ is, by its very nature, an expression of something more than the direct results of experiment. It is obvious, therefore, that the rational formula of any substance must vary with the general theoretical views which from time to time exert the greatest influence in chemical science, and that chemists who hold different opinions with regard to any fundamental point of chemical theory, will assign different rational formulæ to the same bodies. On investigation, however, it will be found that, in very many cases, the different formulæ given to the same substance do not represent distinctly different views of its chemical nature, but that they express the same meaning under different forms. In fact, the question, what is the rational formula of any given substance? resolves itself into these two different parts: (1) what is its chemical function or its place in a general chemical classification? (2) by what formula is this function most suitably expressed? In this article we shall endeavour to show, by the discussion of one or two illustrative examples, the manner in which answers to these questions can be arrived at.

The chemical properties of compounds of the lowest order of complexity appear to depend solely on their chemical composition, and hence the empirical formulæ which express their composition are at the same time the only possible rational formulæ which can be given to them. In more complex compounds, on the other hand, the chemical properties depend, not only on the nature and proportions of their elementary constituents, but also on the mode in which these constituents are combined. Thus acetic acid, lactic acid, formate of methyl, ethyl-carbonic acid, glycocollate of methyl, methyl-glycollic acid, glucose, and some other substances, would all give the same results on analysis, and would consequently all be represented by the same empirical formula, CH^2O . The very different properties exhibited by these bodies, all composed of the same elements united in the same proportions, can be due to nothing but to differences in the mode or order in which these elements are combined in each of them; and although, in most cases, we are far too ignorant of the manner in which the atoms of compound bodies are grouped together, to attempt the expression of it by the arrangement of symbols in our formulæ, still it is possible to indicate to a great extent, by means of rational formulæ, the different chemical characteristics which result from variations in the mode of combination of the same atoms. This, however, can be done only by a comparative method, that is, by selecting a certain number of representative substances, and giving to all other bodies formulæ which shall express the nature of their relations to the substances so selected.

In the article CLASSIFICATION (i. 1010, *et seq.*) it has been shown that the following substances

HCl	H^2O	H^2N	H^2C
Hydrochloric acid.	Water.	Ammonia.	Marsh gas.

may be thus taken as typical of all compounds of the simplest order, and that, by the assumption of compound radicles, substances of great complexity may also be compared with them. The rational formulæ adopted in this work amount merely to statements that the substances represented by them are comparable, so far as regards their modes of formation and transformation, with one or other of these fundamental types. Assuming, at present, that this is the best system of rational formulæ, the first question

to be considered — namely, the manner of determining the place of a substance in a general scheme of chemical classification — is seen to be in reality a discussion of the grounds upon which a compound is referred to this or that type, and regarded as containing this or that compound radicle.

The rules which are practically recognised by chemists in the formation of rational formulæ, will be better explained in relation to particular instances, than by attempting a general exposition of them which should be applicable to all cases. Hippuric acid, for example, is represented by many chemists by the rational formula,

We will proceed to consider in detail the meaning of this expression, and the manner in which it is deduced from the known properties of the substance it represents.

The analysis of hippuric acid leads at once to the empirical formula $\text{C}^{\text{H}}\text{H}^{\text{O}}\text{NO}^{\text{H}}$; and the quantity represented by this expression, is that which results from all reactions in which hippuric acid is formed, as well as that which reacts in all the transformations which this acid is capable of undergoing. This formula therefore represents, not only the composition of hippuric acid, but also its molecular weight. The principal reactions of hippuric acid, at least those which have been chiefly kept in view in deducing the rational formula above given, are expressed by the following equations:

Reactions of formation —

Reactions of transformation —

In the first of these equations, that representing the formation of hippuric acid by the action of chloride of benzoyl on glycocine, there is an azotised body and a chloride on each side: on the first side, glycocine and chloride of benzoyl, and on the second, hippuric acid and chloride of hydrogen; and on looking at the composition of these substances, it is seen that the difference between glycocine and hippuric acid is just the same as that between hydrochloric acid and chloride of benzoyl. To express these relations in the rational formula of hippuric acid, it is plain that this formula must represent hippuric acid as bearing the same relation to glycocine that chloride of benzoyl does to chloride of hydrogen; that is, it must represent it as glycocine wherein the radicle $\text{C}^{\text{H}}\text{H}^{\text{O}}$, benzoyl, takes the place of an atom of hydrogen. Similarly, equations 2 and 4, which are the converse of each other, show that the relation of hippuric acid to glycocine is the same as that of benzoic acid to water; and equation 5, that it is also the same as that of hydride of benzoyl to hydride of hydrogen: but benzoic acid is to water, and hydride of benzoyl is to hydride of hydrogen, just what chloride of benzoyl is to hydrochloric acid: these last three equations therefore lead to exactly the same rational formula for hippuric acid as the first; that is, to the formula

or an equivalent expression.

Again, equation 3 shows that hippuric acid contains an atom of hydrogen, which is so far different from the rest that it can be replaced by an atom of another metal, as potassium, while all the other atoms remain in unaltered combination. To express this, we must further break up the formula and write one H separate from the remainder. Here, however, the question arises, how is this result to be combined with the previous one. Are we to represent this exceptional atom of hydrogen as belonging to the original compound glycocine, or to the radicle benzoyl, which we have already admitted as replacing one atom of hydrogen? The answer to this question is obtained by considering the properties of glycocine and chloride of benzoyl, the substances from

which hippuric acid is put together in the reaction represented in equation 1. Glycine contains an atom of hydrogen replaceable by metals; chloride of benzoyl does not: hence the natural conclusion is that the replaceable hydrogen of hippuric acid belongs to the glycocine and not to the benzoyl. This is expressed by the formula

whereas the opposite conclusion would be represented by $C^2H^4(C^2H^2O.H)NO^2$.

Equation 6 states that an atom of hydrogen and an atom of nitrogen can be removed from hippuric acid and replaced by an atom of oxygen. The hydrogen-atom thus removed appears not to be the one which, as we have already seen, is replaceable by metals: for the product of the reaction, benzoglycollic acid, still contains a similarly replaceable atom of hydrogen. A second H must therefore be separated from the rest in the formula of hippuric acid, and thus we get the expression

There is reason to believe that the atom of hydrogen in glycocine, which can be replaced by metals, owes its special characters to its being in more direct combination with one of the oxygen-atoms of the compound than with the nitrogen: hence, if the conclusion arrived at in the last paragraph but one be admitted, it follows that the radicle C^2H^2O in hippuric acid is not directly combined with oxygen, but is probably primarily united with the nitrogen. This supposition is strengthened by the reaction represented in equation 7, where, when the other elements are completely oxidised into carbonic anhydride and water, the benzoyl and part of the hydrogen remain united with the nitrogen in the form of benzamide. This can be expressed in the rational formula of hippuric acid by arranging the symbols in such a way as to represent the nitrogen and the group C^2H^2O as in direct combination; for example, thus—

where the atom of hydrogen represented in direct combination with the nitrogen is the one which is displaced, at the same time as the latter, when hippuric acid is acted on by nitrous acid (equation 6), and the second hydrogen-atom written apart from the rest, in the lowest line of the formula, is the one replaceable by metals.

There is still the group of atoms, $C^2H^2O^2$, which remains intact throughout all the transformations hitherto considered, except that represented by equation 7, where it is completely oxidised. We might therefore legitimately regard it as a diatomic radicle, and assign to hippuric acid the rational formula

as the one which expresses all its principal transformations. But the adoption of this formula for hippuric acid would involve the representation of glycocine by

formulae which, though expressing several very important relations of these bodies, not only do not indicate the possible formation of Heintz's diglycolamidic acid, $C^4H^2NO^4$, and triglycolamidic acid, $C^6H^2NO^6$, or of the diglycollic acid, $C^4H^2O^4$, discovered by Wurtz and by Heintz, but conceal the analogy of glycollic acid to lactic acid, which latter cannot be represented with a radicle containing O^2 , since, by the action of pentachloride of phosphorus, it yields the chloride $C^2H^2OCl^2$. For these reasons, a formula in which the radicle $C^2H^2O^2$ is broken up thus, $C^2H^2O.O$, is a more satisfactory representation of glycocine, and consequently of hippuric acid, than that given above. Thus we come finally to the expression

as the ultimate rational formula of hippuric acid.

If, however, we extend our consideration, not merely to the transformations of hippuric acid itself, but also to those of the substances out of which it is built up, or into which it can be decomposed: if, for instance, we take into account the decomposition of benzoic acid into a carbonate and benzene, and of glycocine into a carbonate and

methylamine, when distilled with baryta, we must break up this formula still further and write it thus:

or in some equivalent form.

Two points arise from the foregoing discussion which are of sufficient importance to be dwelt upon somewhat more at length. They are, first, the purely relative character of rational formulæ, or their dependence on the particular transformations which they are intended to represent; secondly, the necessity of assigning comparable formulæ to comparable substances.

Rational formulæ being used in the sense which has been indicated in this article, that is, as descriptive only of the bodies to which they are assigned, it is obvious that, if a substance can react in several different ways, it may receive as many distinct rational formulæ, each of which shall be truly descriptive of it relatively to a particular set of transformations; although it can only have one completely rational formula, that is, only one formula indicating all the transformations which it is capable of undergoing. This is nothing more than what we meet with in common language, where, as we know, several distinct partial descriptions of the same object may be each of them quite accurate as far as they go, although there cannot be more than one complete description of it. This is almost too simple a matter to need to be specially pointed out, were it not that some chemists maintain that the same substance cannot have more than one rational formula. For instance, in the *Annalen der Chemie und Pharmacie*, vol. cxiii. pp. 225, 226 (February, 1860), we find the following passage in reference to the two formulæ $\left\{ \begin{array}{c} \text{C}^3\text{H}^4\text{O}'' \\ \text{C}^2\text{H}^3 \end{array} \right\} \text{O}$ and $\left\{ \begin{array}{c} \text{C}^3\text{H}^4\text{ClO}'' \\ \text{C}^2\text{H}^3 \end{array} \right\} \text{O}$, which Wurtz, in order to express the

different ways in which that body reacts, had assigned to the product of the action of alcohol on chloride of luctyl:

"If two isomeric bodies are recognised as distinct substances because they contain their proximate constituents grouped in different ways; if further the rational constitution, as distinguished from the empirical constitution, is that which indicates the proximate constituents of a compound together with the part which they play therein; and if finally the rational formula is the symbolic expression of the conception which we form to ourselves, at any given time, respecting the rational constitution of a body, it is not possible that, as Wurtz supposes in the case of chloropropionic ether, a compound can have two rational formulæ at the same time; that is, that it can be variously constituted. No one will share the opinion that the chloropropionic acid which produces lactic acid is not identical, but merely isomeric, with that which is converted by hydrogen into propionic acid."

"To advocate at one time two different rational formulæ for the same compound, that is, to pretend that it contains now one group of atoms, and now another as its proximate constituents, and contains them perhaps differently combined together, as is expressed by Wurtz's two formulæ for chloropropionic ether, is to assert an impossibility."

On examining these quotations, it will be seen that the use of rational formulæ which is contemplated by them is not quite that which has been explained in this article. The author plainly regards rational formulæ as symbolic expressions of suppositions respecting the constitution of compounds, whereby it is sought to explain their chemical properties. Regarding the reactions of compound bodies as determined, not only by the nature of their elements, but also by the way in which their constituent atoms are united, he considers that rational formulæ ought to represent the ultimate structure of bodies, and thus show why they exhibit the particular properties by which they are characterised. If we had the means of ascertaining with certainty the constitution of bodies, there can be no question that formulæ by which it was expressed would be the best rational chemical formulæ, and that of such formulæ, only one could be true for each substance; but, since our only mode of learning how bodies are constituted is by studying the reactions by which they are formed and transformed, it seems the safest course to be satisfied, for the present, with formulæ which simply indicate what these reactions are, resting assured that the best way of arriving at a knowledge of their cause is by endeavouring to attain a distinct and complete conception of their manner.

When considering any reaction for the purpose of deducing from it a rational

formula for the bodies which take part in it, we have always to distinguish between the constituents which are unaffected by the reaction and those which are added, separated, or replaced by others. Thus when chloride of benzoyl acts on ammonia, producing benzamide,

we have the group $\text{C}^{\text{H}^{\circ}}\text{O}$ common to the reagent and to the product, while Cl in the former is replaced by H°N in the latter. It has been explained in the article CLASSIFICATION (i. 1014, 1015) that the group which remains constant throughout a reaction is the radicle of the substances concerned in it, while the atoms that are affected by the reaction are those which serve to characterise the type of the reagent and product respectively. In the rational formula of any substance, the radicle expresses its genetic

relations, and the type its chemical function. In the formula $\text{C}^{\text{H}^{\circ}}\text{O} \left\{ \begin{smallmatrix} \text{H} \\ \text{H} \end{smallmatrix} \right\} \text{N}$, for benzamide, the radicle $\text{C}^{\text{H}^{\circ}}\text{O}$ indicates that the substance belongs to the same chemical family as benzoic acid, oil of bitter almonds, and chloride of benzoyl; while the symbol of nitrogen outside the bracket, and the two Hs within, denote that its chemical function is that of a primary monamide (AMIDES, i. 169). This formula, however, plainly does not indicate the possibility of a reaction such as that of pentachloride of phosphorus on benzamide, namely,

To obtain a formula which shall do so, we must, as before, distinguish between the atoms which are affected by the reaction and those which remain in unaltered combination; we thus get from this equation the rational formula for benzamide, $\text{C}^{\text{H}^{\circ}}\text{H}^{\circ}\text{N} \left\{ \begin{smallmatrix} \text{H} \\ \text{H} \end{smallmatrix} \right\} \text{O}$, which represents it as the hydrate of the radicle $\text{C}^{\text{H}^{\circ}}\text{H}^{\circ}\text{N}$.

The consideration of two different reactions thus leads to the representation of benzamide at one time as an amide, at another as a hydrate, but it is possible to express both these reactions by a single rational formula, if we represent benzamide as at once an amide and a hydrate. This is done by the formula $(\text{C}^{\text{H}^{\circ}}\text{H}^{\circ}) \left\{ \begin{smallmatrix} \text{H} \\ \text{H} \end{smallmatrix} \right\} \text{N} \left\{ \begin{smallmatrix} \text{H} \\ \text{H} \end{smallmatrix} \right\} \text{O}$, where $\text{C}^{\text{H}^{\circ}}\text{H}^{\circ}$, the group of atoms which remains unaltered throughout both reactions, is the radicle, and the type $\text{H}^{\circ}\text{N} \left\{ \begin{smallmatrix} \text{H} \\ \text{H} \end{smallmatrix} \right\}$.

It is important to notice here that a formula derived from a simple type can only express reactions of the kind which is characteristic of that type, and that, as soon as we have to express more than one kind of reaction by the same formula, we must make use of a complex type. It is obvious, however, that complication of type involves simplification of radicle, and *vice versa*; so that a formula expressing all the reactions in which a given substance could possibly take part, whether as reagent or product, would be one containing only radicles of the greatest possible simplicity; that is, consisting of single elementary atoms. All rational formulæ containing compound radicles are necessarily partial, for they cannot express any reactions in which the constituents of those radicles are separated from each other. Such formulæ are nevertheless, the most commonly useful, for it is more frequently necessary to point out the relations of one substance to others of a comparable degree of complexity, than to indicate the reactions by which it can be put together from its constituent atoms, or by which these can all be separated from each other. (See further, *Preliminary Report on Organic Chemistry*, by G. C. Foster. Reports of British Associat. for 1859, pp. 7-11.)

The second point which, as has been stated, arises out of the discussion of the formula of hippuric acid, is the necessity of giving comparable formulæ to comparable substances, or of adopting a uniform system of rational notation; that is, always expressing similar reactions in the same way. What is meant will become more clearly intelligible by an example of that which, we contend, is an illogical and inconsistent use of formulæ. In Kolbe's *Lehrbuch der organischen Chemie* (Braunschweig, 1860, ii. p. 117), the decomposition of hippuric acid, when boiled with binoxide of lead, is represented by the following equation:

* In this equation, and in what follows in reference to it, H=1, O=8, C=6, &c.

Hippuric acid is here represented as benzoic acid, $\text{HO} \cdot (\text{C}^{\text{H}}\text{H}^{\text{H}})[\text{C}^{\text{O}}\text{O}^{\text{H}}], \text{O}$ (according to Kolbe), wherein amido-acetoxyl, $\text{C}^{\text{H}} \left\{ \begin{smallmatrix} \text{H}^{\text{H}} \\ \text{H}^{\text{N}} \end{smallmatrix} \right\} \text{O}^{\text{H}}$ (the radicle assumed by Kolbe to exist in glycocine or amido-acetic acid), replaces one atom of hydrogen; while benzamide is represented as ammonia in which an atom of hydrogen is replaced by benzoyl, although, as we have already seen, hippuric acid bears exactly the same relation to glycocine that benzamide does to ammonia. Chloride of benzoyl reacts on glycocine exactly as it does on ammonia, forming in the one case hippuric acid, in the other benzamide; yet the above formulæ represent the products as related to the reagents quite differently in the two reactions. In the first, substitution is represented as having taken place within the radicle $(\text{C}^{\text{H}}\text{H}^{\text{H}})\text{C}^{\text{O}}\text{O}^{\text{H}}$; in the second, this radicle is represented as being itself substituted for hydrogen.

The same chemist furnishes us with another example of the illogical use of formulæ, in the expressions by which he represents the products of the action of chloropropionic ether (Wurtz's *ether chlorolactique*) on ethylate of sodium and on butyrate of sodium respectively. The reaction is in both cases perfectly similar, and may be described as the combination of the reagents, with elimination of chloride of sodium. Kolbe nevertheless formulates the first product, diethylic lactate, as chloropropionic ether wherein the chlorine is replaced by binoxide of ethyl, but represents the second, butyro-lactate of ethyl, as chloropropionic ether wherein the chlorine is replaced — not by binoxide of butyryl but—by butyryl in which binoxide of hydrogen is substituted for an atom of hydrogen. The formulæ in question, retaining the atomic weights used by the author, are—

This incorrect use of rational formulæ caused Kolbe to predict that butyro-lactate of ethyl would undergo a decomposition, when boiled with dilute hydrochloric acid, different from that which is found actually to occur. (See Ann. Ch. Pharm. cxiii. 235.)

We have drawn attention to these examples of the wrong use of formulæ, because it is necessary to bear clearly in mind that, whatever system of rational formulæ we may prefer, and whatever may be our opinions as to what can and what ought to be expressed by them, the language of chemical symbols obeys the same laws as all other languages, and ceases to have value or meaning when dissimilar expressions are used to represent identical relations.

When it has been ascertained by the study of their reactions, that two or more substances are of allied constitution, there are two ways in which the relations between them may be expressed by rational formulæ. In the first, or *additive* system, substances of similar function are represented as containing, as a common constituent, the first term of the series to which they belong, united in each of them to a different additional group. In this system of formulæ, methylic, ethylic, and amylic alcohols would be respectively represented as water combined with methylene, with ethylene, and with amylene: thus—

In these formulæ, the constant constituent denotes the chemical function; the variable addition, or *copula*, characterises the family to which the substance belongs.

Formulæ of the second kind may be called *substitutive*. They are such as those commonly employed in this work. In this system, a series of allied bodies are not represented as containing the first term as such, but as derived from it by substitution. Thus, the three alcohols above mentioned are represented as derived from water by the substitution of the radicles methyl, ethyl, and amyl for hydrogen: namely—

The earliest rational formulæ used in organic chemistry, namely, those by which Dumas and Boullay (Ann. Ch. Phys. xxxvii. 15, 1828) represented the constitution of the compound ethers, were additive; and formulæ of this kind long remained in almost exclusive use by chemists of the French school. Similar formulæ were proposed by Mitscherlich (Ann. Ch. Phys. lv. 41, 1834; Ann. Pharm. ix. 39) for benzoic acid and some of its derivatives; for example—

All such formulæ, however, were rejected by Berzelius and his followers, on the ground that they represented a mode of combination unknown in mineral chemistry (see Pogg. Ann. xlvii. 289, 1838); until, in order to be able to represent the constitution of trichloroacetic acid as in harmony with the electro-chemical theory, Berzelius himself (*Lehrb. d. Chemie*, 5^e Aufl. i. 709) gave an additive formula to acetic acid, representing it as oxalic acid modified by the copula methyl: thus—

and the same idea was extended by Kolbe, in 1848 (*Handwörterb.* iii. 177 [article, *Formeln, chemische*]; also Ann. Ch. Pharm. lxxv. 288), to the whole series of acids homologous with acetic acid; and by Berzelius to the organic alkaloids, which he regarded as formed by the combination of ammonia with various copulae.

It is obvious, that every additive formula can be easily transformed into an equivalent substitutive formula; thus, for instance, Wurtz's formula for acetic acid, $\text{C}^{\text{H}}(\text{C}^{\text{H}})\text{C}^{\text{O}}\text{O}^{\text{H}}\text{O}$ (Ann Ch. Phys. [3] xxx. 502), which represents it as formic acid wherein methyl is substituted for hydrogen, is the substitutive equivalent of Berzelius's additive formula. All relations of composition and function can therefore be expressed almost equally well in either system. Nevertheless, there are some reasons for giving the preference in general to substitutive formulæ. One of the most important is, that by using the latter kind of formulæ, we can represent entire series (of homologous bodies, for example) by expressions of the same form, which is not always possible with additive formulæ. Thus, if we represent succinic acid as derived from two molecules of water by the substitution of the radicle $\text{C}^{\text{H}}\text{H}^{\text{O}}\text{O}^{\text{H}}\text{O}$ for H^{O} , H^{O} , we can

express all the homologous acids by similar formulæ; for instance, malonic acid = $\text{C}^{\text{H}}\text{H}^{\text{O}}\text{O}^{\text{H}}\text{O}$, oxalic acid = $\text{C}^{\text{O}}\text{O}^{\text{H}}\text{O}$; but if we write succinic acid thus—

$\text{C}^{\text{H}}\text{H}^{\text{O}}\text{O}^{\text{H}}\text{O}$, or, as two molecules of water to which the copula $\text{C}^{\text{H}}\text{H}^{\text{O}}\text{O}^{\text{H}}\text{O}$ is added, it

becomes impossible to represent oxalic acid by a comparable formula. Another somewhat similar objection to the use of additive formulæ is, that they are not applicable to inorganic and organic bodies alike. Thus, although we can easily express the relations between methylic and ethylic alcohols, or between ethylic alcohol, chloride of ethyl, and ethylamine by means of such formulæ, we cannot indicate the relation which exists between the alcohols and such bodies as hydrate of potassium; formulæ, however, which represent all these compounds as derived from water by the substitution of various radicles for one atom of hydrogen, render their mutual relations at once apparent.

A system of formulæ, partly additive and partly substitutive, is employed by Professor Kolbe. One or two specimens of his formulæ have already been given in this article. The chief points of difference between them and the formulæ employed in this work are that oxygen-compounds are employed, instead of hydrogen-compounds, as the types or standards of comparison, and that compounds containing only carbon, hydrogen, and oxygen are referred to the type $\text{C}^{\text{O}}\text{O}^{\text{H}}\text{O}$ (equivalent to $\text{CH}^{\text{H}}\text{O}$) instead of to the type $\text{H}^{\text{O}}\text{O}^{\text{H}}\text{O}$. This mode of formulating organic compounds is an extension of the views advanced by Frankland (Ann. Ch. Pharm. lxxxv. 364) regarding the constitution of the so-called organo-metallic bodies, and was in fact first suggested by the last-named chemist (see Proc. Roy. Inst. ii. 640, May 28, 1858). The manner of representing some of the most important classes of compounds, on this system, will be understood from the following examples:—

The acids of the acetic series are represented as formed from carbonic anhydride by the substitution of hydrogen or an alcohol-radicle for one equivalent of oxygen; the

* A similar formula for acetic acid had been previously suggested by Matteucci (Ann. Ch. Phys. iii. 134, 1833.)

aldehydes are represented as formed by the replacement of one equivalent of oxygen by hydrogen and one by an alcohol-radicle, and the ketones by the replacement of two equivalents of oxygen by alcohol-radicles. The replacement of three equivalents of oxygen by hydrogen or by alcohol-radicles gives the simple ethers, and the similar replacement of all the oxygen gives the alcohol-radicles as they exist in the free state, or their hydrides.

There are some relations of these substances which can be brought out more distinctly by comparing them to a carbon-compound as type than by referring them to the types H^2O and H^2 , as is done in the formulæ commonly used in this work; but the use of an oxygen-compound, such as carbonic anhydride, for this purpose, involves the occurrence of fractions of an atom of oxygen in the formulæ of all substances represented as formed by the substitution of an odd number of atoms of hydrogen, or of any monatomic radicle, for its equivalent of oxygen. This will be seen by referring to the formulæ of the acids homologous with acetic acid, and to those of the simple ethers as given above.

All the advantages of formulæ of this kind, without the inconsistency of being obliged to introduce half-atoms, may be secured by representing the compounds in question as derivatives of the type CH^4 . A few examples will be sufficient to show how this may be carried out.

Type CH^4 .

I.

II.

III.

IV.

V.

These formulæ express very clearly the relations of composition of the bodies represented by them; and if we possessed any reagent whereby we could replace carbon by other elements, in the same way that chloride and sulphide of phosphorus enable us to replace oxygen by chlorine and sulphur respectively, the transformations effected by it would be best represented by formulæ of this kind: just in the same sense that the formulæ $\begin{matrix} C^2H^3O \\ H \end{matrix} O =$ acetic acid, $C^2H^3O.Cl =$ chloride of acetyl, best correspond to the reactions produced by pentachloride of phosphorus. Comparatively few transformations, however, are as yet known which are better expressed by formulæ derived from the type CH^4 , than by those derived from the types HCl , H^2O , and H^2N , though, intrinsically, one set of formulæ is just as admissible, and just as logical, as the other.

With regard to the rational formulæ of polyatomic compounds, another question has arisen, which is one of form rather than of the meaning to be expressed. In many diatomic and polyatomic compounds, a certain dissymmetry of properties, if we may use

the expression, may be observed; that is, the same reaction can be produced twice or oftener with one molecule of the substance, but it does not take place with exactly the same facility each time. Thus, glycollic and lactic acids contain two atoms of hydrogen capable of being replaced by alcohol-radicles; but the replacement of only one atom can be effected by the ordinary processes of etherification, the second atom can only be replaced by indirect means. In order to express this peculiarity in the formulæ of these and similar substances, several chemists have adopted the expedient of writing one of the replaceable atoms as though it were combined with the remaining elements differently from the rest. The following examples will explain what is meant:

So long as such formulæ are understood to be descriptive merely, they are perfectly admissible, and may often be employed with advantage, as indicating, more exactly than the ordinary polyatomic formulæ—such as $\left(\begin{array}{c} (C^2H^2O)'' \\ H^2 \end{array} \right) O^2 =$ glycollic acid, $\left(\begin{array}{c} (C^2H^2O)'' \\ H^2 \end{array} \right) N$ = glycine or glycolamic acid—the properties of the substances to which they are assigned; but, if they are taken as actual expressions of the peculiarities of constitution on which these properties depend, they come to be of questionable service. For the unequal facility with which the two replaceable atoms of hydrogen in glycollic acid, for instance, can be replaced, is no proof that they are not combined in the same way. It may very well be that these two atoms, or even all four atoms of hydrogen, are perfectly equivalent to each other, so long as the original compound remains intact; but that, as soon as one atom is replaced by another element or radicle, the equilibrium of the whole group is modified in such a way that the similar replacement of another atom cannot be effected with the same ease.

On the other hand, however, there are facts which point to a real difference between one of the four units of combining capacity of an atom of carbon and the other three. Thus, for instance, the chloride of methyl formed by the action of chlorine on marsh-gas differs in some of its properties from that produced by the action of hydrochloric acid on methylic alcohol, or by the decomposition of trichloride of cacodyl; a fact which it is difficult to explain, except by supposing it to depend on the different position of the chlorine atom in the two compounds. Some very interesting and important consequences of this supposition have been developed by Butlerow (*Zeitschr. Chem. Pharm.* iv. 549); and by Erlenmeyer (*ibid.* v. 18). Should it, on further investigation, appear to be well founded, some expression of the facts upon which it is based will, of course, have to be given in our rational formulæ; and, in formulæ derived from the type CH^4 , this may easily be done. (See the formulæ of methyl and hydride of ethyl, methyllide of formyl and hydride of acetyl on p. 703.)

In conclusion, we must mention, for the sake of their historical interest, the *Synoptical formulæ* of Gerhardt and Chancel, although this mode of notation is probably no longer employed by any chemist. These formulæ may be considered as abbreviated modes of writing the equations of formation of the bodies which they represent. Thus, for instance, sulphobenzidic acid, formed by the union of one molecule of sulphuric acid and one molecule of benzene, with elimination of a molecule of water, may be represented by the synoptical formula $SO^{4-1} \left\{ \begin{array}{c} H.C^6H^4-2 \\ H \end{array} \right\}$, equivalent to the equation of formation $SO^2C^6H^4 = SO^2H^2 + C^6H^4 - OH^2$; similarly sulphobenzide may be represented by the synoptical formula $SO^{4-2} \left\{ \begin{array}{c} H.C^6H^4-2 \\ H.C^6H^4-2 \end{array} \right\}$, equivalent to the expression $SO^2H^2 + 2C^6H^4 = 2OH^2$. The following are additional examples, extracted from Gerhardt and Chancel's paper (*Comptes rendus des travaux chimiques*, vii. 65; March, 1861), together with the more detailed expressions to which they are equivalent:

Names of substances.	Synoptical formulæ.	Equivalent expressions.
Carbamic acid . . .	$CO^{3-1} \left\{ \begin{array}{c} H.H^3-2N \\ H \end{array} \right\}$	$CO^2H^3 + H^3N - OH^1$
Urea (carbamide) . . .	$CO^{3-2} \left\{ \begin{array}{c} H.H^3-2N \\ H.H^3-2N \end{array} \right\}$	$CO^2H^3 + 2H^3N - 2OH^1$
Carbanilic acid . . .	$CO^{3-1} \left\{ \begin{array}{c} H.C^6H^4-2N \\ H \end{array} \right\}$	$CO^2H^3 + C^6H^4N - OH^1$

Carbanilide	$\text{CO}^{2-2} \left\{ \begin{array}{l} \text{H.C}^{\text{H}^1-2}\text{N} \\ \text{H.C}^{\text{H}^1-2}\text{N} \end{array} \right.$	$\text{CO}^2\text{H}^2 + 2\text{C}^{\text{H}^1}\text{N} - 2\text{OH}^2$
Carbovinic acid	$\text{CO}^{3-1} \left\{ \begin{array}{l} \text{H.C}^2\text{H}^2-2\text{O} \\ \text{H} \end{array} \right.$	$\text{CO}^2\text{H}^2 + \text{C}^{\text{H}^1}\text{O} - \text{OH}^2$
Carbonate of ethyl	$\text{CO}^{3-2} \left\{ \begin{array}{l} \text{H.C}^2\text{H}^2-2\text{O} \\ \text{H.C}^2\text{H}^2-\text{O} \end{array} \right.$	$\text{CO}^2\text{H}^2 + 2\text{C}^{\text{H}^1}\text{O} - 2\text{OH}^2$
Urethane (carbamate of ethyl)	$\text{CO}^{3-2} \left\{ \begin{array}{l} \text{H.C}^2\text{H}^2-2\text{O} \\ \text{H}^2-2\text{N} \end{array} \right.$	$\text{CO}^2\text{H}^2 + \text{C}^{\text{H}^1}\text{O} + \text{H}^1\text{N} - 2\text{OH}^2$
Acetic acid	$\text{CO}^{3-1} \left\{ \begin{array}{l} \text{H.C}^{\text{H}^1-2} \\ \text{H} \end{array} \right.$	$\text{CO}^2\text{H}^2 + \text{CH}^1 - \text{OH}^2$
Acetone	$\text{CO}^{3-2} \left\{ \begin{array}{l} \text{H.C}^{\text{H}^1-2} \\ \text{H.C}^{\text{H}^1-2} \end{array} \right.$	$\text{CO}^2\text{H}^2 + 2\text{CH}^1 - 2\text{OH}^2$

It will be observed that the formulæ here given for acetic acid and acetone do not correspond to any process then known by which these bodies could be formed; but, if taken in an analytical, instead of in a synthetical sense, they indicate the manner in which these substances are decomposed when distilled with alkaline hydrates. The formulæ of urea, carbanilic acid, and carbanilide, must likewise be taken in an analytical sense merely.

Each synoptical formula can obviously express only one mode of formation or decomposition of a substance, and hence cannot be regarded as a general expression of its reactions; thus, considering the formation of benzamide from benzoate of ammonia by loss of water, and its decomposition into benzoic acid and ammonia, we may represent it by the synoptical formula

or

but neither of these expressions would indicate its formation by the action of chloride of benzoyl on ammonia. It is probably this want of generality which has prevented formulæ of this kind from coming into general use.—G. C. F.

FORMYL. CHO.—The radicle of formic acid and its derivatives, being the first term in the series of acid radicles $\text{C}^{\text{H}^1}\text{O}^{2-1}\text{O}$. The same term was formerly applied to the radicle CH: hence the names *chloroform*, *formonitride*, &c.; but it is better to denote this hydrocarbon-radicle by the term *xytyl*.

FORMYLIA, FORMYLAMINE. Names applied to the first base obtained by the action of ammonia on bromide of ethylene, and originally supposed to have the composition $\text{CH}_2\text{H}^2\text{N}$. (See ETHYLENE-BASES, ii. 687.)

FORMYLIN. The name given by Rochleder (Ann. Ch. Pharm. lxi. 120) to a base which he obtained by the decomposition of caffeine, and supposed to have the composition CH^1N . Wurtz, however, showed (Compt. rend. xxx. 9), that it is nothing but methylamine.

FORMYL-DIPHENYL-DIAMINE. See PHENYLAMINES.

FORSTERITE. A white or colourless translucent chrysolite occurring in small crystals on Vesuvius.

FORRESINIC ACID. The name given by Bastick (Pharm. J. Trans. viii. 339) to the acid resin produced by the action of nitric acid on copalin or Highgate resin (ii. 21).

FOURNETITE. A variety of tetrahedrite from Beaujeu (Rhône) and Val Godemar (Hautes Alpes), consisting, according to Mène (Compt. rend. li. 463; lii. 311), of $3\text{Cu}^2\text{S}.2\text{Sb}^2\text{S}^3$, together with PbS and Fe^2As^2 (in the mineral from Beaujeu) or Fe^1As^2 (in that from Val Godemar).

FOWLERITE. Crystallised rhodonite from Franklin, New Jersey. (See RHODONITE.)

FOYALITE. A rock resembling syenite, which forms the mountains Foya and Picota in the Monchique range (Algarvia in Portugal), and consists mainly of orthoclase associated with elaeolite and hornblende, and as accessory constituents, titanite, hexagonal pinchbeck-brown mica, magnetic iron-ore and iron-pyrites. Its structure is coarse to fine grained, also porphyritic. (Blum, Jahrb. Min. 1861, p. 426.)

FRACTURE OF MINERALS. The uneven or irregular surface produced by breaking amorphous minerals is distinguished, as:

1. *Conchoidal*, when the mineral breaks with curved surfaces like those of a shell; this kind of fracture is seen in flint.

2. *Uneven*, when the surface of fracture is rough, with numerous small elevations and depressions.

3. *Splintery*, when the broken surface exhibits protruding points.

4. *Hackly*, when the elevations are sharp and jagged as in broken iron.

The fracture is, for the most part, of constant character in the same mineral species; but the same kind of fracture, especially the uneven and the splintery, is common to so many minerals, as to render these characters of comparatively little value in determining species.

FRAGARIA. *Strawberry.*—Buignet (J. Pharm. [3] xxxvi. 81, 170) has examined several varieties of strawberry, and finds that the free acid contained in them is malic acid, and that the sugar consists of cane sugar, dextroglucose and lævoglucose in varying proportions. The cane-sugar, which is contained in cells distinct from those which contain the malic acid, appears to be the sugar first formed in the fruit, and to be more or less converted into the other kinds of sugar during the osmotic mixture of the several liquids contained in the cells.

FRAIDRONITE. A rock occurring near Lozère in the western range of the Cévennes, where it often traverses the granite and slates. It usually appears to consist of a dark green felspathic basis, mixed with a large quantity of bronze-like mica. The most ordinary variety contains in 100 parts:

Felspar and Mica.							
50.0	SiO ₂	Al ₂ O ₃	MgO	FeO	H ₂ O	FeCO ₃	CaCO ₃
	15.0	5.0	3.4	4.0	1.5	17.5	3.6

The constituents bracketed together seem to consist of a mineral resembling chlorite which serves to cement together the felspar and mica; calespar and spathic iron are also present, but do not appear to be essential constituents of the formation. (Lau, Ann. Min. [5] vi. 412.)

FRANCOLITE. A fluorapatite occurring in spherical aggregations at Wheal Francis, near Tavistock in Devonshire (i. 349).

FRANGULIN. C₁₂H₁₀O^s (A. Casselmann, Ann. Ch. Pharm. civ. 77; Jahresb. f. Chem. 1857, p. 522).—A yellow crystallisable colouring matter, contained in the bark of the berry-bearing alder (*Rhamnus Frangula*). It is accompanied by an amorphous resinous yellow substance, and occurs most abundantly in the bark of the older branches, that of the younger branches containing a larger proportion of the resinous constituent. The yellow substance, called *Rhamnozanthin*, obtained by Buchner (Jahresber. 1853, p. 536) from the root bark of the same shrub was, according to Casselmann, impure frangulin.

Preparation.—1. The comminuted bark is repeatedly exhausted with ammoniacal water at the boiling heat; the dark red extracts are mixed with hydrochloric acid; and the slowly-depositing, brown-black precipitates thereby produced are washed, and treated at the boiling heat with alcohol of 80 per cent., with addition of neutral acetate of lead, nearly the whole then dissolving and forming a brownish-yellow solution. This solution is further treated with neutral acetate of lead to precipitate tannin, &c.; the hot filtered liquid is mixed with water till it becomes strongly turbid, then heated till the turbidity disappears; the liquid is left to itself for a week; and the frangulin which separates is purified by repeated crystallisation from boiling alcohol.—2. The alcoholic solution, after being filtered from the precipitate produced by neutral acetate of lead, is shaken up with hydrate or with basic acetate of lead, the precipitate, which contains all the frangulin, is suspended in very dilute alcohol and decomposed by sulphydric acid; the sulphide of lead is exhausted by boiling alcohol, which leaves the greater part of the resinous matter undissolved; the solution is diluted with water; and the frangulin which separates is repeatedly crystallised from alcohol.

Pure frangulin forms lemon-yellow crystalline masses (composed of microscopic square plates), having a dull, silky lustre, tasteless and inodorous. It melts at about 249° C., and at the same temperature begins to sublime with partial decomposition in golden-yellow microscopic needles. It is insoluble in water, soluble in 160 pts. of warm alcohol of 80 per cent., nearly insoluble in cold alcohol, sparingly soluble in boiling ether, soluble in hot fixed oils, benzene, and oil of turpentine. When dried at 100° C., it has the composition indicated by the formula above given.

Frangulin does not appear to form definite compounds with bases. It dissolves with purple-red colour in *alkalis*, and is precipitated yellow by *acids*. It is not precipitated by metallic salts. With strong sulphuric acid, it forms at ordinary temperatures a dark-red solution, which becomes brown when heated, and from which it is precipi-

rated by water. Strong *nitric acid* dissolves it at the boiling heat without decomposition. Fuming *nitric acid* dissolves it, with evolution of nitrous vapours, forming oxalic acid, and if the action has not been too violent, or the temperature too high, another acid called *nitrofrangulic acid*, to which Casselmann assigns the formula $C^{10}H^{11}A^{3}O^{37}$ or $C^{10}H^{22}N^{10}O^{37}$, representing its formation by the equation:

Hesse (Ann. Ch. Pharm. cxvii. 349) suggests for this acid the formula $C^{10}H^{11}N^{10}O^{18}$. *Nitrofrangulic acid* crystallises from its aqueous solution in small yellow needles; from its alcoholic solution in long, silky, orange-red needles grouped in stars. It is inodorous, has a bitterly astringent taste; detonates when heated; dissolves sparingly in cold, more abundantly and with dark crimson colour in boiling water, easily in alcohol and in ether. It is scarcely attacked by strong acids at ordinary temperatures. *Alkalis* dissolve it with violet-red colour. *Sulphydric acid* passed continuously into the aqueous solution, colours it violet-blue and forms a precipitate of sulphur; the solution then gives a violet-blue precipitate with *hydrochloric acid*.

The solution of the acid forms with the salts of the earth-metals and heavy metals precipitates which are generally of a fiery-red colour.

The *silver-salt*, $C^{10}H^{10}AgN^3O^{37}$ crystallises in cinnabar-red needles. The *copper-salt*, $C^{10}H^{10}CuN^3O^{37}$, is obtained as a violet-blue precipitate, becoming violet-red when dry. Both detonate with great violence when heated.

FRANKINCENSE. An oleo-resin which exudes spontaneously from the spruce fir (*Abies excelsa*). According to Caillot (J. Pharm. xvi. 436), it contains 32.00 per cent. volatile oil, 7.40 resin insoluble in alcohol, 7.40 abietin, 11.47 abietic acid, and 5.57 succinic acid and extractive matter. When melted in water and strained through a cloth, it forms *Burgundy pitch*. (Pereira's *Materia Medica*, 4th ed. ii. 366.)

The substance used as incense in religious ceremonies is *OLIVANUM* (q. v.)

FRANKLINITE. A mineral consisting mainly of the sesquioxides of iron and manganese combined with the protoxides of zinc and iron. It occurs crystallised in forms of the regular system, chiefly the octahedron and dodecahedron, also the cube, ienai-tetrahedron 202 (fig. 180), and triakis-octahedron, 20 (fig. 183), and in combinations like figs. 194, 195, 196, 199, 200, 202, and others. Cleavage octahedral, indistinct. It likewise occurs massive, coarse or fine-granular to compact. Hardness = 5.5 to 6.5. Specific gravity = 5.07 to 5.09. Lustre metallic. Colour iron-black. Streak dark reddish-brown. Opaque. Fracture conchoidal. Brittle. Acts slightly on the magnet. Infusible before the blow-pipe; when strongly heated on charcoal, it yields oxide of zinc; gives the manganese reaction with borax.

From the mean of five analyses by Rammelsberg (*Mineralchemie*, p. 169), it is found to contain 25.30 ZnO, 64.51 FeO², and 13.51 Mn²O³ = (103.32) or 45.16 iron, 9.38 manganese, 20.30 zinc, and 25.16 oxygen (= 100), whence Rammelsberg deduces the formula $\frac{1}{2}FeO \left\{ \frac{1}{2}Fe^{2}O^3 \right\} \frac{1}{2}Mn^{2}O^3$ which is of the general form $3M'O.R^2O^3$ or $\left(\frac{M'}{R^2} \right)^2 O^3$.

Franklinite was formerly regarded as belonging to the spinel group $M'O.R^2O^3$, with which, indeed, it agrees in crystalline form; but this formula appears to have been deduced from incorrect analyses.

Franklinite occurs abundantly at Hamburg, New Jersey, near the Franklin furnaces, together with red oxide of iron and garnet, in granular limestone; also at Stirling Hill in the same locality, where it is associated with willemite. The attempts to work it for zinc have proved unsuccessful; but it is ground up to a dark paint, and used also as an ore of iron. The zinc is said to give increased tenacity to the iron. Franklinite is also said to occur in amorphous masses at Altenberg, near Aix-la-Chapelle. (Dana, ii. 106.)

FRAXETIN. $C^{14}H^{20}O^8$. (Salm-Horstmar, Pogg. Ann. cvii. 327.—Rochleder, *ibid.* 331.)—A compound formed, together with glucose, by digesting fraxin with dilute sulphuric acid. (See FRAXIN.)

It separates from the acid liquid in colourless needle-shaped crystals, or dendritic groups, and when recrystallised from alcohol, forms rectangular rhombic or six-sided tablets. It is inodorous, but has a slightly astringent taste. It dissolves in 1000 pts. of cold, and 300 pts. of boiling water, the hot concentrated solution having an acid reaction; somewhat more easily in alcohol, and to a slight extent in warm ether. It melts at the melting point of tin, without turning brown, and solidifies in the crystalline form on cooling.

Fraxetin dissolves in strong *sulphuric acid*, forming a bright yellow solution, from which, after dilution with water, it separates in the crystalline form on careful addition of ammonia. *Hydrochloric acid* likewise dissolves it without decomposition.

When thrown into *nitric acid*, it colours the liquid successively dark violet, garnet-red, rose-red and yellow; but the solution ultimately becomes colourless. The aqueous solution of fraxetin is coloured yellow by *ammonia* and *alkaline carbonates*, also by *baryta*, *strontia*, and *lime* in the solid state, the baryta and strontia becoming covered with a red and afterwards with a blackish green deposit, and the lime first with an orange-coloured, and then with a brownish deposit. The carbonates of the earth-metals colour the solution of fraxetin yellow, and give rise to the formation of a precipitate insoluble in pure water, and exhibiting a green fluorescence. The *actatus of barium* and *strontium* colour the solution yellow, and on evaporating it, a green substance remains with the crystals. *Nitrate of silver* added to the solution forms a black cloud; *ferric chloride* colours the liquid greenish-blue; *carbonate of lead* immersed in it, acquires a lemon-yellow colour. Fraxetin dissolves in *acid sulphite of ammonium*, forming a solution which is merely coloured yellow by ammonia, being thereby distinguished from *æsculetin*, the yellowish solution of which in acid sulphite of ammonium assumes a darker colour on addition of ammonia, and when subsequently shaken up with air, becomes blood-red, and finally dark indigo-blue. (Rochleder, *Gm.* xvi. 24.)

FRAXIN. *Paviin*.—A fluorescent substance existing in the bark of the common ash-tree (*Fraxinus excelsior*), and probably in that of other species of *Fraxinus*; also, together with *æsculin*, in the bark of the horse-chestnut (*Æsculus Hippocastanum*); and apparently of all species of the genera *Æsculus* and *Pavia*. L. Gmelin, in 1840 (*Ann. Ch. Pharm.* xxxvii. 352), first observed that a decoction of the bark of the manna ash (*Fraxinus ornus*, L.), exhibits a peculiar blue colour by reflected light, and attributed this appearance to a peculiar iridescent substance (*Schillerstoff*) existing in the bark. Salm-Horstmar in 1856 (*Pogg. Ann.* xcvii. 637) observed a similar appearance (fluorescence) in the infusion of the bark of *Fraxinus excelsior*, and in 1857 (*Pogg. Ann.* c. 607),* he obtained the substance on which this effect depends, in the separate state, examined many of its properties, and gave it the name of fraxin. This substance was further examined and analysed by Rochleder (*Pogg. Ann.* cvii. 331). Stokes in 1858 (*Chem. Soc. Qu. J.* xi. 17) obtained from horse-chestnut bark, previously known to contain a substance exhibiting a sky-blue fluorescence, viz. *æsculin* (i. 60), another fluorescent substance exhibiting a bluish-green tint, to which he gave the name paviin, from the genus *Pavia*, in all species of which it appears to exist in greater abundance than in the genus *Æsculus*. Subsequently, in 1859 (*Chem. Soc. Qu. J.* xii. 126), Stokes suggested that this body, paviin, was identical with fraxin, and the correctness of this idea has been demonstrated by the experiments of Rochleder, who has also obtained fraxin from horse-chestnut bark.

Preparation.—a. From the bark of *Fraxinus excelsior*. The decoction of the bark stripped at the flowering time is precipitated by neutral acetate, and the filtrate by basic acetate of lead; the latter precipitate is diffused in water and decomposed by sulphydric acid; and the liquid is evaporated to the crystallising point. (Salm-Horstmar.)

b. *From Horse-chestnut bark*.—1. The aqueous decoction of the bark is mixed when cold with such a quantity of a ferric salt, that on adding ammonia to a sample of the liquid, the precipitate immediately separates in flocks, and the supernatant liquid exhibits a yellow colour and strong fluorescence; the whole is then precipitated by ammonia; about one-fourth of the filtrate precipitated by acetate of lead, avoiding an excess; the precipitate immediately redissolved by addition of acetic or of dilute nitric acid; this solution added to the remaining three-fourths of the above-mentioned filtrate after the latter has been acidulated; the mixture precipitated by ammonia (A), the filtrate with basic acetate of lead (B); the two precipitates separately dissolved in acetic acid; and the filtered solutions left to crystallise.

The solution of A yields fraxin (paviin), and that of B, *æsculin* (Stokes). Fraxin or paviin may also be separated from *æsculin* by its greater solubility in ether. (i. 60.)

2. Horse-chestnut bark is exhausted with alcohol of 35° Bm.; the filtered decoction is precipitated by an alcoholic solution of neutral acetate of lead; the precipitate (containing fraxin and the tannic acid of the bark) is washed with alcohol, suspended in water, and decomposed by sulphydric acid; the fluorescent watery liquid is evaporated in vacuo over oil of vitriol; the pulverised residue is treated with a small quantity of water at 0° C.; the tannic acid solution is rapidly separated from the crystals of fraxin; and the crystals are purified by recrystallisation. (Rochleder.)

Properties.—Fraxin crystallises in tufts of yellowish-white needles (Salm-Horstmar); in colourless crystals resembling those of sulphate of zinc (Rochleder). It

* Keller, in 1853 (*Repert. Pharm.* xlv. 438), by precipitating the aqueous decoction of ash-bark with basic acetate of lead, and evaporating the filtrate, obtained bitter prisms, regarded by him as a base, and designated by Buchner as *fraxin* line. Rochleder and Schwarz (*Ann. Ch. Pharm.* lxxxvii. 186), by the same process, obtained a bitter brownish-yellow extract containing needle-shaped crystals, which, when purified, proved to be nothing but mannite, a result corroborated by Stenhouse (*Phil. Mag.* [4], vii. 501).

is inodorous, but has a slightly bitter and afterwards astringent taste. It dissolves sparingly in cold, easily in hot water, sparingly in cold, moderately in hot alcohol; and is separated from the alcoholic solution by animal charcoal; insoluble in ether (Salm-Horstmar), more soluble in ether than aesculin (Stokes).* The concentrated aqueous solution is yellow and has an acid reaction; when largely diluted, it exhibits by daylight a strong blue fluorescence (blue-green according to Stokes, who moreover, finds that the optical properties of fraxin from ash-bark, and of pavlin from horse-chestnut bark, are absolutely identical). The fluorescence is increased by the presence of a trace of alkali, but disappears on addition of acids. The alcoholic solution is likewise fluorescent (Salm-Horstmar).

The aqueous solution is coloured sulphur-yellow by alkalis, the crystals also turning yellow in air containing ammonia; it is coloured green by ferric chloride, and then yields a lemon-yellow precipitate; it likewise forms a yellow precipitate with acetate of lead. (Salm-Horstmar.)

Fraxin (from ash-bark) melts at a gentle heat (Salm-Horstmar), at 320° C. forming a red liquid (Rochleder) and solidifies to an amorphous mass, which, according to Rochleder, dissolves in water with orange-red colour. At a higher temperature, it decomposes, yielding a crystalline sublimate, soluble in water, and forming a solution which becomes yellow and fluorescent on addition of ammonia.

Fraxin digested with dilute sulphuric acid is resolved into glucose and fraxetin. The equation which represents this decomposition, varies of course, according to the formula assigned to fraxin, which cannot be considered as definitively settled. Rochleder, from his first analyses of fraxin (from ash-bark) dried between 100° and 120°, assigned to it the formula $C^{42}H^{23}O^{27}$ or $C^{42}H^{46}O^{27}$, and represented its decomposition under the influence of acids by the equation:

Wurtz, however (Rép. Chim. pure, i. 473), concluded from Rochleder's own analyses, that its formula was most probably $C^{72}H^{22}O^{28}$ or $C^{72}H^{20}O^{13}$, according to which its decomposition would be represented by the equation:

More recently, Rochleder (Pogg. Ann. cvii. 331) from the quantity of glucose yielded by the decomposition of fraxin (from horse-chestnut bark) concludes that its formula is $C^{72}H^{30}O^{17}$, its decomposition taking place as shown by the equation:

FRAXININE. See foot-note, p. 708.

FRAXINITE. A name applied by Mouchon (Vierteljahrs. per Pharm. iii. 433) to the dried extract of ash-leaves, previously precipitated by basic acetate of lead and freed from excess of lead by sulphydric acid. It is not a definite substance.

FRAXINUS. The dried leaves of the common ash (*Fraxinus excelsior*) contain, according to Sprengel (J. f. ökonom. Chem. vii. 269) 39.3 per cent. of substances soluble in water (tannin, &c.), 42.3 per cent. matter soluble in dilute potash, also wax, resin, woody-fibre, &c. and 6.22 per cent. ash. According to Garot (J. Pharm. [3] xxiv. 308) the leaves contain a large quantity of malate of calcium.

The soft white wood of the same tree, of specific gravity 0.7 to 0.9, yields 2.3 per cent. ash (Mollérat), 0.66 (Sprengel).

The following is the composition of the ash of the wood and leaves, according to Sprengel's analysis.

	K ² O	Na ² O	CaO	MgO	Al ² O ³	Fe ² O ³	Mn ² O ³	SO ³	P ² O ⁵	SiO ²	Cl
Leaves .	22.2	2.6	50.3	6.3	0.02			5.1	6.6	2.3	3.9 = 99.5
Wood .	22.0	34.3	23.1	5.8	3.3		1.6	3.1	1.5	3.3	2.0 = 100.0

The existence of a fluorescent substance, fraxin, in ash bark has been noticed in a preceding article. The aqueous decoction of the bark exhibits the blue or blue-green fluorescence due to fraxin; the alcoholic extract exhibits a blood-red fluorescence from admixture of chlorophyll with the fraxin. (Salm-Horstmar.)

The seed of the ash tree, formerly used officinally, as *Semen lingue avis*, yields to ether 16 per cent. of an oil having the odour of bugs. (Keller, Buchn. Repert. xlv. 439.)

The bark of the manna ash (*Fraxinus ornus*, L.; *Ornus europæus*, Pers.) contains manna, which exudes from it, partly spontaneously, but more freely from incisions. The same bark contains a fluorescent substance (L. Gmelin, p. 708), probably fraxin,

* This observation applies to fraxin from ash-bark, as well as to pavlin from horse-chestnut bark. (Chem. Soc. Qu. J. xii. 17.)

and according to Dufour (Compt. rend. li. 31), easily yields a fluorescent aqueous infusion.

FREIBERGITE. An argentiferous variety of tetrahedrite. (Dana, ii. 512.)

FREISLEBENITE. *Antimonial Sulphuret of Silver.* *Schilfglaserz.*—A mineral occurring in monoclinic prisms longitudinally striated and cleaving parallel to ∞P . Hardness = 2–2.5. Specific gravity 6.4–6.194 (Hausmann). Lustre metallic. Colour and streak light steel-grey, inclining to silver-white; also blackish lead-grey. Yields easily to the knife and is rather brittle. Fracture conchoidal to uneven. Before the blowpipe on charcoal, it emits copious white vapours and a slight sulphurous odour, deposits oxide of antimony and oxide of lead round the assay, and finally leaves a white metallic globule.

Analyses.—1. From the Himmelsfürst mine near Freiberg. Specific gravity 6.194 (Wöhler, Pogg. Ann. xvi. 146).—2. From Hiendelencina in Spain. Specific gravity 6.6–5.7 (Escosura, Ann. Min. [5] viii. 495).—3. From Przibram, Bohemia (Payr, Jahresber. f. Chem. 1860, p. 746).

	S	Sh	Pb	Ag	Cu	Fe	
1.	18.74	27.38	30.27	22.93	1.22	0.11	= 100.65
2.	17.60	26.83	31.90	22.46	.	.	= 98.78
3.	18.41	27.11	30.77	23.08	.	0.68	= 100.05

From the second analysis, Rammelsberg (*Mineralchemie*, p. 82) deduces the formula $9M^2S_4Sb^2S^3$ which may be supposed to be made up of $3(2M^2S.Sb^2S^3) + 3M^2S.Sb^2S^3$, or $3M^2Sb^2S^3.2M^2SbS^3$, the first member of which is analogous to Brogniardite or Jamesonite, the second to red silver ore and Boulangerite.

Freislebenite occurs also at Kupnik in Transylvania and at Ratiboritz, the ore of this last region containing bismuth, according to Zincken. An antimonial sulphide of silver is said to occur with native silver and native copper at the copper mines of Michigan. (Dana, ii. 79).

FRENCH BERRIES. See YELLOW BERRIES; also RHAMNUS.

FRENCH POLISH. A solution of shellac in alcohol, sometimes also containing gum elemi and copal. (See *Ure's Dictionary of Arts, &c.*, ii. 298.)

FRITILLARIA IMPERIALIS. *Crown Imperial.*—The bulbs of this plant are recommended by Basset (Compt. rend. xxxvii. 408) as a substitute for the potato, especially as a source of starch, of which they contain a rather larger proportion than the potato, as will be seen by the following table.

	Water.	Starch.	Soluble matter.	Dry residue.
Potato	70	20	4	6
Crown Imperial . .	68	23	5	4

FRITT. A term applied to the mixture of the materials for glass-making, after it has been calcined at a heat not sufficient to melt it.

FRUIT. The word fruit, in botanical language, signifies the ovary or seed-vessel arrived at maturity, or in its progress towards maturity after the impregnation of the seed. Every fruit consists of two parts, the seed and the pericarp, the latter comprising everything that is external to the seed, and being formed of the integuments of the ovary, often greatly thickened and hardened, together with any parts of the flower, such as bracts, calyxes, &c. that may remain attached to the ovary after impregnation. The pericarp, moreover, consists of three parts, the epicarp, which is the external integument or skin, the endocarp or putamen, which is the inner coat or shell, and the sarcocarp or mesocarp, intermediate between the other two, and generally having a more or less fleshy consistence; it is, in fact, the sarcocarp which forms the fleshy or pulpy mass of those succulent fruits, such as the apple, pear, peach, plum, grape, &c., to which the term fruit is mostly applied in ordinary language.

All parts of the flower are modifications of the leaf, the ovary in particular being made up of a leaf or a number of leaves folded or rolled up. Hence it may be expected that the fruit in its early stages of development, will have much the same chemical composition as the leaves themselves, and will be acted upon in the same manner by external agencies. Unripe fruits are, in fact, almost always green, and, like other green parts of the plant, decompose the carbonic acid of the air, liberating the oxygen and assimilating the carbon, and forming within their cells a variety of compounds, some soluble in water, such as vegetable acids, gum, and sugar, others insoluble, such as cellulose, pectose, and starch; at the same time they take up a certain amount of inorganic salts. During the whole of this stage, the fruit increases rapidly in bulk and weight. But as it approaches maturity, it loses its green colour, becoming brown, yellow, or red, and then no longer acts on the air like the leaves, but on the contrary absorbs oxygen, which unites with a portion of the carbon and hydrogen of the fruit, converting them into carbonic acid and water, which are given off. In this latter stage, indeed, the fruit undergoes a slow combustion, several of the proximate principles which it contains in the unripe state, chiefly the vegetable acids and tannin, being

thereby burnt away, so that the fruit becomes less sour and astringent; at the same time, the starch in the cells of the fruit is transformed into sugar, and the insoluble pectose into pectin and other soluble substances of allied composition, and having more or less of a gelatinous character. It is in this state that the fruit is generally eaten; if left for a longer time on the tree, and in many cases by mere exposure to the air after removal, it undergoes a further oxidation, by which the sugar and the remaining acid are likewise destroyed, so that the fruit becomes insipid; in this state it is said to be over-ripe. After a still longer time, the cellulose itself is attacked, so that the pericarp is ultimately destroyed and the seed set at liberty.

The diminution of acidity in fruits as they ripen, is sometimes attributed to neutralisation of the free acids by alkalis conveyed to the fruit by the sap; the sour taste is also said to be masked by the sugar and gelatinous substances developed in the course of maturation. The latter explanation is doubtless true to a certain extent, but with regard to the former, direct experiments by Decaisne and Frémy have shown that the proportion of mineral bases does not increase as the fruit ripens, but that, on the other hand, the proportion of acid in the ripe fruit is always less than in unripe, the decrease, as already observed, being due to oxidation. (Pelouze et Frémy, *Traité*, iv. 361.)

The following analyses by Bérard (*Gmelin's Handbuch*, viii. [1] 154) of fruits in the ripe and unripe state — which must be regarded as merely approximate — confirm in a general way the view of the ripening process above given, showing that, as the fruit ripens, the sugar increases, the gum sometimes increases, sometimes decreases, the woody fibre increases to a certain extent absolutely, but diminishes relatively to the weight of the entire fruit. With regard to the relative quantity of acid in the ripe fruit, Bérard's analyses show an increase in most cases, which is contrary to the results obtained by Frémy; the latter are doubtless the more trustworthy of the two.

Composition of ripe and unripe Fruit. (Bérard.)

	Summer Peaches.		Greengages.		Apricots.		
	unripe.	ripe.	unripe.	ripe.	unripe.	somewhat ripe.	ripe.
Chlorophyll	0.27	0.0	0.03	0.08	0.04	0.03

	100.00	100.00	100.00	100.00	100.00	100.00	76.85

In the gooseberries, the seeds as well as the pulpy matter are included in the woody fibre. The hard pear was ripe, and analysed immediately after it was plucked; the

soft pear was of the same variety, and had been kept for some time exposed to the air, the oxygen of which it had converted, without change of volume, into carbonic acid, losing at the same time 0.77 per cent. carbon and becoming richer in sugar and poorer in gum and woody fibre. The over-ripe pear, also of the same variety, had been kept till its weight was reduced from 100 to 76.85 parts.

A very important part of the ripening process in succulent fruits, such as the apple, pear, plum, grape, &c., those in short to which the term fruit is applied in ordinary language, consists in the gradual transformation of substances of the pectous group.

Unripe fruits contain pectose, a substance insoluble in water, alcohol, and ether; which, by the action of the acids in the fruit, and of a peculiar ferment called pectase, is gradually transformed into other substances, pectin, pectic acid, pectosic acid, &c., all soluble in water, possessing more or less of a gelatinous character, and differing in composition from pectose only by containing one or more molecules of water in addition. The first change appears to consist in the conversion of the pectose into pectin and parapectin by the action of the acids (chiefly citric and malic) of the fruit under the influence of heat, the fruit at the same time losing its hardness. As the process of ripening advances, the pectin and parapectin likewise disappear, being converted successively, by the action of pectase, into pectosic, pectic, and metapectic acids. Over-ripe fruits always contain metapectic acid, without a trace of pectin.

The conversion of the starch of the unripe into the sugar of the ripe fruit is effected partly by the citric and malic acids, partly by the metapectic acid.

When fruits are boiled, the formation of pectin takes place in the same manner as in the ripening, the action being likewise accelerated by the presence of acids. The formation of jelly, which takes place after some time, depends upon the conversion of pectin, by the action of pectase, into pectic or pectosic acid, or on the solution of the pectic acid in the salts of an organic acid contained in the fruit. The juice of gooseberries often gelatinises very quickly when mixed with that of raspberries; because the latter is rich in pectase, which converts the pectin of the former into gelatinous pectosic acid. (Frémy, *Ann. Ch. Phys.* [3] xxiv. 5; *Jahresber. f. Chem.* 1847-8, p. 807.)

According to Buignet (*Ann. Ch. Phys.* [3] lxi. 230), the sugar of fruits is formed, not from starch, but from an astringent substance resembling tannin, which is contained in the unripe fruit, and diminishes in quantity as the fruit ripens. This substance is said by Buignet to unite with iodine even more readily than starch, forming a colourless insoluble compound, which is converted by dilute acids into dextroglucose, identical with that formed from starch. Buignet further states, that the presence of starch cannot be detected in any green fruit, excepting the banana, either by iodine or by the microscope.

Payen, on the other hand (*Compt. rend.* liii. 313), has given a method by which the presence of starch in unripe fruits and its gradual conversion into sugar may be easily demonstrated. A thin slice cut out of the middle of the fruit is washed with water, and immersed in an aqueous solution of iodine mixed with a little alcohol; a blue colour is then immediately produced, varying in intensity according to the quantity of starch present. The reaction is, however, often masked by the presence of coloured or colouring matters, or of nitrogenous compounds in the fruit; moreover, the starch, when present in very small and only partially united granules, quickly loses the colour produced by iodine.

These or similar causes of error may perhaps have led to the negative results obtained by Buignet as to the presence of starch in unripe fruits.

The sugar of fruits consists partly of cane-sugar, $C^{12}H^{22}O^{11}$, partly of inverted sugar, $C^{12}H^{24}O^{12}$, a lævo-rotatory uncrystallisable sugar, identical in composition and optical rotatory power with the mixture of lævo- and dextro-glucose produced from cane-sugar by the action of acids, or of Berthelot's glucose-ferment (*q.v.*). According to Buignet (*loc. cit.*), the cane-sugar is formed first, and is gradually but in most cases only partially transformed, during maturation, into inverted sugar, the changes being produced, not by the action of acids (for the quantity of inverted sugar in different fruits bears no proportion to the quantity of acid present), but to a nitrogenous substance resembling Berthelot's glucose-ferment obtained from yeast. This statement respecting the conversion of the cane-sugar into inverted sugar is, however, not quite in accordance with the observations of Berthelot and Buignet (*Compt. rend.* li. 1094) on the formation of sugar during the ripening of oranges; from which it appears that the inverted sugar predominates in the unripe, and the cane-sugar in the ripe fruit, and that the weight of the inverted sugar alters but little, whereas that of the cane-sugar increases during ripening in proportion to the weight of the entire fruit, as well as to that of the juice and of the solid substances contained in it.

The following table contains the analyses of a considerable number of ripe fruits by Fresenius, and others working under his direction (*Ann. Ch. Pharm.* ci. 219; *Jahresber. f. Chem.* 1857, 636). The fruit having been pressed or saturated, and the soluble and

insoluble portions separated by straining through a colander, determinations were made in separate portions of the former; of the amount of dry substance, ash, sugar (by means of Fehling's solution of cupric oxide and soda), free acid (by titration with caustic soda), and albuminous substances (by determining the amount of nitrogen, and reckoning 100 pts. of albuminous substances for every 15.5 nitrogen). The insoluble portion was dried at 100° C., and the amount of ash determined; when possible, the weight of the stones or kernels was separately estimated; and a separate portion of the insoluble matter was digested for some time with dilute sulphuric acid, to determine the amount of pectous substances left undissolved by that acid.

The *sugar* in the table consists of glucose and fruit-sugar (dextro- and lævo-glucose); the amount of *free acid* is reduced to its equivalent in malic acid; *pectous substances*, &c., denotes soluble substances of the pectous group, together with gum, colouring matter, suspended fat, and combined organic acids. The *ash* of the insoluble portion is already included in the weight of the kernels, skins, &c., and is therefore placed within brackets.

From these analyses, the following comparative estimates may be made of the average amount of sugar, free acids, pectin, &c., in different kinds of fruit.

I. Comparison of Fruits as to their average Amount of Sugar.

	Per cent.		Per cent.
Peach	1.57	Currant	6.10
Apricot	1.80	Mussel Plum	6.26
Plum, round red	2.12	Gooseberry	7.15
Greengage	3.12	Red Pear	7.45
Mirabelle	3.58	Apple	8.37
Raspberry	4.00	Sour Cherry	8.77
Blackberry	4.44	Mulberry	9.19
Strawberry	5.73	Sweet Cherry	10.79
Bilberry	5.78	Grape	14.93

II. Comparison of Fruits as to their average Amount of free Acid, reduced to its Equivalent in Malic acid.

	Per cent.		Per cent.
Red Pear	0.07	Blackberry	1.19
Mirabelle	0.58	Sour Cherry	1.28
Sweet Cherry	0.62	Plum, round red	1.30
Peach	0.67	Strawberry	1.31

Bilberry	100	12.05	16.91	Apple	100	16.89	3.61
Gooseberry	100	12.18	3.57	Greengage	100	18.52	1.22
Mirabelle	100	13.04	1.53	Sweet Cherry	100	18.61	1.53
Apricot	100	13.31	2.07	Grape	100	22.81	5.81

The very small amount of albuminous substance in fruit's (see Table, pp. 713-715) shows that they cannot be regarded as nutritious articles of diet; in fact, an egg weighing 45 grms., and containing 5 grms. of albuminous matter, is equivalent in nutritive power to 550 grms. of cherries, 690 grms. grapes, 970 grms. strawberries, 1260 grms. apples, and 2000 grms. (or 4 lbs.) of red pears. The great excess of non-azotised matter in fruits shows that they possess rather the character of so-called respiratory food. In this respect a pound of starch, or about 5.5 lbs. of potatoes, might be replaced by 6.4 lbs. grapes, 6.5 lbs. greengages, 6.7 lbs. cherries, 6.7 lbs. apples, 7.8 lbs. red pears, 7.8 lbs. mussel plums, 9.4 lbs. gooseberries, 10.8 lbs. currants, 12.3 lbs. strawberries, and 12.9 lbs. raspberries.

The value of fruit as an article of diet depends, however, chiefly on its refreshing character and agreeable taste, on the demulcent qualities of the gum and pectin, and on the physiological action of the free acid and alkaline salts contained in it. The efficacy of lemon-juice as a remedy for sea-scurvy, may be attributed in a great degree to the large quantity of potash-salts which it contains, inasmuch as the deficiency of potash in the salt-meat, which forms so large a proportion of the diet of sea-faring men, appears to be one of the chief causes of that disease.

The agreeable taste of fruit depends partly on its aroma, partly on a due proportion between the acid, sugar, gum, pectin, &c., and between the water, the soluble, and the insoluble constituents. Luscious fruits, like the peach, greengage, and mulberry, which seem to melt in the mouth, contain a very large proportion of soluble substances. A due proportion of gum, pectin, and other gelatinous substances serves to mask the taste of the free acid, if present in rather large proportion as compared with the sugar. Such is the case with the peach, apricot, and greengage (Table III., p. 716), which contain but a small quantity of sugar as compared with the free acid, but a large proportion of gum and pectous substances.

The very sour taste of certain baccate fruits, as the currant and gooseberry, arises from the presence of a considerable quantity of free acid, with only a small quantity of gum and pectin to disguise it.

The proportion of sugar in fruits is largely increased by cultivation, as may be seen by comparing the composition of the wild and cultivated strawberries and raspberries in the table on p. 713. (Fresenius.)

FUCUS. See SEA-WEED.

FUCUSAMIDE. $C^{12}H^{11}N^2O^2$.—A compound isomeric with furfuramide, and obtained from fucosol in the same manner as furfuramide from furfurol, namely by the action of ammonia; but as fucosol is much less soluble in ammonia than furfurol, a larger quantity of ammonia must be used in the preparation, and the two liquids mixed by frequent agitation. Fucusamide crystallises from hot alcohol in groups of long needles; its reactions are similar to those of furfuramide. (Stenhouse, *Ann. Ch. Pharm.* lxxiv. 289.)

FUCUSINE. $C^{12}H^{11}N^2O^2$. (Stenhouse, *loc. cit.*)—An organic base, isomeric with fucusamide, and therefore with furfuramide and furfurine, and obtained from fucusamide in the same manner as furfurine from furfuramide. When pure fucusamide is boiled for twenty minutes, with moderately concentrated potash or soda-ley, it melts, and is converted, without evolution of ammonia, into a slightly brown oil, which solidifies on cooling in the form of a yellowish resin. This substance contains fucusine, but does not yield that base in the crystalline form, even by solution in alcohol or ether. The best mode of obtaining the fucusine from it is to digest the mass, at a temperature a little above its melting point, with nitric acid; cool the liquid till the resin solidifies; decant the solution, and leave it to itself till the nitrate of fucusine crystallises out; purify this salt by recrystallisation from water; and decompose its pure aqueous solution with a slight excess of ammonia. The fucusine then slowly separates in small laminae united in stellate groups. This form of crystallisation distinguishes fucusine from furfurine.

Hydrochlorate of Fucusine is very soluble, and separates from highly concentrated solutions in short flexible needles.

Chloroplatinate, $2(C^{12}H^{11}N^2O^2.HCl).PtCl_4$.—When tetrachloride of platinum is added to a cold aqueous solution of hydrochlorate of fucusine, the double salt separates in the form of a yellow crystalline precipitate; but if the solutions are mixed hot, and especially if a little alcohol is added, broad four-sided prisms are obtained, having two wide and two narrow faces, and differing altogether from the long needle-shaped crystals of the corresponding furfurine-salt.

Nitrate of Fucusine, $C^{12}H^{11}N^2O^2.NO^3H$, crystallises from a hot aqueous solution in long prismatic needles united in stellate groups, but when crystallised from alcohol it forms large rhombic prisms of great regularity and peculiar lustre. The crystals obtained from strong alcohol become opaque after a while, but those which separate

from a weak alcoholic solution retain their transparency. The salt when heated to 100°C . quickly becomes coloured, and decomposes.

Oxalates of Fucusine.—When crude fucusine is digested with excess of oxalic acid, and the solution filtered hot, the acid oxalate, $\text{C}^{15}\text{H}^{12}\text{N}^2\text{O}^4\cdot\text{C}^2\text{H}^2\text{O}^4$, is deposited in small needle-shaped crystals, which are generally coloured at first, but by repeated crystallisation and the use of animal charcoal, may be obtained in colourless silky needles. It is not very soluble in cold water, but dissolves readily in boiling water and in alcohol. The solutions have a distinct acid reaction.

The neutral oxalate resembles the acid salt in appearance, but is much more soluble.

FUCUSOL. $\text{C}^8\text{H}^{10}\text{O}^2$ (Stenhouse, Phil. Mag. [3] xviii. 122; xxxvii. 226; Ann. Ch. Pharm. xxxv. 301; lxxiv. 278.)—A volatile oil isomeric with furfural, and obtained by treating sea-weed, *e. g.* *Fucus nudosus*, *F. vesiculatus*, *F. serratus*, &c. with dilute sulphuric acid in the same manner as bran is treated for the preparation of furfural.

The oil thus obtained contains a large quantity of acetone, which may be removed by washing with water, redistilling at a lower temperature, and rejecting the first portion which passes over. It also contains metafurfural, or a similar impurity, from which it may be separated by repeated rectification with water, as in the purification of furfural. Lastly, it is dried over chloride of calcium and redistilled. The quantity of fucusol thus obtained from sea-weed, is only about a fourth of that of the furfural obtained from bran.

Fucusol resembles furfural in most of its properties. When recently prepared it is colourless, but turns yellow and brown in a few days, especially when it contains metafurfural. In the pure state it may be kept unaltered for a long time in hermetically sealed tubes. Specific gravity 1.150. Boiling point between 171° and 172°C . It dissolves in 14 pts. of water at 13°C . and in 12 pts. of strong aqueous ammonia at 13.5° .

Fucusol is much less stable than furfural. Sulphuric acid colours it yellowish-brown, hydrochloric acid green, and nitric acid light yellow; if, however, it contains metafurfural, all these acids colour it purple-red. Potash-ley colours it yellow at first, but the colour afterwards changes to dark-red. It imparts a deep yellow colour to the skin, and on moistening the yellow spots with aniline, a rose colour is produced (the same reaction is exhibited by furfural). With ammonia, fucusol forms fucusamide, and with sulphide of ammonium it forms thiofucusol, isomeric with thiofurfural.

Moss (*Sphagnum*) and various species of lichen (*Cetraria islandica*, *Usnea*, *Ramalina*, &c.), distilled as above with dilute sulphuric acid, yielded an oil which appeared to be identical with fucusol, inasmuch as it formed with ammonia an amide which, when treated with boiling potash-ley, formed a difficultly crystallisable base whose platinum-salt crystallised in the same form as that of fucusine (p. 717). Fern (*Pteris aquilina*) yielded an oil which appeared to be intermediate in its properties between furfural and fucusol, the base formed by treating its amide with potash, crystallising with facility and in the same form as furfural, while the platinum-salt resembled that of fucusine. (Stenhouse.)

FUEL. *Combustible; Brennstoff.*—Although this term might be correctly applied to any substance capable of combustion, its application is generally limited to those materials which are practically employed for generating heat.

The artificial application of heat for various useful purposes appears to have been always a prominent feature of distinction between man and the brute creation. In remote ages the use of fuel was, for the most part restricted to the warming of dwellings, and the preparation of food. Its industrial applications seem to have been few. In later times, however, the importance of the application of heat in the useful arts has been continually increasing. Not only is heat, generated by the combustion of fuel, the principal agent in the extraction of metals from their ores, in their subsequent fashioning into useful forms, in the manufacture of bricks, pottery, and glass, and in the various chemical arts; but, since the invention of the steam engine, it has become the most important source of motive power, in its applications both to the industrial arts and to commercial intercourse.

With this widely extended range of utility in the application of fuel, it naturally follows that the chemical principles involved in its use are of much importance. The general nature of the phenomena of combustion and the development of heat being described under the heads COMBUSTION and HEAT, it will only be requisite here to show in what manner the value and applicability of different kinds of fuel are influenced by the principles there elucidated.

The different kinds of fuel are all of vegetable origin, either directly or indirectly. In the different conditions of wood, peat, and coal, it is the ligneous tissue of plants that constitutes fuel; in each of these conditions there is a general similarity of elementary composition, accompanied by considerable differences in the relative proportions of the

elementary constituents, and by specific differences of character, apparently depending more upon the arrangement of those constituents than upon their actual amount.

The chief elementary constituents of fuel are carbon, hydrogen, and oxygen, together with a small proportion of nitrogen; and in all kinds of fuel there is, besides these constituents, a greater or less amount of earthy or inorganic substance, remaining as ash when the fuel is burnt, and originating partly from the plant-tissues, partly from their mechanical admixture with earthy substances. The amount of ash in fuel varies considerably, from less than 1 per cent. to 10, and even 20 per cent. in some instances; but, on the average, 5 per cent. of ash is as much as there should be in good fuel.

One of the most important points of difference between the various kinds of fuel consists in the amount of volatilisable substance they contain; and their applicability for various purposes depends in a great measure on this circumstance, as much as upon their respective capability of generating heat. Fuel which contains a large amount of combustible volatilisable substance, and gives rise to a copious evolution of hydrocarbon vapour and gases, burns with flame, while the more purely carbonaceous fuels, containing little or no volatilisable substance, burn without flame or with only a small flame. It has been very generally considered that fuel which possesses the character of burning with the largest flame is especially suitable for use in generating steam, and for evaporating, as well as for certain metallurgical operations; while the more carbonaceous kinds are generally found better adapted for iron smelting, and for producing high temperatures.

The presence of water in fuel is obviously objectionable, whether it be employed for evaporation or for producing high temperatures: for, in the one case, the vaporisation of the water contained in the fuel consumes an equivalent quantity of heat, and thus reduces the effect produced by the fuel; in the other case, the water-vapour produced tends to reduce the temperature obtainable by the combustion.

The amount of water in fuel may vary from nothing to 40 per cent. or more, and some kinds of fuel give rise to the production of a further portion of water than that which they actually contain. The great difference between the capability of fuel to produce high temperatures, according as it contains or produces water by combustion, has long been known, and the practice of kiln-drying and of charring fuel, is founded on the knowledge of this fact.

By charring or carbonising fuel, the whole of the water it contains, or is capable of producing, may be separated; and though a considerable portion of the carbon is also volatilised, partly in the state of hydrocarbon compounds, and partly as carbonic acid and carbonic oxide, the residual carbonaceous portion has, weight for weight, a greater capability of producing a high temperature than the raw fuel, and in some cases is otherwise more suitable for certain metallurgical operations.

The extent to which the volatilisation of carbon takes place, in carbonising fuel, depends greatly upon the mode in which the operation is conducted. As a rule, the yield of carbonaceous residue is greatest when the carbonisation is conducted rapidly. This is the case to the greatest extent with wood, which yields on the average 23 per cent. of charcoal by rapid charring, and only 14 per cent. by slow charring. In the carbonisation of coal, the difference is much less, and the amount of coke obtained, which varies very much, depends more upon the special character of the coal used.

COAL.—This is by far the most important of the materials employed as fuel. The varieties of coal are very numerous, and the differences between some varieties are very marked, though on the whole they are more differences of degree than of kind. According to these differences in the varieties of coal, they are generally divided into three classes, viz. 1. Anthracite; 2. Bituminous coal; and 3. Lignite; though, in many instances, it is not possible to recognise any absolute distinction between coals commonly referred to different classes.

There is an equal absence of any positive line of demarcation between coal and those more earthy combustible minerals, termed shales, with which it is usually associated; but from a practical point of view, the amount of earthy substance often constitutes a good criterion as to whether any particular mineral be suitable for fuel, and should consequently be regarded as coal. The determination of the question, even by this means, will sometimes be influenced by circumstances; thus, for instance, while 30 per cent. of ash in a combustible mineral of this description, might not prevent its being usefully employed as fuel at the place where it is raised, it would not be so regarded for the purpose of transport. From a variety of similar circumstances, the application of the term coal is entirely conventional. A scientific definition of coal is out of the question.

Anthracite.—The coals belonging to this class are characterised by containing a much larger amount of carbon than any other varieties, and but very little volatilisable substance.

Anthracite is less readily combustible than almost any other kind of fuel; it requires a strong draught, and must be gradually heated before being thrown on the fire, otherwise it decrepitates and crumbles to powder, which stops the draught and causes much waste. When properly burned, it generates a very high local temperature, and is on that account especially adapted for melting furnaces.

Bituminous Coal.—The coals belonging to this class are characterised by containing a more or less considerable proportion of bituminous substance capable of being decomposed by heat, and yielding volatile, oily, and gaseous products. Some of these coals, when heated, undergo a kind of fusion, swelling up considerably as decomposition goes on, and leaving a bulky porous residue of carbon. These are called *caking coals*. Other bituminous coals do not present this character; but when heated, or in burning, retain their form, and split or open up into columnar fragments. These are commonly called *dry or freeburning coals*. The cannel coals, which properly belong to the bituminous class of coals, behave differently from either caking or dry coals when heated, though they burn most like the latter, and they are especially characterised by giving a very copious luminous flame.

In composition, bituminous coals generally are distinguished by containing a larger proportion of both hydrogen and oxygen than anthracite contains; but there is no recognised relation between their specific characters and their elementary composition. Even the property of caking seems to be more dependent on the constitution, than on the mere composition of the coals.

Dry or Freeburning Coals.

LIGNITE and BROWN COAL.—The various kinds of combustible minerals to which these names are applied are but little employed as fuel in this country; but in the colonies they are of more importance. Lignite and brown coal are highly hygroscopic, and, in the air-dried condition, generally contain from 15 to 20 per cent. of water. In composition they approximate more or less to wood.

Wood is but little used as fuel except in countries where it is abundant, and where coal is scarce. The amount of water in wood varies considerably according to the kind of wood, and the time it has been kept. On the average, air-dried wood contains about 20 per cent. of water. The average composition of wood is

PEAT; TURF.—The chief obstacle to the use of peat and turf as fuel is the difficulty of obtaining them in a dry state. As they usually occur in bogs or mountain districts, they contain from 80 to 90 per cent. of water, and, even in the ordinary air-dried condition, the amount of water is not less than from 20 to 40 per cent.

The term turf is most correctly applicable to the more fibrous and spongy varieties of bog fuel, consisting, in great part, of mosses that have undergone but little alteration of structure.

The term peat should be restricted to those varieties in which the ligneous tissues of the mosses, &c., have been, to a more or less considerable extent, converted into a compact mass, which is sometimes as pasty as moist clay, and, when air-dried, presents much resemblance to some kinds of coal belonging to the lignite class.

The appearance and texture of air-dried peat and turf present great variations between these two extreme conditions, the most important points of difference being the density and the liability to absorb water. The density of air-dried turf is sometimes as low as 0·2 or about 12 lbs. per solid cubic foot; the density of peat is sometimes as much as 1·23 or about 78 lbs. per solid cubic foot. Turf will sometimes absorb more than its own weight of water, while good peat will not take up more than about 10 per cent.

In composition there is but little difference between turf and peat or the different kinds of each, but the amount of ash varies considerably, and is sometimes as high as 10, or even 20 per cent.

Of the elementary constituents of fuel, only the carbon and hydrogen are combustible, and capable, by their combustion, of contributing to the generation of heat. Consequently, the amount of heat generated by any kind of fuel, or its calorific power, depends upon the amount of carbon and hydrogen it contains. There being no absolute measure of heat, the calorific power of fuel can only be estimated relatively, by comparing the effects produced by equal weights of different kinds of fuel.

In the combustion of hydrogen, the amount of heat generated is always the same, but in the combustion of carbon, it differs according to the nature of the compound produced by the combustion. When carbon is fully oxidised and converted into carbonic acid, the amount of heat generated is much greater than when it is only converted into carbonic oxide, so that, as regards the use of fuel, carbon has two degrees of calorific power, corresponding to the two degrees of oxidation.

The quantity of heat generated by the combustion of hydrogen is 4.265 times as great as that generated by the combustion of an equal weight of carbon to carbonic acid, according to the most accurate determinations by Favre and Silbermann.

In expressing the calorific power of fuel, the amount of heat generated by the combustion of carbon to carbonic acid is taken as the standard of comparison. This calorific power of carbon is expressed as a definite quantity, by the number of parts by weight of water capable of being heated from a given temperature to a temperature 1° higher (4° to 5° C.), by the combustion of one part by weight of carbon. This numerical expression of calorific power will, of course, vary according as the thermometric scale to which it refers is that of Fahrenheit, Centigrade, or Reaumur, and it will vary in the same ratio as the degrees of those different scales bear to each other.

	Reaumur.	Centigrade.	Fahrenheit.	Relative calorific power.
Ratio of thermometric degrees . . .	0.8	1	1.8	
Calorific power of carbon . . .	1010	8080	14,544	1.000
Calorific power of hydrogen . . .	43,077.5	34,462	62,032	4.265

In this comparison of the calorific power of carbon and that of hydrogen, no particular unit of weight is referred to; it merely indicates that a pound, a grain, or a ton of carbon or of hydrogen will raise the temperature of as many pounds, grains, or tons of water from 4° to 5° C., as correspond with the number expressing their calorific power respectively for each thermometric scale. The unit of heat, or that quantity of heat which raises the temperature of the unit of weight of water from t° to t° + 1°, will vary according to the thermometric scale and the unit of weight to which it refers. According to the Centigrade scale and the French system of weights, the unit of heat is the quantity which raises the temperature of a kilogramme of water from 4° to 5° C., while the unit of heat for the Fahrenheit scale and the British system of weights is the quantity which raises the temperature of a pound of water from 40° to 41° F., and these two units bear the following relation to each other.

British unit of heat.		French unit of heat.
1	=	0.251996
3.96832	=	1.

It is important to bear in mind these differences of expression, inasmuch as they often have to be taken into account in calculations; but the expression of the relative calorific power of carbon and of hydrogen, as stated above, is not affected by them.

Since the calorific power of fuel, or its theoretical fuel value, depends on the amount of combustible carbon and hydrogen it contains, it follows that, the percentage composition of any particular fuel being ascertained by analysis, it is easy, by means of the data given for the relative calorific power of carbon and of hydrogen, to calculate the relative calorific power of the fuel, that of carbon being taken as unity. There are three possible cases which may obtain in regard to this calculation, viz.:

1. When the combustible portion of the fuel consists entirely of carbon, as in the case of coke or charcoal, the percentage of carbon in the fuel expresses its relative calorific power, as compared with pure carbon.
2. When the combustible portion of the fuel contains both carbon and hydrogen, the relative calorific power is found by multiplying the percentage amount of hydrogen by 4.265 and adding the product to the number expressing the percentage of carbon.
3. When the fuel contains, besides carbon and hydrogen, more, or less oxygen, this constituent must be considered as already combined with an equivalent quantity of either carbon or hydrogen, which is consequently rendered ineffective for generating heat. In such cases, it is only the surplus carbon and hydrogen, over and above the quantity equivalent to the oxygen in the fuel, that can generate heat by combustion.

Consequently the greater the amount of oxygen in fuel, the smaller will be its relative calorific power. The presence of oxygen in fuel, acts in a twofold manner in reducing the calorific power; by reducing the actual amount of carbon and hydrogen, and also by rendering part of that amount ineffective for generating heat.

The influence exercised by the oxygen contained in fuel in diminishing the calorific power will also depend upon whether it is the carbon or hydrogen that is rendered ineffective in generating heat, and the conditions under which the fuel is burnt will determine, in great measure, which of these effects is produced.

Since in carbonic acid, oxygen is combined with three-eighths of its weight of carbon, and in water it is combined with one-eighth of its weight of hydrogen, the quantity of carbon rendered ineffective by a given quantity of oxygen would be three times as much as the quantity of hydrogen rendered ineffective by the same quantity of oxygen. According to the older determinations of the heat generated by the combustion of hydrogen and carbon, which made the calorific power of hydrogen just three times as great as that of carbon, the result obtained by calculation was the same in either case; but adopting the more accurate data afforded by the experiments of Favre and Silbermann, the result will differ in some instances considerably, according as it is assumed that hydrogen or carbon is rendered ineffective for generating heat.

The relative calorific power of fuel may be calculated by means of the following formulæ, in which p represents the relative calorific power; and C, H, O represent the amounts of carbon, hydrogen, and oxygen in one part of the fuel:

1. Fuel containing only carbon $p = C$.
2. Fuel containing carbon and hydrogen $p = C + 4.265 H$.
3. Fuel containing carbon, hydrogen, and oxygen $\left\{ \begin{array}{l} p = C - \frac{8}{3}O + 4.265 H \\ \text{or } p = C + 4.265 (H - \frac{1}{3}O) \end{array} \right.$

If it is desired to express the calorific power of fuel in heat-units, the amount of carbon and the amount of available hydrogen in one part of the fuel are to be respectively multiplied by the numbers expressing the calorific power of carbon and of hydrogen, and the sum of the two products represents the relative calorific power of the fuel in heat-units:

1. $p = 8080 C$.
2. $p = 8080 C + 34462 H$.
3. $p = 8080 C + 34462 (H - \frac{1}{3}O)$.

In the following table the relative calorific power of several combustible substances is given both as calculated by the above formulæ and as expressed in heat-units:

1 Fuel.	2 Composition of Fuel.					3 Weight of Oxygen for combustion.			4 5 6 Calorific power in heat-units.			7 Weight of water heated from the freezing-point to boiling.	8 Weight of water at 100° C. converted into steam

The numbers in column 7 are obtained by dividing those in column 6 by 100, or those in column 6 by 180, upon the assumption that equal quantities of heat are requisite for raising the temperature of x pts. of water y degrees, or y pts. of water x degrees. Thus the heat generated by the perfect combustion of one pound of carbon would be sufficient to raise the temperature of 8080 pounds of water from 4° to 5° C., or of 14,544 pounds from 40° to 41° F. or of 80.8 pounds of water from the freezing to the boiling point:

Quantity of water. 8080lbs.	x	Increase of temperature. 1° C.	=	Quantity of water. 80.8lbs.	x	Increase of temperature. 100° C.
or						
Quantity of water. 14,544lbs.	x	Increase of temperature. 1° F.	=	Quantity of water. 80.8lbs	x	Increase of temperature. 180° F.

This assumption is not strictly correct, since the specific heat of water increases slightly as the temperature increases beyond its point of greatest density; but the approximation is sufficiently near for ordinary calculations.

The numbers in column 8 are obtained by dividing the numbers in column 7 by 5.5, on the assumption that the quantity of heat requisite to convert water at the boiling point, into steam under the ordinary atmospheric pressure, is 5.5 times as much as would be requisite for raising the temperature of the same weight of water from the freezing to the boiling point.

Whatever mode of expressing the calorific power of fuel may be adopted, it must be remembered that the results obtained by any of the above formulæ are to be considered merely as representing the relative quantities of heat generated by the combustion of equal weights of the fuel and of the standard with which it is compared. The results so obtained do not represent either the relative value of fuel, or the thermal effect capable of being produced by its combustion.

The thermal effect of fuel, or the temperature of the fire, does not depend solely on the calorific power or the amount of heat generated by its combustion; but likewise on the quantity and nature of the products resulting from the combustion.

The total heat generated by the combustion of any fuel, is communicated to the products of combustion, which in all ordinary cases are gaseous, producing in them, at the moment of combustion, a temperature determined, partly by the calorific power of the fuel, and partly by the nature of the products of combustion. Thus, for instance, taking the simplest case, carbon requires for its combustion to carbonic acid, 2.67 times its weight of oxygen, producing 3.67 times its weight of carbonic acid, the temperature of which is raised, at the moment of combustion, above the original temperature of the oxygen, by the diffusion of the heat generated throughout the carbonic acid produced. The quantity of heat generated by the combustion of carbon is capable of raising the temperature of a quantity of water equal to 8080 times the weight of the carbon burnt, from 4° to 5° C., and would raise the temperature of a quantity of water equal to the weight of the carbonic acid, produced about 2202° C.

Parts by weight of water. 8080	x	Increase of temperature. 1° C.	=	Increase of temperature. 2201° 63 C.	x	Parts by weight of water. 3.67
--------------------------------------	---	-----------------------------------------------	---	-----------------------------------------------------	---	--------------------------------------

But since the specific heat of water, or its capacity for heat, is much greater than that of carbonic acid, the increase of temperature in the carbonic acid produced by the combustion of carbon, is proportionately greater than the increase of temperature that would be produced in a quantity of water equal to 3.67 times the weight of carbon burnt.

The quantities of heat requisite to produce an equal increase of temperature in equal weights of carbonic acid and of water being in the proportion of 0.2614 : 1.0000, the quantities of heat requisite to raise the temperature of 3.67 pts. water and 3.67 pts. carbonic acid one degree are therefore as

Parts by weight of water. 3.67	x	Specific heat in heat-units. 1.000	:	Parts by weight of carbonic acid. 3.67	x	Specific heat in heat-units. 0.2164	=	3.67 : 0.794.
-----------------------------------------	---	---------------------------------------------	---	-------------------------------------------------	---	----------------------------------------------	---	---------------

Consequently the increase of temperature in the 3.67 pts. of carbonic acid, to which the heat generated by the combustion of 1 pt. carbon is communicated, at the moment of combustion, may be ascertained by dividing the number of heat-units by the quantity of heat which raises the temperature of the 3.67 pts. carbonic acid one degree:

$$\frac{8080}{0.794} = 10,174^{\circ} \text{ C.}$$

The heat generated in the combustion of hydrogen is sufficient to raise the temperature of a quantity of water equal to 34,462 times the weight of the hydrogen burnt

from 4° to 5° C.; but hydrogen requires for combustion 8 times its weight of oxygen, producing 9 times its weight of water-vapour. The quantity of heat generated is much greater than in the combustion of carbon; but the product of combustion through which that heat is diffused is nearly $2\frac{1}{2}$ times as much as in the combustion of an equal weight of carbon. A portion of the heat generated by the combustion of hydrogen, becomes latent and ineffective for increasing the temperature of the product, being consumed in determining the vaporous condition of the water produced. The latent heat of water, or the quantity of heat requisite to convert 1 pt. of water at 100° C. into steam, is 537 times as much as is requisite to raise the temperature of an equal weight of water from 4° to 5° C. The quantity of heat that becomes latent in the 9 pts. water-vapour produced by combustion of hydrogen, will therefore be 4833 heat-units, which must be deducted from the total heat generated, in order to ascertain the quantity of heat available for producing increase of temperature.

	Parts by weight of water-vapour.		Heat units.
Total heat of combustion of hydrogen			31,462
Latent heat of water in heat-units	9	\times 537	= 4,833
Available heat			29,629

The specific heat of water-vapour being 0.475 as compared with that of water = 1.000, the quantities of heat requisite to raise the temperature of 9 pts. water and 9 pts. water-vapour are therefore as:

Parts by weight of water.	Specific heat in heat-units.	Parts by weight of water-vapour.	Specific heat in heat-units.	
9	\times 1.000	: 9	\times 0.475	= 9 : 4.275

And the increase of temperature produced will be $6930^{\circ} \cdot 7$ C.:

$$\frac{29629}{4.275} = 6930^{\circ} \cdot 7 \text{ C.}$$

Hence as will be seen from the following comparison, thermal effect and calorific power are not necessarily equal; but, on the contrary, the thermal effect depends upon other circumstances, more than upon the calorific power of the fuel burnt.

	Weight.	Weight of oxygen.	Ratio.	Weight of products.	Ratio.	Heat units.	Ratio.	Thermal effect.	Ratio.
Carbon	1	2.67	1	3.67	1	8080	1.000	10174^{\circ}	1.000
Hydrogen	1	8	3	9.00	2.4	34462	4.265	6930^{\circ}	0.681

In both these instances, the combustion is supposed to have been effected in oxygen, and with only just as much as is chemically equivalent to the carbon and hydrogen burnt. But in all cases of the application of fuel, atmospheric air is the source of the oxygen that supports the combustion. The nitrogen it contains, in the proportion of 77 per cent., not only takes no part in the generation of heat, but, on the contrary reduces the thermal effect below what it would be by combustion in oxygen.

In the combustion of carbon in air, the quantity of nitrogen in air containing 2.6 pts. by weight of oxygen is 8.94:

Atmospheric air.

$$\begin{array}{c} \text{O} \\ 23 \\ \text{N} \\ 77 \end{array} : 77 = 2.67 : 8.94$$

The specific heat of nitrogen being 0.244, the quantity of heat requisite to raise the temperature of that quantity of nitrogen from 4° to 5° C. is

$$\begin{array}{c} \text{Parts by weight} \\ \text{of nitrogen.} \end{array} \quad \begin{array}{c} \text{Heat-unit.} \end{array}$$

$$2.181 = 8.94 \times 0.244$$

And, adding to this the quantity of heat requisite to raise the temperature of the carbonic acid produced, as found above, the quantity of heat requisite for raising the temperature of the whole products of combustion in air from 4° to 5° C. will be

$$\begin{array}{c} \text{Heat-units.} \end{array}$$

$$2.975 = 2.181 + 0.794$$

And the increase of temperature produced will be

$$2715^{\circ} \text{ C.} = \frac{8080}{2.975} = \frac{\text{total heat of combustion.}}{\text{quantity of heat requisite to heat the products and nitrogen from } 4^{\circ} \text{ to } 5^{\circ} \text{ C.}}$$

In the combustion of hydrogen in air, the quantity of nitrogen in air containing 8 pts. of oxygen is:

Atmospheric air.

$$26.78 : 8 = \frac{N}{77} : \frac{O}{23}$$

the quantity of heat requisite to raise its temperature from 4° to 5° C. is:

Heat-units.

$$6.534 = 26.78 \times 0.244$$

and the increase of temperature produced will be

$$2741^{\circ} \text{C.} = \frac{29629}{4.275 + 6.534} = \frac{\text{available heat of combustion.}}{\text{quantity of heat requisite to heat the products and nitrogen from } 4^{\circ} \text{ to } 5^{\circ} \text{ C.}}$$

The difference between the temperatures capable of being produced by the combustion of carbon and hydrogen in oxygen and in air is in both cases very considerable; but it is much greater in the case of carbon, since the amount of heat generated by its combustion is much less than that generated by hydrogen.

	Calorific power.	Ratio.	Temperature produced				Difference	Ratio.
			In oxygen.	Ratio.	In air.	Ratio.		
Carbon	8,080	1.000	10,174 $^{\circ}$	1.000	2715 $^{\circ}$	1.002	7459 $^{\circ}$	1.000
Hydrogen	34,462	4.265	6,930 $^{\circ}$	0.681	2741 $^{\circ}$	1.009	4189 $^{\circ}$	0.561

This comparison will suffice to show that, in all cases where high temperatures are required, it would be a great advantage to have an available means of increasing the amount of oxygen in the air supporting combustion; and that, in such cases, a very great saving of fuel might be effected by the use of oxygen, or of air containing a larger amount of oxygen than is present in atmospheric air.

There is another circumstance which influences the temperature capable of being produced by the combustion of fuel, and renders it less than would be indicated by the above calculation. In the combustion of fuel in a furnace, the conditions are such that, while at the outside the fuel is in contact with atmospheric air, there is within the furnace, a constant tendency to the production of an atmosphere consisting of carbonic acid, water-vapour, and nitrogen. To maintain the combustion of fuel, it is necessary not only to keep up a continual supply of air, but also to remove the gaseous products of combustion as they are formed. This is generally done by means of a draught, produced by a chimney; but, in any case, the gaseous products of combustion become mixed with the fresh supply of air, and exercise a great influence in reducing its efficacy in supporting combustion (i. 1101). Hence it is necessary to maintain an excess of oxygen in the atmosphere surrounding the fuel within the furnace, and, for this purpose, the quantity of air supplied must, in all ordinary cases of the use of fuel, be greater than that containing just enough oxygen to produce carbonic acid and water with the combustible constituents of the fuel burnt. In practice it is generally considered that the quantity of air requisite for the perfect combustion of fuel in ordinary furnaces, amounts to twice as much as that containing oxygen enough to convert its combustible constituents into carbonic acid and water.

In this way, the quantity of the products of combustion, through which the heat generated is distributed, is nearly doubled, and there is consequently a proportionate reduction of the temperature produced. In the case of carbon burnt with twice as much air as would be sufficient theoretically for its conversion into carbonic acid, the gaseous products of combustion would amount to 24.22 times the weight of the carbon burnt, and in the case of hydrogen to 80.56 times the weight of hydrogen burnt.

	Parts by weight of air.	Volume of air at 60 $^{\circ}$ F. per pound of fuel, cubic feet.	Parts by weight of gaseous products.
Carbon	1	23.22	303.30
Hydrogen	1	79.56	908.62
			24.22
			80.56

The specific heat of air being 0.2377, the quantities of heat requisite for raising the temperature of these additional quantities of air from 4° to 5° , and the temperatures produced will be:

$$\text{Combustion of Carbon.} \quad 2.7596 = 11.61 \times 0.2377 \quad \text{and} \quad 8.2672 = 34.78 \times 0.2377.$$

$$1550^{\circ} \text{C.} = \frac{8080}{2.7596 \times 2.9755} \quad \text{and} \quad 1550^{\circ} \text{C.} = \frac{29629}{8.2672 \times 10.8093}.$$

It will be evident that the admission into a furnace, of more air than is requisite will be attended with a proportionate waste of heat, and that it is desirable

always to effect combustion with the least sufficient supply of air. If the air be forced into the furnace by means of a fan or blast-pipe, as in a forge, fuel may be burnt with much less air than when it is drawn in by means of a chimney, and with greater economy of the heat generated. This economy may be effected to a greater extent with fuel which contains but little volatilisable substance.

The general formulæ for ascertaining the thermal effect of any kind of fuel from its composition are as follow:

$$T = \frac{\text{For Combustion in Oxygen.}}{cC + c'H - lW} \\ s \cdot 3.67C + 9H + s'W$$

$$T = \frac{\text{For Combustion in Air.}}{cC + c'H - lW} \\ s \cdot 3.67C + 9H + s'W + s''N + s'''A$$

Here T = increase of temperature produced by combustion.

C and H = quantities of carbon and hydrogen available in 1 pt. by weight of the fuel.

W = total quantity of water yielded by 1 pt. by weight of the fuel.

l = latent heat of water.

s, s', s'', s''' = specific heat of carbonic acid, water-vapour, nitrogen, and air.

c and c' = calorific power of carbon and hydrogen.

N = quantity of nitrogen in air necessary for converting combustible constituents of 1 pt. by weight of fuel into carbonic acid and water.

A = extra quantity of air supplied for combustion.

The results obtained by these formulæ apply only to the perfect combustion of the combustible constituents of fuel into carbonic acid and water; and they express the highest possible capabilities of fuel as compared with pure carbon, and when burnt under the most favourable conditions.

But in all ordinary cases, the practical effect obtainable from fuel is much less than its relative capability as indicated by calculation. This is the case whether the effect to be produced be high temperature or vaporisation; and, in some cases, the practical effect may amount to only a small fraction of the calorific power or the thermal effect.

One of the most obvious, though by no means the most considerable, causes of the difference between the relative capability of fuel and the practical effects, consists in the waste of fuel as dust and cinders. With some kinds of fuel that are very brittle, such as anthracite and some of the Welsh steam coals, the waste due to this character may be very considerable, especially if the firing is improperly managed; but with care and with some kinds of fuel, the waste of fuel as dust and cinders may be very small.

Another cause of loss is imperfect combustion. This may be due to an insufficient supply of air, and the consequent production of carbonic oxide. At a sufficiently high temperature, carbonic acid combines with a further quantity of carbon, equal to that which it contains; but this combination is essentially different from the direct combination of carbon with oxygen. Though there is a true chemical change, it is not combustion, but is more analogous in its effects to the vaporisation of ice by superheated steam. Instead of heat being generated, it disappears, and the loss of heat resulting from this action may be very considerable, since the heat generated will only be that corresponding to the lower calorific power of carbon. Thus, for example:

	Heat-units.
The heat generated by the combustion of carbon to carbonic acid is	8080
While the heat generated by the combustion of twice the weight of carbon to carbonic oxide is	4946
Loss of heat by production of carbonic oxide	3134

This action will always take place, to some extent, when fuel is burnt in thick layers, and when it is burnt very rapidly in confined spaces, as in the furnaces of steam-vessels.

Imperfect combustion may also result from the presence of volatilisable substance in fuel. When fuel containing water, or volatilisable combustible substance, is first thrown upon a fire, heat is abstracted from the fire by the production of steam and hydrocarbon vapours. The temperature is thus considerably reduced. In the case of air-dried wood, more than three-fourths would be thus vaporised, and in the case of ordinary Newcastle coal, more than one-third, the vapour so given off from wood being chiefly water, and that from the coal consisting chiefly of hydrocarbons, as shown below:

One part by weight of yields vaporisable	C	Wood.	Coal.	Percentage composition.	
				Wood.	Coal.
	H	·1853	·2522	24·38	64·10
	HO	·0083	·0460	1·10	11·80
	N, &c.	·5674	·0638	73·40	16·20
		·0090	·0313	1·10	7·90
		<u>·7700</u>	<u>·3933</u>	<u>100·00</u>	<u>100·00</u>
Calorific power in heat units		1784	3623		

If the temperature in the furnace is sufficiently high, and these vapours are mixed with a sufficient proportion of atmospheric air, they will be burnt; but if the volatilisable portions were not burnt, the loss of calorific power would be in the case of wood, more than one-half, and in the case of coal nearly one-third.

When these hydrocarbon vapours burn, or come in contact with highly heated fuel, they are immediately decomposed, with separation of carbon in a very fine state of division; and if the temperature of the atmosphere within the furnace, be insufficient to determine the combination of the whole of this carbon with oxygen, some of it escapes unburnt, producing smoke and soot. In a flame of this kind, which burns without smoke, the deposition of unburnt carbon is immediately effected by reducing the temperature of the flame, as in holding a piece of cold metal in a gas-flame.

Then since the combustion of these vapours in a boiler furnace takes place just as the burning vapour is passing away from the fire, along the surface of the boiler towards the chimney, the abstraction of heat may be sufficient to reduce the temperature of the mixed gas below the point at which it would be capable of effecting the combustion of the suspended carbon. The carbon thus eliminated by the decomposition of the hydrocarbon vapours, and that prevented from being burnt in consequence of the cooling of the burning gas, is partly deposited as soot, and partly swept away mechanically by the gaseous products of combustion, giving rise to smoke.

The tendency to the production of soot and smoke in the combustion of fuel containing volatilisable substance will be greater in proportion to the amount of volatilisable substance in the fuel, and more especially in proportion to the amount of carbon in the vapour produced. In the case of Newcastle coal, the amount of carbon in the vapour is nearly three times as great as in the vapour from wood, and it is also in a condition likely to give rise to elimination of carbon.

This production of soot and smoke involves a corresponding loss of heat, and to prevent this loss, provision must be made for supplying a sufficiency of air for effecting the perfect combustion of the vaporous products, without reducing the temperature of the atmosphere in the furnace. This is generally done by introducing air through the furnace-door, above the fire, and at the back of the fire, so as to become heated before mixing with the vaporous products. Mechanical arrangements for supplying the fuel in continuous small portions to the furnace, have also been used with the same object.

The possible waste of heat resulting from the presence of volatilisable combustible substance in fuel, may be judged of by comparing the calorific power of Newcastle coal with that of the fixed carbon it contains. The average of Newcastle coal contains 60 per cent. of fixed carbon, so that if the coal be burnt in such manner that only this portion of it is effective in generating heat, its calorific power might be regarded as 0·60 as compared with carbon.

But this coal contains 82·12 per cent. carbon, and 4·60 per cent. available hydrogen; consequently its calorific power is

$$·8212 + (·046 \times 4·265) = 1·017;$$

and if the volatile products were not burnt at all, the waste of heat would amount to four-tenths, and if only the carbon of the volatile products remained unburnt, the waste would amount to nearly one-fourth.

The extent to which heat may be wasted in consequence of imperfect combustion from this cause, and the liability to the production of smoke and soot in the case of different kinds of fuel, may be seen from the following table:

	Welsh coals.	Average wood.	Peat.	Lancashire coal.	Derbyshire coal.	Newcastle coal.	Scotch coal.
Total carbon	83·78	40·36	60·0	77·90	79·68	82·12	78·53
Amount of carbon volatilised	15·09	18·53	19·0	22·56	23·01	25·22	28·34
„ „ available hydrogen	4·27	0·83	1·0	4·13	3·64	4·60	4·40

Whenever fuel is employed for generating steam or for analogous purposes, it is desirable to effect perfect combustion as far as possible; but there are some applications of fuel in metallurgical operations, where it is advantageous to have a highly carbonaceous flame, and where this is of greater importance than obtaining the full heating effect of the fuel. Thus, for instance, in the manufacture of malleable iron, it

is necessary that the body of flame and heated gases passing through the working chamber of the puddling furnace, should not contain free oxygen in sufficient quantity to oxidise, or, as it is technically termed, to "cut" the metal.

Besides the actual loss of heat in consequence of imperfect combustion, and in other ways, a large portion of the heat generated by the combustion of fuel is always consumed in producing the draught by which the products of combustion are removed from the furnace, and the fresh supply of air maintained. This portion of the heat is not available under ordinary circumstances for producing any other useful effects. The amount of heat so consumed varies according to the nature of the products of combustion, and according to the use to which the fuel is applied. In every case the whole quantity of heat corresponding to the temperature at which the gaseous products of combustion are discharged from the place where the heating effect is to be produced, is ineffective.

In boiler furnaces it has been found that, to maintain a sufficient draught by means of a chimney, the temperature of the gaseous products of combustion must not be reduced below 315°C . For example, the amount of heat thus consumed in the two extreme cases of the combustion of carbon and of hydrogen in twice as much air as is necessary for their conversion into carbonic acid and water vapour, will be:—

	Parts by weight, products of combustion.		Quantity of heat = 1° in temperature of products. Heat units.		Temperature of products.		Heat units.
Carbon	. 1	=	24.22	5.735245	x	315°	= 1807
Hydrogen	. 1	=	80.56	19.076526	x	315°	= 6015

The amount of heat which thus passes away without producing its desired effect, will be proportionately greater as the temperature at which the products of combustion pass to the chimney, is higher than 315°C .; but it may be assumed that the minimum consumption of heat in producing a draught by means of a chimney, amounts in round numbers to one-fourth of the available heat generated. When the combustion of fuel is effected in this manner, its practical effect for heating and evaporation will therefore be only three-fourths of the capability indicated by calculation.

If the perfect combustion of fuel could be effected in boiler furnaces, with no more air than sufficient for converting its combustible constituents into carbonic acid and water vapour, the loss of heat from the circumstance just mentioned, might be reduced to one-half what it is when fuel is burnt with double that quantity of air. By using a fan-blower to drive the air into the furnace, instead of drawing it in by means of a chimney, the economy of heat might be carried still further, inasmuch as the gaseous products of combustion at, or even below, 315°C ., might then be employed for heating purposes, to which they cannot be applied when the heat they contain is required to produce a draught.

In reverberatory furnaces, the amount of heat which passes away in the gaseous products of combustion is very much greater than it is in boiler or evaporating furnaces, in consequence of the much higher temperature generally required to be maintained in those furnaces.

In the manufacture of malleable iron, the temperature at which the iron is required to be kept in puddling furnaces is about 1650°C . At that high temperature, the dispersion of heat by radiation and conduction is so great, that it is necessary to keep up a rapid current of heated gases through the working chamber of the furnace and a rapid combustion of fuel to maintain the temperature required. By the heating of the iron, the atmosphere in the furnace is rapidly brought below this temperature, and must be constantly replaced by fresh portions of gaseous products of combustion, heated above that temperature. It is only the heat corresponding to the difference between the temperature of the iron and the higher temperature of the atmosphere in the furnace, that is available for heating or for maintaining the temperature of the iron. The circumstance that the specific heat of iron is not much more than half as great as that of the atmosphere in the furnace, favours the heating of the iron; but, in any case, it is only part of this available heat that is really effective in raising or maintaining the temperature of the iron. The higher the temperature of the iron, the smaller will be the effective portion of the available heat, because, as the temperature rises, the dispersion of heat by radiation and conduction increases very considerably. Mr. Prideaux has estimated that even when the iron is first put into the puddling furnace, and with the furnace atmosphere at a constant temperature of 1815°C ., the effective portion of the available heat is not more than one-half of the whole, and that when the temperature of the iron is 1370°C ., less than one-eleventh of the whole is effective. In furnaces where welding heat is required, the amount of heat that is effective is still less, not being more than one-sixty-fourth of the whole heat generated, the remaining 63

parts being wasted. By increasing the temperature of the atmosphere in the furnace, and the difference between that temperature and the temperature to be maintained in the iron, so as to increase the rate of heating, a great economy of fuel may be effected, because, in that case, a greater amount of the available heat becomes effective. Thus, Mr. Prideaux shows that, if the atmosphere in a furnace, where a welding heat is required, be maintained at a temperature of 2039° C., one-sixteenth of the heat generated will be effective instead of only one-sixty-fourth. In this case, an increase of temperature amounting to one-eighth is attended with a four-fold economy of heat.

B. H. P.

FULLER'S EARTH. *Walkerde. Walkthon.*—An argillaceous deposit occurring in connection with the chalk, oolite, &c. It is earthy, with a shining streak; greenish-grey, oil-green, white, yellowish, reddish or red-brown. Specific gravity = 1.7–2.4. It feels either greasy or harsh; adheres a little to the tongue; falls to pieces in water. It is found at Nutfield near Reigate in Surrey; near Maidstone in Kent, Woburn in Bedfordshire; at Vahls near Aix-la-Chapelle, Rosswein in Saxony, Zwickowitz in Bohemia, and elsewhere. (*Dana*, ii. 504.)

The term *fuller's earth* was originally confined to a sandy argillaceous earth met with in the upper part of the stratum just mentioned, on account of its use in *fulling* or cleansing cloth, when first woven, from grease and other impurities; but it is now extended to the entire formation to which this earth belongs. (See *Ure's Dictionary of Arts*, &c. ii. 307.)

FULMINATES. $C^2N^2M^2O^2$ (M denoting a monatomic metal).—This name is applied to a class of salts polymeric with the cyanates and cyanurates, but distinguished from them by the property of detonating violently when heated or struck. Howard first showed (*Phil. Trans.* 1800) that nitrate of mercury or nitrate of silver heated with alcohol and excess of nitric acid, yields a peculiar, crystalline, easily detonating precipitate, viz. *fulminating mercury* or *fulminating silver*; but the composition of these precipitates remained unknown till 1824, when it was discovered by Liebig (*Ann. Ch. Phys.* [2] xxiv. 298; *Ann. Ch. Pharm.* xxvi. 546), whose determination was afterwards confirmed by Gay-Lussac (*Ann. Ch. Phys.* [2] xxv. 285).

Fulminic acid, or fulminate of hydrogen, has not been obtained; and the only fulminate of which a satisfactory analysis has been made, is the silver-salt, which, according to Gay-Lussac and Liebig, contains 7.92 per cent. carbon, 9.24 nitrogen, 72.19 silver, and 10.65 oxygen, agreeing with the empirical formula $CNAgO$, which requires 8.00 carbon, 9.33 nitrogen, 72.00 silver, and 10.67 oxygen. This is the formula of cyanate of silver. But there can be no doubt that the formula of fulminate of silver is a multiple of this, and most probably $C^2N^2Ag^2O^2$: for, in the first place, the fulminates are formed by the action of nitric acid and a nitrate on alcohol, which is a 2-carbon compound; secondly, many of the reactions of the silver-salt show that one-half of the silver is in a different state from the other half; and thirdly, several double fulminates are known, including a fulminate of silver and hydrogen, $C^2N^2AgHO^2$. Hence Gay-Lussac and Liebig assigned to neutral fulminate of silver the formula $Cy^2Ag^2O^2$, supposing it to be derived from a dibasic fulminic acid, $Cy^2H^2O^2$. This view is supported by the fact that in many reactions of fulminating silver, hydrocyanic acid is produced.

Berzelius (*Bers. Jahresber.* xxiv. 89) supposed that the fulminates contain a metallic nitride, e. g. fulminating silver = $AgO.AgN.C^4NO^2$, this mode of representation being intended to afford an explanation of the fact that, in many reactions of fulminating silver, only half the silver is separated; also that fulminate of silver and potassium, $KO.AgN.C^4NO^2$, detonates as strongly as fulminating silver itself, the detonation in either case being attributed to the sudden decomposition of the compound AgN .

The formation of the fulminates by the action of nitric acid upon alcohol, together with their explosive properties, induced Laurent and Gerhardt (*Précis de Chimie organique*, ii. 445) to regard them as compounds containing nitril, NO^2 , a radicle which is frequently introduced into organic molecules by the action of nitric acid, and almost always imparts to them more or less of an explosive character; they accordingly represented fulminating silver by the formula $C^2N(NO^2)Ag^2$.

This view of the composition of the fulminates receives strong confirmation from the recent experiments of Kekulé (*Ann. Ch. Pharm.* ci. 200; cv. 279), and of Schischkoff (*ibid.* ci. 213), which have shown: 1. That fulminating mercury, treated with chlorine, or with hypochlorite of calcium, yields chloropierin, a compound certainly containing the radicle nitril, viz. $C(NO^2)Cl^1$ (i. 923); and with bromine, it yields dibromonitrace-tonitrile, $C(NO^2)Br^2N$, or bromopierin, $C(NO^2)Br^2$, according as the fulminating mercury or the bromine is in excess. — 2. Fulminuric or isocyanuric acid, $C^2N^2H^2O^2$, a compound produced by the action of alkaline chlorides or iodides on fulminating

mercury (p. 738), also yields chloropicrin when treated with hypochlorite of calcium, and trinitracetonitrile, $C^3(NO^3)_3N$, when treated with strong nitric acid. Schischkoff has also observed that when the same acid is decomposed by zinc in presence of a mineral acid, the hydrogen eliminated from the latter is almost wholly absorbed. This reaction, together with the explosive character of the fulminates, also points to the existence of an oxide of nitrogen in these compounds; and this being the case, the mode of formation of fulminuric acid shows that the nitro-compound must also exist in fulminic acid.

Kekulé assigns to fulminic acid the formula $C(NO^2)(CN)H^2$ or $C(NO^2)CyH^2$, which amounts to supposing: 1. That half the carbon and half the nitrogen in fulminic acid are so arranged as to yield cyanogen-compounds under the influence of certain reagents.—2. That the remaining half of the nitrogen exists in fulminic acid in the same form as in the so-called nitro-compounds. This view is in accordance with the following reactions.

Fulminating mercury, suspended in water and treated with chlorine gas, yields chloropicrin, gaseous chloride of cyanogen, and chloride of mercury, without any evolution of carbonic anhydride, according to the equation:

Fulminating mercury treated with sulphydric acid yields sulphocyanate of ammonium and carbonic anhydride:

According to Kekulé's formula, fulminic acid belongs to the same type as marsh-gas, and exhibits a very close analogy with the bodies in the following series [$NO^2 = X$]:

Marsh-gas	CH H H H.
Chloride of Methyl	CH H H Cl.
Chloroform	CH Cl Cl Cl.
Nitroform	CH X X X.
Chloropicrin	CX Cl Cl Cl.
Chloride of Dinitromethylene	CX X Cl Cl.
Acetonitrile	CH H H Cy = C^3H^3N .
Trichloracetoneitrile	CCl Cl Cl Cy = C^3Cl^3N .
Trinitracetonitrile	CX X X Cy = C^3X^3N .
Dibromonitracetoneitrile	CX Br Br Cy = C^2XBr^2N .
Fulminating Silver	CX Ag Ag Cy = C^2XAg^2N .
Fulminic acid (<i>hypo</i>)	CX H H Cy = C^2XH^2N .

According to these formulæ, the compounds to which fulminic acid is most intimately related are chloropicrin and acetonitrile; its formula is in fact the same as that of mononitracetoneitrile.

The formation of fulminic acid by the action of nitrous acid upon alcohol may be explained as follows. On the one hand cyanic acid is formed:

on the other, nitro-acetic acid; and these two compounds by their mutual action produce fulminic acid:

Kekulé regards the formation of fulminating mercury as analogous to that of chloroform. In the one case, alcohol is subjected to the simultaneous action of oxidising and chlorinising agents; in the other, the alcohol is likewise oxidised (converted into cyanic acid), while, at the same time, cyanogen and mercury are present and ready to take the place which the chlorine occupies in chloroform, the strong nitric acid likewise introducing the group NO^2 . In fact, fulminating mercury might be regarded as nitrated chloroform in which 2 at. Cl are replaced by mercury and one by cyanogen. This view receives some corroboration from the fact that the analogous compound, chloropicrin, is produced by adding chloride of sodium to a mixture of alcohol and strong nitric acid.

Schischkoff (Compt. rend. li. 99) doubles the preceding formula of fulminic acid, but otherwise agrees with Kekulé in supposing that it contains both cyanogen and nitryl:

According to this formula, the acid may be regarded as derived from ethylic alcohol, by the substitution of cyanogen for oxygen (Cy^2 for O), and of 2 at. nitryl for 2 at. hydrogen. Schischkoff further supposes, that when alcohol is acted upon by nitric

acid, dinitroethylene, $C\left\{\begin{smallmatrix} H \\ (NO_2)_2 \end{smallmatrix}\right.$ (not yet isolated), and hydrocyanic acid are formed, and produce fulminic acid by their union:

In like manner, a fulminate may be regarded as a compound of a metallic cyanide with dinitroethylene in which the hydrogen is replaced by an equivalent quantity of a metal: a view which accords with the fact that in the double decomposition of fulminates, *e.g.* of the silver-salt by potash, only half the metal is separated.

Schischkoff formerly regarded fulminic acid as a compound of 2 at. cyanic acid and 1 at. nitracetonitrile = $(CHNO)^2.NC^2(NO^2)H^2$ (Ann. Ch. Pharm. ci. 213; Gm. xii. 551).—[For Gentile's views of the constitution of the fulminates, see J. pr. Chem. lxxxiv. 101; Rép. Chim. pure, 1862, p. 196.]

Fulminate of Copper is obtained in green crystals, very slightly soluble in boiling water and highly explosive, by boiling fulminating mercury with water and copper, and filtering the hot liquid. When fulminating silver is used instead of the mercury-salt, a greenish-blue powder is obtained, less explosive, and likewise very slightly soluble in water, forming a sky-blue solution.

Fulminate of Copper and Ammonium, $C^2N^4\left\{\begin{smallmatrix} Cu \\ (NH_4)_2 \end{smallmatrix}\right\}O^4$.—Formed by mixing a solution of fulminate of copper with a large excess of ammonia, 1 at. copper being then replaced by 1 at. ammonium. When a stream of sulphuretted hydrogen is passed through the solution of this salt, the copper is completely precipitated, and the filtered solution is found to contain hydrosulphocyanic acid and urea:

The formation of urea from this salt exhibits in a striking manner the close relation between the fulminates and cyanates. (Gladstone, Ann. Ch. Pharm. lxi. 1.)

Fulminate of Copper and Potassium.—By digesting fulminate of silver and potassium with copper, the silver is precipitated and a liquid obtained, which is neither precipitated by potash, nor turned blue by ammonia, unless it be previously mixed with hydrochloric acid. (Liebig.)

Fulminate of Hydrogen, or Fulminic Acid, does not appear to exist in the free state.

Fulminate of Mercury. *Mercuric fulminate*. *Fulminating Mercury*.—This salt, discovered by Howard, is produced when mercury or mercuric oxide is heated with alcohol and strong nitric acid; also by boiling fulminating silver with mercury and water, and by precipitating the zinc-salt with solution of mercuric chloride.

To prepare it, 1 pt. of mercury is dissolved in 12 pts. nitric acid of specific gravity 1.3; and the solution, when cold, is mixed with 11 pts. alcohol of 85 to 88 per cent., and the mixture is heated in the water-bath. It then enters into ebullition, and must be removed from the fire as soon as it begins to show turbidity, then left to cool, decanted, and the mercuric fulminate collected on a filter and purified by recrystallisation from boiling water. The mother-liquor yields a fresh quantity by evaporation (Chevalier, Ann. Ch. Pharm. xxiii. 107). The reaction by which this compound is produced, is attended with the evolution of a white cloudy vapour, the *ethereal nitrous gas* of the older chemists, containing nitrogen and its oxides, carbonic acid, hydrocyanic acid, aldehyde, acetic acid, acetic ether, formic acid, formic ether, a large quantity of nitrous ether, &c., together with vapour of mercury. The nature and quantity of these products varies according to the proportions of the mixture, the duration of the action, the degree of heat employed, &c.

Cloez found in the mother-liquors of the preparation a peculiar acid, called *homolactic acid* (*g. v.*), resembling lactic acid.

Mercuric fulminate crystallises in white silky needles, soft to the touch, having a sweetish metallic taste, highly explosive, very slightly soluble in cold, more soluble in boiling water, soluble in ammonia.

Decompositions.—1. Fulminating mercury heated to 186° C., or forcibly struck, detonates with great violence; the explosion is likewise produced by contact with strong sulphuric or nitric acid, by a spark from flint and steel, or by the electric spark. When moist, it may be handled without risk of explosion, but in the dry state it is a most dangerous substance, and all manipulations performed upon it should be conducted with the greatest caution.

10 grains of fulminating mercury yield, when exploded, 4 cubic inches of permanent gas at 0° C., and 29.5 in. bar.; but at the moment of explosion this volume is greatly augmented by the expansion produced by the heat of the explosion, and by the admixture of mercurial vapour. The explosive force within a small space is much greater than

that of gunpowder, but, at the same time, it is more sudden, and therefore not so well adapted for propelling a ball, being, in fact, more likely to burst the gun: for propelling a ball, a gradual expansive force is required, such as will continue its impulsive action on the projectile during the whole time of its passage along the bore of the gun. Fulminating mercury is, however, admirably adapted, by its ready inflammability, for the priming of percussion caps, for which purpose it is prepared on the large scale:—1 kilogramme of mercury yields, by the preceding process, 1½ kilogrammes of fulminate, which will serve for priming 40,000 caps. (Gerh. ii. 354; see also *Ure's Dictionary of Arts, &c.*, ii. 308.)

2. Hot *nitric acid* decomposes fulminating mercury, yielding carbonic acid, acetic acid, and mercuric nitrate.—3. Moderately dilute *sulphuric acid* decomposes it without detonation, but with rise of temperature and evolution of gas. In this reaction, 84 per cent. of a white non-detonating powder is separated, apparently a mixture of metallic mercury with mercurous oxalate (mercurous sulphate, according to Berthollet), whilst also a small quantity of mercury appears to remain dissolved in the liquid containing the sulphuric acid.

4. Aqueous *hydrochloric acid* decomposes fulminating mercury, without any considerable evolution of gas, forming mercuric chloride and mercurous oxalate (Howard). According to Ittner, it produces a large quantity of hydrocyanic acid.—5. *Sulphydric acid* converts fulminating mercury immersed in aqueous ammonia into sulphide of mercury and hydrosulphocyanic acid (Pagenstecher):

6. Boiling *potash-solution* separates a large quantity of mercuric oxide, without evolution of ammonia, and yields a filtrate, which, as it cools, deposits yellow detonating flakes and needles, probably consisting of potassio-mercuric fulminate, and forms with nitric acid a white precipitate, which detonates strongly by percussion. *Baryta, strontia*, and *lime* behave like potash (Liebig). According to Pagenstecher (Br. Arch. vii. 293), potash-ley exerts no action in the cold; when hot, it separates mercuric oxide, but the filtrate yields by evaporation, not a detonating salt, but only carbonate of potassium. This reaction might be represented by the equation:

7. A solution of fulminating mercury in warm aqueous *ammonia* deposits, on cooling, yellow, strongly detonating, granular crystals; but if the solution be boiled for some time, it deposits, on cooling, a yellowish white, non-detonating powder (Liebig). According to Pagenstecher, fulminating mercury dissolves abundantly in ammonia, without separation of oxide; the solution, when exposed to the air, gives off ammonia, and becomes covered with a crystalline crust of unaltered fulminating mercury, which renews itself as often as it is broken.

8. Finely divided *zinc, copper*, or *silver* (the last in contact with platinum-foil), boiled in water with fulminating mercury, decomposes that compound, yielding metallic mercury and fulminate of zinc, copper, or silver (Liebig). A pasty mixture of fulminating mercury with pulverised *iron* and water, moderately warmed, becomes strongly heated, and dries up almost completely to a red-brown mass; this, when mixed with lukewarm water and filtered, yields a filtrate which, on evaporation, leaves a small saline residue containing ammonia; and on the filter there remains a black-brown residue which contains globules of mercury; yields prussian blue with hydrochloric acid; and when heated after drying, burns with bright sparkling, but without detonation. (Pagenstecher.)

Fulminates of Silver.—1. The *neutral salt*, or *fulminating silver*, $\text{C}^2\text{N}^2\text{Ag}^2\text{O}^2$, is formed by heating aqueous nitrate of silver with strong nitric acid and alcohol, the same phenomena and products appearing as in the formation of fulminating mercury (p. 732). Neutral nitrate of silver does not yield fulminating silver when boiled with alcohol; the formation of that compound requires the presence of nitrous acid, inasmuch as cyanogen is thereby produced; when nitrous acid vapour is passed into an alcoholic solution of nitrate of silver, fulminating silver quickly separates in large needles, without ebullition of the liquid (Liebig, Ann. Ch. Pharm. v. 287):

2. Fulminating silver is also produced by boiling fulminating mercury with water, pulverised silver, and platinum-filings. (Liebig.)

Preparation.—Nitrate of silver is heated with alcohol and strong nitric acid till the liquid begins to boil up; and the crystals of fulminating silver which form during the ebullition and as the liquid cools, are collected on a filter, washed with cold water, and dried either in the cold, or at most at the heat of the water-bath.

Howard and Cruickshank dissolve 1 pt. of silver in a mixture of 24 pts. water and 24 pts. of the strongest nitric acid, add 24 pts. of alcohol, and obtain 1.5 pt. of fulminating silver. Brugnatelli (A. Gehl. i. 665) pours 5 pts. alcohol and then 5 pts. fuming nitric acid on 1 pt. of pulverised lunar caustic, and at the proper time cools the mixture, which boils up and deposits fulminating silver, with water, to prevent the fulminating silver from being decomposed. Accum recommends 2.5 pts. of fuming nitric acid and 7 pts. of alcohol to 1 pt. of nitrate of silver. Descotils (Ann. Chim. lxii. 198) adds the alcohol to the nitric acid as the silver dissolves in it; as however the alcohol interferes with the solution of the silver, the product is, according to Liebig, greatly diminished thereby. Wagenman (Gilb. Ann. xxxi. 110) mixes a solution of 1 pt. silver in 8 pts. nitric acid of specific gravity 1.18, heated to 50° or 60° C., with 8 pts. alcohol of specific gravity 0.85; heats the liquid again to 50° or 60°, and adds 4 pts. of fuming nitric acid, which causes foaming and formation of fulminating silver in quantity at least equal to $\frac{3}{4}$ of the silver used. According to Liebig, the quantity of alcohol here recommended is too small; and the liquid becomes too hot, whereby the fulminating silver is decomposed (Liebig). Gay-Lussac and Liebig dissolve 1 pt. of silver in 20 pts. nitric acid of specific gravity 1.308; add to the solution 27 pts. alcohol of 86 per cent.; heat the mixture till it boils up; remove the liquid, which is becoming turbid, from the fire; mix it, in order to moderate the frothing, with another 27 pts. of alcohol; and obtain, after the liquid has completely cooled, about 1 pt. of fulminating silver. The mother-liquor of fulminating silver is green if the silver contains copper, and when evaporated deposits all the copper in the form of oxalate; there then remains a liquid containing silver, which, when further evaporated, leaves a red salt, easily soluble in water. (Liebig.)

The preparation of fulminating silver requires the greatest caution. Capacious vessels must be used, so that the liquid may not boil over, as in that case the salt might dry on the outside and then explode; all flame must be removed to a distance, lest the vapours should take fire; and the mixture must be stirred with wooden rods, not with glass rods or other hard bodies. Contact with hard bodies must especially be avoided after the preparation is dry. Paper shovels must be used to transfer it, and it must be kept in vessels of paper or paste-board, not of glass, and the vessels must be loosely covered, as an explosion might arise from the friction of glass stoppers, or from pressing the cover of the box to fix it.

Fulminating silver forms small, white, opaque, shining needles, having a strong, bitterish metallic taste, and very poisonous. It is but very slightly soluble in cold water, dissolves in 36 pts. boiling water, and separates on cooling. It dissolves much more freely in aqueous ammonia, and is left behind unaltered as the ammonia evaporates. It is used for making crackers and other detonating toys.

Decompositions.—1. Fulminating silver gradually blackens when exposed to white or to blue light, giving off carbonic anhydride and nitrogen, and leaving a black substance, mixed with a small quantity of the undecomposed salt (Liebig).—2. It explodes much more violently than fulminating mercury, by heat, by the electric spark, by friction or percussion, or by contact with oil of vitriol. A heat of 100° to 130° C. is not sufficient to induce the explosion of dry fulminating silver; and it does not explode by mere pressure, unless the pressure be very strong. In the moist state, it requires a much harder blow to explode it than when dry, but it will sometimes explode, even under water, by friction with a glass rod. It explodes with peculiar readiness when rubbed with glass-dust or sharp sand; also, when dry, with the edge of a playing card. It may, however, be rubbed to powder in a porcelain mortar with a cork or with the finger (Liebig). When well washed, and then exposed to the sun till it is dry, it explodes on the slightest touch. According to Schmidt (Schw. J. xli. 72), oil of vitriol causes moist fulminating silver to detonate as strongly as the dry compound. The light accompanying the explosion, which is most easily seen in the dark, is reddish-white with a tinge of blue; it is succeeded by a grey vapour having a peculiar electrical odour. Gunpowder mixed with fulminating silver is not ignited by the explosion, but merely scattered about (Liebig). Fulminating silver, mixed with 20 times its weight of finely pulverised sulphate of potassium, gradually decomposes when heated in a tube, yielding 2 vols. carbonic anhydride to 1 vol. nitrogen (also carbonate of ammonia, if moisture is present), and doubtless leaves paracyanide of silver, CNAg^+ ; for the residue mixed with cupric oxide and ignited again yields the same gaseous mixture, in about the same quantity and the same proportions as by the first ignition (Gay-Lussac and Liebig). Therefore, in the first instance:

afterwards, when ignited with cupric oxide:

A mixture of 1 pt. fulminating silver and 40 pts. cupric oxide, when heated, immediately gives off, without detonation, the whole of the carbonic anhydride and nitrogen gases in the proportion by vol. of 2 to 1. (Gay-Lussac and Liebig.)

3. Fulminating silver thrown into a bottle filled with chlorine explodes before it reaches the bottom, and therefore does not burst the bottle (E. Davy). Fulminating silver, well moistened with water and exposed to a current of chlorine gas, absorbs a large quantity of the gas, turns yellow, and is finally converted, without any formation of carbonic or chloric acid, into chloride of silver and a yellow oil, heavier than water, having a pungent odour, attacking the eyes strongly, and having a sharp burning taste which almost paralyses the tongue. If the mixture be agitated with water and distilled, gas is given off before the water begins to boil, and a colourless oil passes over, having a somewhat less powerful odour. This oil gives off gas under water, is insoluble in aqueous alkalis, but dissolves in alcohol; and the alcoholic solution, if mixed first with potash, then with a ferric salt, and then with an acid, exhibits a green colour. This oil is therefore related to chlorocyanic oil (p. 282). (Liebig, Pogg. Ann. xv. 564.)

4. Nitric acid boiled for some time with fulminating silver decomposes it, forming nitrate of ammonia and nitrate of silver.

5. Dilute sulphuric or oxalic acid decomposes fulminating silver without effervescence, forming hydrocyanic acid and ammonia. (Gay-Lussac and Liebig.)

6. Aqueous hydrochloric acid immediately converts all the silver of fulminating silver into chloride of silver, with evolution of the odour of hydrocyanic acid (Desootils). By a comparatively small quantity of hydrochloric acid, the fulminating silver is converted into chloride and acid fulminate of silver, $C^2N^2HAgO^2$; but on adding hydrochloric acid till the filtrate is no longer clouded by it, the acid fulminate is converted into chloride of silver, hydrocyanic acid, and a peculiar chlorinated acid (*chlorhydrocyanic acid*), containing a quantity of chlorine which appears to amount to 2.5 times as much as that which is contained in the chloride of silver produced. This acid tastes pungent and sweetish, reddens litmus strongly, and does not precipitate nitrate of silver. It decomposes when exposed to the air for some hours, more quickly when heated, yielding ammonia, which neutralises the still undecomposed portion of the acid. After neutralisation with potash, whereby it first acquires a rose-red, then a yellow colour, or after it has been saturated with ammonia by spontaneous decomposition, it colours ferric salts deep red. The acid saturated with potash, gives off ammonia when evaporated, and leaves a residue which effervesces strongly with acids, and whose aqueous solution precipitates nitrate of silver (Gay-Lussac and Liebig, Ann. Ch. Phys. xxv. 285).

7. Aqueous hydriodic acid decomposes fulminating silver in a similar manner, yielding iodide of silver and an iodated acid, analogous to the chlorinated acid, but forming a deep red precipitate with sesquichloride of iron, without being first neutralised; no odour of hydrocyanic acid is perceptible in this reaction (Gay-Lussac and Liebig). Hydrofluoric acid does not decompose fulminating silver.

8. A small quantity of aqueous sulphydric acid decomposes fulminating silver, forming sulphide of silver and cyanic acid; a larger quantity forms sulphide of silver and hydrosulphocyanic acid:

and

9. Aqueous solutions of alkaline sulphides, e. g. protosulphide of barium, acting in insufficient quantity, decompose cyanide of silver, yielding a fulminate of silver and the alkali-metal, and sulphide of silver (Liebig):

With a larger proportion of the metallic sulphide, an alkaline fulminate ($C^2N^2K^2O^2$) appears to be formed at ordinary temperatures, and, with the aid of heat, a compound of the alkali with a sulphuretted acid different from hydrosulphocyanic acid.

10. Aqueous solutions of the fixed alkalis, as also magnesia, boiled with fulminating silver, gradually separate not quite half the silver in the form of a black oxide, a solution of fulminate of silver and potassium, sodium, barium, strontium, calcium, or magnesium being formed at the same time (Gay-Lussac and Liebig):

11. Aqueous solutions of the alkaline chlorides, even when added in excess, precipitate only half the silver in the form of chloride, and form fulminate of silver and potassium, &c. (Gay-Lussac and Liebig):

At the boiling heat, alkaline chlorides and iodides convert fulminic acid into fulminic acid. (Liebig, Schischkoff; see p. 738.)

12. *Copper or mercury*, boiled with fulminating silver and water, ultimately separates all the silver in the metallic state, forming fulminate of copper or fulminate of mercury (Liebig). When the boiling with mercury is continued for a short time only, fulminate of silver and mercury is formed. *Zinc*, even when boiled for several days with fulminating silver, separates only half the silver, so that fulminate of silver and zinc is formed. When fulminate of silver is boiled with water and *iron filings*, a red-brown filtrate is obtained, which, when evaporated, yields reddish laminated crystals of fulminate of iron. (Liebig.)

Fulminate of Silver and Ammonium. $C^2N^2Ag(NH^1)O^2$.—From a solution of fulminate of silver in hot aqueous ammonia, this salt crystallises on cooling in white, shining, crystalline grains, having a pungent metallic taste, while argentate of ammonia remains in solution. It detonates with three times the force of fulminating silver, and with extreme facility, even under the liquid, when touched with a glass rod; if, however, the liquid contains excess of ammonia, the explosion does not extend throughout the mass. It is very sparingly soluble in water. (Liebig.)

Fulminate of Silver and Barium.—Dingy white crystalline grains, which detonate with violence, dissolve sparingly in water, and are decomposed by hydrochloric acid. Zinc immersed in the boiling aqueous solution throws down silver; the filtrate deposits on evaporation a yellow powder, which between 160° and 160° C. burns away without detonation, like cyanate of silver, leaving carbonate of barium mixed with zinc, and when treated with hydrochloric acid, yields sal-ammoniac with effervescence, and cannot therefore be a fulminate. (Liebig.)

Fulminate of Silver and Calcium.—Small yellow crystalline grains, of high specific gravity, and dissolving readily even in cold water. (Liebig.)

Fulminate of Silver and Hydrogen, or *Acid Fulminate of Silver*, $C^2N^2AgHO^2$.—Precipitated in the form of a white powder, on mixing the aqueous solution of fulminate of silver and potassium with nitric acid not in excess:

This salt dissolves readily in boiling water, crystallising out on cooling; reddens litmus. By boiling with silver-oxide, it is converted into neutral fulminate of silver, and by boiling with mercuric oxide, into fulminate of silver and mercury. (Liebig, Ann. Ch. Phys. xxiv. 302.)

Fulminate of Silver and Magnesium.—*a. Basic*.—Obtained by boiling fulminating silver with magnesia and water. Rose-coloured powder, insoluble in water, which merely decrepitates when heated, giving off carbonic acid and ammonia, and leaving a residue of magnesia and silver.—*b. Neutral*.—White, thread-like crystals, resembling capillary native silver, and detonating strongly. (Liebig.)

Fulminate of Silver and Mercury, or *Argento-mercuric Fulminate*.—Formed by boiling fulminate of silver and hydrogen with mercuric oxide and water, or by boiling fulminating silver for not too long a time with mercury and water. From the filtrate the compound crystallises in small shining needles. (Liebig.)

Fulminate of Silver and Potassium, $C^2N^2AgKO^2$.—300 pts. (1 at.) fulminating silver are decomposed by not quite 74.6 pts. (1 at.) chloride of potassium dissolved in water; or water in which fulminating silver is suspended is kept in a state of ebullition, and aqueous chloride of potassium added as long as it occasions turbidity, but no longer; the liquid is then decanted from the chloride of silver, and cooled till it crystallises. If it be filtered instead of being decanted, a brownish liquid is obtained which yields brownish crystals; but if it be boiled for some time after dilution with water, it loses its colour, deposits black flakes, and when decanted from these, yields colourless crystals. The compound is obtained less pure by boiling fulminating silver with aqueous potash, and decanting from the precipitated oxide of silver.

It forms white, shining, somewhat elongated laminae, which have a repulsive metallic taste, and do not blue reddened litmus paper; detonates very easily and with great violence. It dissolves in 8 pts. of boiling, and in a larger quantity of cold water. Nitric acid added, not in excess, to the aqueous solution, throws down a white powder, consisting of fulminate of silver and hydrogen. Hydrochloric acid added to the solution mixed with potash, throws down a precipitate, which continues to redissolve in the liquid till all the potassium is converted into chloride; any further quantity of the acid throws down chloride of silver, with simultaneous formation of hydrocyanic acid, carbonic acid, and sal-ammoniac. Chloride of potassium does not decompose this salt. Copper immersed in the aqueous solution, throws down all the silver by forming fulminate of copper and potassium. The solution does not precipitate ferric sulphate, or yield prussian blue on subsequent addition of hydrochloric acid (Liebig.)

Fulminate of Silver and Sodium, prepared by a similar process, forms small, red-brown, metal-shining laminae, more soluble in water than the potassium-salt, but otherwise exhibiting similar reactions. (Liebig.)

Fulminate of Silver and Strontium.—Dingy white crystalline grains, which detonate with violence, and are sparingly soluble in water. (Liebig.)

Fulminate of Silver and Zinc.—By boiling fulminating silver with zinc and water—whereby only half the silver is precipitated, even after long-continued ebullition—and evaporating the yellow filtrate, yellow detonating crystals are obtained, together with a yellow non-detonating powder. (Liebig.)

Fulminates of Zinc The neutral salt, also called *fulminating zinc*, was first obtained by Liebig, who showed that when zinc is boiled with fulminating mercury and water, mercury is separated, and a yellow liquid produced, which, on cooling, deposits yellowish, slightly detonating crystals; and was more particularly examined by E. Davy (Dublin Soc. Transact. 1829). To prepare it, 1 pt. of fulminating mercury is placed under water in contact with 2 pts. of zinc filings, and the whole frequently shaken, till all the mercury is precipitated and an amalgam formed, after which the filtrate is left to evaporate spontaneously.

The salt forms transparent, colourless, rhombic tables, which are tasteless, detonate very strongly at 195° C. or by percussion, or by contact with oil of vitriol,—are insoluble in water, but dissolve in aqueous alkalis. If the filtrate be evaporated, not in the cold, but at a gentle heat, there remains a deep yellow crust, together with yellow needles, which do not detonate by contact with sulphuric acid, but when heated, detonate as readily, but not so violently, as the first-mentioned crystals; this latter product is insoluble in cold water and alcohol, but dissolves sparingly in boiling water and very readily in ammonia.—An aqueous solution of fulminate of zinc poured into a bottle filled with chlorine gas yields a volatile, strongly smelling oil, which has a sweet and bitter taste, does not detonate, is insoluble in water, and reddens litmus after some time only.

Fulminate of Zinc and Hydrogen, or *Acid Fulminate of Zinc*.—The aqueous solution of fulminating zinc, recently prepared by the action of zinc on fulminating mercury, is precipitated by excess of baryta-water, which separates a large quantity of oxide of zinc; the excess of baryta is removed by a stream of carbonic acid; the filtrate, which contains fulminate of zinc and barium, and throws down fulminate of silver from a solution of the nitrate, is treated with the exact quantity of sulphuric acid required to remove the barium; and the liquid is filtered. The filtrate contains a large quantity of zinc. (Fehling, Ann. Ch. Pharm. xxvii. 130.)

The reaction is as follows:

then:

finally:

The solution has a powerful odour, like that of hydrocyanic acid; tastes agreeably sweet at first, but afterwards pungent and astringent. When kept in a bottle, it gradually loses its odour, becomes yellow, and deposits a yellow powder, but still forms an explosive yellow precipitate with nitrate of silver. (E. Davy.)

By saturating the solution with different bases, the double salts of fulminating zinc are obtained, in which the hydrogen is replaced by an equivalent quantity of another metal or of ammonium [they were regarded by Davy as pure fulminates]. These salts detonate, according to Davy, between 175° and 230° C.; most of them are soluble in water, and have a sweetish rough taste; their solutions precipitate nitrate of silver.

Aluminium-salt.—Yellow, indistinctly crystalline,* neutral, slightly detonating, easily soluble.

Ammonium-salt. The solution evaporated to a syrup, solidifies in the crystalline form. The salt has an alkaline reaction, deflagrates with a yellow flame when heated, and on exposure to the air, becomes moist, but does not decompose.

Barium-salt.—Crystallises from the syrupy solution in flat, transparent, four-sided prisms, which are alkaline, explode like the potassium-salt, turn yellow when exposed to the air, and are soluble in alcohol. (E. Davy.)

Cadmium-salt.—White opaque needles, which slowly turn yellow on exposure to the air, more quickly when heated, are very explosive, sparingly soluble in water.

Calcium-salt.—Very small, alkaline, detonating crystals, which turn yellow when heated, become moist when exposed to the air, and are sparingly soluble in water.

Chromic-salt.—Small, yellow-green, detonating crystals, easily soluble in water.

Cobalt-salt.—Delicate yellow needles, detonating, sparingly soluble in cold, more soluble in boiling water.

Gold-salt.—Obtained by precipitating a solution of fulminate of zinc and barium with a dilute solution of chloride of gold. Brown explosive powder, soluble in ammonia, hydrochloric acid, and strong sulphuric acid. The solution in sulphuric acid yields, when diluted with water, a dark purple precipitate; and the liquid filtered therefrom yields, by evaporation, besides a deposit of metallic gold, hexagonal prisms, which are explosive, insoluble in water and in hydrochloric acid, but soluble in nitro-hydrochloric acid.

Lead-salt.—White crystalline powder.

Magnesium-salt.—Long, flat, four-sided prisms, which are opaque; neutral; explode by heat or percussion, but not by contact with oil of vitriol; and dissolve readily in water and in alcohol.

Manganese-salt.—Viscous, very explosive mass.

Nickel-salt.—Yellow, or yellowish green crust, very explosive, slightly soluble in water.

Palladium-salt.—Brown explosive precipitate, insoluble in water.

Platinum-salt.—Obtained by decomposing fulminate of zinc and barium with sulphate of platinum. Brown precipitate which explodes without detonation; the filtered liquid yields, by evaporation, small yellowish brown prisms which detonate very strongly.

Potassium-salt.—Transparent, colourless, rhombic prisms, which have an alkaline reaction, and a sweetish rough taste; explode violently with a pale red flame, by heat, percussion, or contact with oil of vitriol; deliquesce in the air; but are insoluble in alcohol. (E. Davy.)

Sodium-salt.—Efflorescent, oblique rhombic prisms with dihedral summits. Detonates like the potassium-salt.

Strontium-salt.—Small, transparent needles.

FULMINIC ACID. See FULMINATES (p. 730).

FULMINURIC ACID. $C^4H^2N^2O^3$. *Isocyanuric acid.*—An acid isomeric with cyanuric acid, which appears to have been discovered, independently and about the same time (1855), by Liebig (Ann. Ch. Pharm. xcv. 282), and by Schischkoff (Petersb. Acad. Bull. xiv. 98; Ann. Ch. Pharm. xevii. 53). It is produced by the action of alkaline chlorides or iodides at the boiling heat on fulminating mercury, 3 at. fulminic acid (containing 2 at. carbon), being converted into 2 at. fulminuric acid, according to Liebig: $3C^2N^2H^2O^2 = 2C^2N^2H^2O^3$; or according to Schischkoff, 1 at. fulminic acid (containing 4 at. carbon) being resolved into 1 at. fulminuric and 1 at. cyanic acid:

Schischkoff originally regarded fulminuric acid as a compound of 1 at. cyanic acid and 1 at. nitracetonitrile = $CNHO.NC^2(NO^2)H^2$: subsequently (Compt. rend. li. 99),

he has expressed its composition by the formula $N \begin{Bmatrix} C^2(NO^2)H^2O \\ Cy \\ H \end{Bmatrix}$.

Preparation.—1. *Of the Ammonium-salt.*—Well washed fulminating mercury (60–75 grms.) is mixed in a glass flask with 700 to 800 cub. cent. of water, 60 cub. cent. of a cold-saturated solution of sal-ammoniac then added, and the whole heated to the boiling point. In a few minutes, a yellow crystalline powder begins to separate. As soon as the deposition of this precipitate has ceased, the vessel is removed from the sand-bath, and caustic ammonia added as long as a white precipitate is formed, after which the liquid is immediately filtered and evaporated to the crystallising point. The yellow crystals thus obtained are washed with water, and afterwards with alcohol, then dissolved in hot water, and the solution decolorised by well-washed blood-charcoal, or bone-charcoal. The filtrate on cooling yields dazzling white crystals of great beauty. (Liebig.)

2. *Of the Potassium-salt.*—Liebig prepares this salt in the same manner as the ammonium-salt. Schischkoff's mode of preparation is as follows:

2 pts. of moist fulminating mercury are added by small portions, and with constant stirring, to a nearly saturated and gently boiling solution of 1 pt. chloride of potassium, the ebullition being continued till no more fulminating mercury remains at the bottom. The liquid, which has a yellow colour, arising from the formation of a precipitate of indefinite constitution, is then filtered hot, in order that the principal product, a compound of fulminurate of potassium with mercuric oxide, which is a curdy substance, sparingly soluble in cold water, may not be deposited during the filtration; and the yellow precipitate on the filter is washed with hot water. The filtrate, on cooling, deposits the curdy compound of mercuric oxide and fulminurate of potassium, a further quantity

of which may be obtained by concentrating and cooling the mother-liquor and the wash-water. The portions which separate out in the second and third coolings are contaminated with the yellow precipitate, but may be purified by solution in boiling water. Ultimately a mother-liquor is obtained, containing an excess of chloride of potassium and a considerable quantity of mercuric chloride. To obtain the fulminate of potassium from the curdy compound, water is poured upon the latter, and sulphydric acid gas passed through the liquid, whereupon sulphide of mercury separates, together with crystals of the potassium-salt; and to obtain the latter, the entire liquid is heated, filtered hot, and left to crystallise. On cooling, it deposits shining colourless crystals of the potassium-salt, a further quantity of which may be obtained by repeatedly evaporating and cooling the mother-liquor. In this manner, 150 pts. of fulminating mercury yield 20 pts. of fulminate of potassium (Schischkoff). Liebig makes no mention of the curdy compound of mercuric oxide and fulminate of potassium. The reason of Schischkoff's having obtained it, is probably that he used a saturated solution of chloride of potassium, whereas Liebig used a dilute solution. Liebig's method is evidently the easier of the two.

From the potassium- or ammonium-salt, the lead or silver-salt may be prepared by double decomposition, and the free acid may then be obtained by decomposing the lead-salt with sulphydric, or the silver-salt with hydrochloric acid.

Properties.—The aqueous solution of the acid left to evaporate in a warm place, solidifies to a compact, yellowish, indistinctly crystalline mass (Liebig; Schischkoff). From a saturated alcoholic solution, the acid separates, according to Schischkoff, in small colourless prisms; Liebig, on the other hand, did not obtain crystals from the alcoholic solution. The crystals are anhydrous, and permanent in the air (Schischkoff). The solution has an acid reaction, and a very sour taste. It dissolves very easily in water; the solution in a small quantity of water forms a syrup, and may be evaporated without decomposition (Liebig). The acid is soluble in boiling alcohol (Liebig); in alcohol and in ether (Schischkoff).

Decompositions.—1. The acid and its salts explode when heated, the decomposition of the acid taking place at 150° C. (Schischkoff); the acid detonates slightly when heated (Liebig).—2. The aqueous solution of the acid is decomposed by boiling with mineral acids, a salt of ammonia being formed, carbonic anhydride evolved, and a brown substance produced, which has not been further examined (Liebig). *Sulphuric acid* decomposes the salts of fulminuric acid without blackening, forming sulphate of ammonia, and eliminating a mixture of carbonic anhydride and carbonic oxide. Weak *hydrochloric acid* has scarcely any action on the fulminurates; but the strong acid decomposes them, with formation of ammonia and evolution of carbonic anhydride. On saturating the excess of hydrochloric acid with an alkali, and adding a calcium or barium salt, a white precipitate is formed; but if the action of the hydrochloric acid has been long continued, and the liquid has been afterwards evaporated to dryness, no such precipitation takes place.—3. *Nitrous acid* passed through a solution of fulminuric acid, decomposes it, with evolution of gas (carbonic anhydride), and forms an acid which does not precipitate calcium-salts, but yields with nitrate of silver an insoluble salt containing nitrogen.—4. *Caustic potash* heated with fulminuric acid or its salts, gives off a large quantity of ammonia, and forms carbonate of potassium; and the solution, when neutralised by an acid, forms no precipitate with chloride of calcium or nitrate of silver.—5. *Caustic baryta*, heated with fulminuric acid or its salts, decomposes them, with evolution of ammonia and formation of a white precipitate containing carbonate of barium. This precipitate dissolves in hydrochloric or nitric acid; and after the excess of acid has been neutralised by ammonia, a precipitate is formed, probably identical with that which is produced on adding a barium salt to fulminuric acid which has been decomposed by hydrochloric acid (Schischkoff).—*Sulphydric acid* and *sulphide of potassium* have no action on fulminurates, even at the boiling heat.

Fulminurates. Fulminuric acid appears to be monobasic; at all events, all the fulminurates hitherto obtained contain only 1 at. metal in place of hydrogen.

Fulminate of ammonium, $C^2N^2H^2(NH^4)O^2$.—The preparation of this salt has already been described. It forms monoclinic crystals isomorphous with the potassium-salt, and having $a : b : c = 1 : 1.8205 : 2.4015$. Angle of inclined axes = $79^{\circ} 6'$. The crystals are prismatically elongated in the direction of the orthodiagonal, and are bevelled at the ends by the faces $-P$. Inclination of $oP : +P\infty = 120^{\circ} 6'$; $oP : -P\infty = 133^{\circ} 58'$; $-P : -P$ in the clinodiagonal principal section = $74^{\circ} 42'$ (Rammelsberg, Jahresber. f. Chem. 1857, p. 289). The crystals possess great refractive and dispersive power, and exhibit double refraction (Liebig, Rodd). Dispersive power = 0.1006 nearly. For a perpendicularly incident ray, the angle of refraction of the extraordinary ray = $4^{\circ} 22'$. The acute angles of the crystals exhibit prismatic colours, in consequence of their high dispersive power. They also exhibit a splendid scarlet colour, arising from the superposition of the coloured

images of the ordinary and extraordinary rays, the violet of the first falling on the red of the second; the beauty of the red is moreover heightened by the neutralisation of the yellow (Rood, Ann. Ch. Pharm. xev. 291). The crystals are anhydrous; when heated, they fuse, blacken, and give off hydrocyanic acid, ammonia, and afterwards hydrated cyanic acid, which, combining with the ammonia, forms in the upper part of the tube, a solid crystalline mass of urea (Liebig). The salt sustains a heat of 150° C. without alteration, but above that temperature it explodes like the other fulminurates (Schischkoff). It dissolves sparingly in cold, readily in hot water; is insoluble in alcohol and ether. (Liebig.)

Fulminurate of Barium, $\text{C}^{\text{N}}\text{H}^{\text{N}}\text{Ba}^{\text{O}} + 2\text{aq}$.—Obtained by double decomposition in the form of a crystalline pulp composed of short, thin, white needles, which dissolve completely in a very large quantity of hot water, and separate on cooling in hard isolated crystals, which are colourless and transparent, and often take the form of rhombic prisms, terminated by a macrodiagonal dome (Liebig). According to Rammelsberg, the salt forms monoclinic crystals, exhibiting the faces ∞P , $+\text{P}\infty$, $-\text{P}\infty$, oP , $[\text{P}\infty]$, and prismatically elongated in the direction of the principal axis. Ratio of axes $a : b : c = 1 : 2.032 : 2.348$. Angle of inclined axes $= 72^{\circ} 27'$; $\text{oP} : \infty\text{P}$ in the clinodiagonal principal section $= 54^{\circ} 36'$; $\text{oP} : \infty\text{P} = 97^{\circ} 57'$; $\text{oP} : +\text{P}\infty = 120^{\circ} 36'$; $\text{oP} : -\text{P}\infty = 140^{\circ} 45'$; $\text{oP} : [\text{P}\infty] = 114^{\circ} 0'$. The crystals refract doubly, but in a much less degree than the ammonium and potassium-salts, the angle of refraction of the extraordinary ray for perpendicular incidence being only $1^{\circ} 9'$ (Rood). Between 150° and 180° C. they give off 8.52 per cent. (1 at.) water, and become opaque; at a higher temperature, they decompose like the potassium-salt. (Liebig.)

Fulminurate of Calcium is soluble in water and in alcohol. (Liebig.)

Fulminurate of Copper has not been prepared. An *ammoniocupric fulminurate*, $4\text{NH}_3 \cdot \text{C}^{\text{N}}\text{H}^{\text{N}}(\text{Cu}^{\text{O}})_2$, or *fulminurate of ammonocuprammonium*, $\text{C}^{\text{N}}\text{H}^{\text{N}}(\text{N}^{\text{H}}_4)(\text{NH}_4)_2\text{Cu}^{\text{O}}_2$, is obtained by mixing fulminuric acid with a solution of a copper-salt in excess of ammonia and heating the liquid to boiling. The liquid, as it cools, deposits the salt in beautiful, shining, dark blue prisms, which undergo no change in the air at ordinary temperatures, or even at 150° C., but are decomposed, with explosion, at higher temperatures. It is nearly insoluble in water, and very sparingly soluble in ammonia, so that very small quantities of fulminuric acid may be separated in this form. (Schischkoff.)

Fulminurate of Ethyl.—When fulminurate of potassium is immersed in alcohol, and hydrochloric acid gas passed through the liquid, chloride of potassium is formed, together with fulminuric ether; as soon as the reaction is complete, the stream of gas must be discontinued, because an excess of hydrochloric acid decomposes the ether, with formation of a crystalline body. After the excess of alcohol and the chloride of ethyl formed at the same time have been distilled off, and a sufficient quantity of water has been added to the solution of chloride of potassium, the fulminuric ether separates in the form of an aromatic liquid; the portion which remains dissolved may be separated by agitating the watery liquid with common ether. Fulminuric ether is decomposed by alcoholic potash, even at ordinary temperatures, with formation of fulminurate of potassium; it cannot be distilled without decomposition. Its alcoholic solution mixed with phenylamine deposits, after a few days, colourless, silky prismatic crystals, which melt and turn brown at 100° C., and perhaps consist of the phenylamide of fulminuric acid. (Schischkoff.)

Fulminurate of Iron (ferrosium), separates in beautiful, pale green crystals on heating a fulminurate with ferrous acetate. (Schischkoff.)

Fulminurate of Lead.—Neutral lead-salts are not precipitated by the alkaline fulminurates. A *basic lead-salt*, $\text{Pb}^{\text{O}} \cdot \text{C}^{\text{N}}\text{H}^{\text{N}}\text{Pb}^{\text{O}}_2$, is obtained on adding basic acetate of lead to a solution of the fulminurate of an alkali-metal, as a white crystalline precipitate, which dissolves in boiling water and separates in hard yellowish crystals on cooling. When decomposed by sulphydric acid, it yields fulminuric acid. (Liebig.)

The *fulminurates of Lithium and Magnesium* are soluble in water and in alcohol.

Fulminurate of Mercury.—The acid is not precipitated by mercurous or mercuric salts. Mercuric oxide heated in a solution of the acid dissolves in it, and the liquid on cooling deposits a mass resembling the curdy compound of mercuric oxide with fulminurate of potassium. (Schischkoff.)

Fulminurate of Potassium, $\text{C}^{\text{N}}\text{H}^{\text{N}}\text{K}^{\text{O}}$.—This salt, the preparation of which has been already described, forms long prisms, having a strong lustre and great refracting power (Liebig). A hot saturated solution, rapidly cooled, solidifies, from formation of a mass of very small silky needles; but by gentle evaporation, the salt is obtained in large and very regular crystals isomorphous with the ammonia-salt (Schischkoff). According to Rammelsberg (*loc. cit.*), they exhibit the faces ∞P ,

$\infty P\infty$, oP , $+P\infty$, $-P\infty$, $-2P$, and are prismatically elongated in the direction of the orthodiagonal. Ratio of axes $a:b:c = 1:1.8704:2.3113$. Angle of inclined axes = $83^\circ 32'$; $\infty P:\infty P$ in the clinodiagonal principal section = $56^\circ 34'$; $oP:\infty P = 93^\circ 4'$; $oP:+P\infty = 125^\circ 2'$; $oP:-P\infty = 132^\circ 51'$.

The crystals are doubly refracting, and for perpendicular incidence, the angle of refraction of the extraordinary ray is between 5° and 6° (Rood, *loc. cit.*). They are anhydrous (Liebig). The salt when heated exhibits a faint glow, and gives off a small quantity of gas, like a mixture of an organic substance with nitre. It undergoes no change at $225^\circ C$, but at a higher temperature it melts, gives off a large quantity of hydrocyanic acid, and afterwards becomes black, and explodes with a red flame. When slowly decomposed in a covered crucible by a heat gradually raised to redness, it yields pure white cyanate of potassium mixed with cyanide (Schischkoff). Heated with chloride of potassium in a combustion-tube, it gives off hydrocyanic acid, then carbonate of ammonia, and a gaseous mixture containing 2 vol. carbonic anhydride to 1 vol. nitrogen, like the gas evolved by the decomposition of dry fulminate and cyanate of silver mixed with sulphate of potassium. The residue consists of cyanide of potassium mixed with chloride (Liebig). The salt is less soluble in cold water than the ammonia-salt (Liebig, Schischkoff), but dissolves in hot water as easily as the latter (Liebig). It dissolves in 10 pts. of cold and a much smaller quantity of boiling water, but is insoluble in alcohol and ether. (Schischkoff.)

Fulminate of Silver.—A hot solution of fulminate of ammonium or potassium mixes with nitrate of silver without turbidity, but as the liquid cools, fulminate of silver separates from it in long, very thin needles, having a silky lustre (Liebig, Schischkoff). The crystals retain their lustre at $100^\circ C$, and do not diminish in weight (Liebig). The salt is not blackened by light, and does not undergo any change at 150° , but at a higher temperature it explodes without noise, and gives off hydrocyanic acid (Schischkoff). It is decomposed by heat in the same manner as cyanate of silver (Liebig). It dissolves very sparingly in cold, but with moderate facility in boiling water, and may be recrystallised without alteration. (Liebig, Schischkoff.)

Fulminate of Sodium is more soluble than the potassium-salt, and crystallises from the aqueous solution by slow evaporation in long prisms. (Schischkoff.)

Fulminate of Strontium forms monoclinic crystals, exhibiting the combination $+P:-P.oP.\infty P\infty$. Ratio of axes $a:b:c = 1:2.718:3.458$. Angle of inclined axes = $82^\circ 50'$; $+P:+P$, in the clinodiagonal principal section = $47^\circ 42'$; $-P:-P$ in the same = $53^\circ 4'$; $+P:-P$ in the orthodiagonal principal section = $140^\circ 49'$; in the basal section = $149^\circ 28'$; $oP:+P = 102^\circ 57'$; $oP:-P = 107^\circ 35'$.

FULMINURIC ETHER. See FULMINURATE OF ETHYL (p. 740).

FUMARAMIDE. $C^4H^4N^2O^2 = N^2 \left\{ \begin{matrix} (C^4H^2O^2) \\ H^2 \end{matrix} \right\}$. (Hagen, Ann. Ch. Pharm.

xxxviii, 275.)—A compound formed by the action of ammonia on fumarate of ethyl, and deposited in white scales, when the ether, mixed with aqueous ammonia, is set aside for some time in a cold place. It is insoluble in cold water, but dissolves in boiling water and separates out unchanged on cooling. It is insoluble in alcohol. (Hagen.)

Fumaramide yields by dry distillation, ammonia, a crystalline sublimate, and a carbonaceous residue. Heated with aqueous alkalis, it gives off ammonia, and when heated for some time with water, it is converted into fumarate of ammonium:

Compound of Fumaramide with Mercuric Oxide.—Red oxide of mercury boiled in water with fumaramide is rapidly decolorised, and yields a white pulverulent compound, which must be carefully washed with boiling water and dried at 100° . It is decomposed by hydrochloric and sulphydric acids. (Dessaignes, Ann. Ch. Pharm. lxxxii. 233.)

FUMARIC ACID. $C^4H^4O^4 = (C^4H^2O^2) \left\{ \begin{matrix} H^2 \\ O^2 \end{matrix} \right\}$. Lichenic acid. Paramaleic acid.

(Lassaigne [1819], Ann. Ch. Phys. [2] xi. 93.—Pfaff, Schw. J. xlvii. 476.—Winckler, Repert. Pharm. xxxix. 48, 368; xlviii. 39, 363.—Pelouze, Ann. Ch. Phys. [2] lvi. 429.—Schödler, Ann. Ch. Pharm. xvii. 148.—Rieckher, *ibid.* xlix. 31.—Delffs, Pogg. Ann. lxxx. 435.—Dessaignes, J. Pharm. [3] xxxii. 48.)—An acid isomeric with maleic acid, differing from maleic acid by containing 1 at. less of water, and from succinic acid by containing 2 at. less of hydrogen. It exists ready formed in several plants, viz. *Fumaria officinalis*, *Corydalis bulbosa*, *Glauicum flavum*, *Lichen islandicus*, and *Boletus pseudo-ignarius*. It is produced by the dehydration of maleic acid; by molecular transformation of maleic acid, namely, when that acid is heated with hydriodic or hydrobromic acid (Kekulé, Ann. Ch. Pharm. Suppl. ii.

85); and, according to Mulhhausen (Ann. Ch. Pharm. ci. 171), is found among the products of the oxidation of protein-compounds by nitromuriatic acid.

Lassaigne, in 1819, first showed that in the dry distillation of maleic acid, there is produced, besides maleic acid, another acid, which was further investigated by Pelouze in 1834, who called it paramaleic acid. Pfaff in 1826 found in Iceland moss (*Lichen islandicus*) an acid to which he gave the name of lichenic acid; and Winckler in 1833 obtained from fumitory (*Fumaria officinalis*) an acid designated as fumaric acid. The identity of this acid with paramaleic acid was demonstrated by Demarcay in 1834, and with lichenic acid by Schödler in 1836. The boletic acid found by Braconnot in *Boletus pseudo-igniarius*, and supposed by him to be a distinct acid, was shown by Bolley (Ann. Ch. Pharm. lxxxvi. 46) to be likewise identical with fumaric acid.

Preparation.—1. *From Fumitory.*—The aqueous decoction of the fresh flowering herb, together with the roots, after straining, subsidence, and decantation, is evaporated, first over the open fire and then over the water-bath, to a thin syrup; and this syrup, while still hot, is mixed with a small quantity of hydrochloric acid, and left for about a fortnight in a cool place, till the fumaric acid has separated in hard brown crystals. The mother-liquor is then diluted with water and poured off; the crystals washed with cold water, suspended in water, and slightly supersaturated with carbonate of potassium; the filtrate slightly supersaturated with sulphuric acid, heated in the water-bath, and filtered from the resulting dark brown resinous precipitate; the still brownish crystals of fumaric acid which form on cooling are dissolved in hot water; and the solution is digested with animal charcoal and filtered: it then, on cooling, yields snow-white crystals, amounting to 6.156 per cent. of the fresh herb (Winckler). The fumarate of calcium contained in the expressed juice may also be decomposed by oxalic acid. This salt is deposited spontaneously from the *Extractum Fumaricæ*, after two years' standing, in crystalline grains, which may be separated by diluting the extract with an equal quantity of cold water, then decanting and washing with cold water; when decomposed by aqueous oxalic acid, they yield a brownish acid, which may be freed from an admixed red-brown substance by mixing it with sand and subliming, or by solution in ether and filtration (Winckler, Répert. Pharm. xxxix. 48).—Trommsdorff (N. Tr. xxv. 2, 152) precipitates the recently expressed juice of fumitory—after separation of the scum which forms on boiling—with acetate of lead; decomposes the washed precipitate with sulphydric acid; and obtains, by evaporating and cooling the filtrate, brownish crystals which may be purified with animal charcoal. A similar process is followed by Demarcay. Delffs washes the yellowish green precipitate thrown down by acetate of lead (after it has somewhat diminished in volume by standing); dries it in the air on bibulous paper; rubs it to powder; stirs it up with nitric acid gradually added (whereupon the mass swells up, but gives off only a small quantity of nitrous vapours); agitates the resulting mixture of nitrate of lead and free fumaric acid, after 24 hours with a little water; filters; washes the residue with water; and extracts the fumaric acid with boiling alcohol of ordinary strength. The alcoholic solution is then evaporated; the residue dissolved in ammonia; the excess of ammonia expelled from the solution by heating; and a certain quantity of lead which remains in it, removed by sulphydric acid (the greater part of the colouring matter also separates with the sulphide of lead); the acid fumarate of ammonium is brought to the crystallising point; the crystals, if much coloured, are purified by pressure and recrystallisation; the salt is then dissolved in hot water; and the solution treated with nitric acid, to separate the fumaric acid, which then, after the liquid has cooled, crystallises out completely, but only after a considerable time. The nitric acid, if added in slight excess, generally effects the complete destruction of the colouring matter. By this process, Delffs obtained more than 5 drachms of pure fumaric acid from 20 lbs. of the herb.

2. *From Iceland Moss.*—Sixty-four pts. of the lichen are macerated for some time in water containing carbonate of potassium; the filtrate is precipitated with acetate of lead; the washed brownish precipitate decomposed by sulphydric acid; the filtrate evaporated; and the crystals of the acid, which still contain lime, are purified (Pfaff). The chopped lichen is macerated for six days with water and milk of lime, the mixture being frequently stirred; and the expressed turbid liquid is evaporated to half its bulk, acidulated with acetic acid, then heated, mixed with basic-acetate of lead, as long as reddish flocks containing brown colouring matter continue to separate, and filtered hot. The filtrate, on cooling, deposits white or brown-yellow needles of the lead-salt, and an additional quantity, though impure, on further evaporation; the lead-salt may be decomposed by sulphydric or sulphuric acid. The impure acid is purified by boiling with dilute nitric acid, and cooling to the crystallising point. (Schödler.)

3. *From Glaucium luteum.*—The expressed juice is boiled and precipitated by ammonia; the filtrate evaporated; mixed while still hot with a small quantity of nitric

acid; then with nitrate of lead; and left to cool till the lead-salt separates mostly in the crystalline form. (Probst, Ann. Ch. Pharm. xxxi. 248.)

4. *From Malic or from Maleic acid.*—Malic acid is heated for some time to a temperature a little above 130° , whereupon water passes over, together with maleic acid, and fumaric acid remains behind in the solid state; or, crystallised maleic acid is boiled in a long glass tube, so that the evolved water may continually flow back again, till the maleic is converted into fumaric acid (Pelouze). Dessaignes (Compt. rend. xlii. 524) obtains fumaric acid by heating malic acid for several hours with hydrochloric acid. On the other hand, fumaric acid is converted into malic acid by heating it with hydrochloric acid in sealed tubes. (See below.)

Properties.—The acid obtained from malic acid crystallises from the aqueous solution, in broad, striated, colourless prisms, sometimes rhombic, sometimes hexagonal (Pelouze); that obtained from fumitory, in scales united in stellate groups (Winckler); that from Iceland moss, in needles (Pfaff); in crystals aggregated in cauliflower-like tufts (Schödlér). The acid sublimes in long white needles (Lassaigne Winckler). It requires a high temperature to melt it; volatilises somewhat above 200° C. even before melting, and sublimes for the most part unaltered, but partly resolved into water and fumaric anhydride. It is inodorous, tastes very acid, and reddens litmus strongly (Winckler, Pelouze, and others). It dissolves sparingly in cold, readily in hot water; also in alcohol and ether.

Decompositions.—1. When fumaric acid is heated, a small portion of it is resolved into fumaric anhydride, $C^4H^2O^3$, which volatilises, and water (Pelouze).—2. It may be set on fire by a flaming body, and then burns with a pale blue flame (Winckler).—3. When triturated and heated with *peroxide of lead*, it first gives off water, and then takes fire, without emitting any odour of formic acid (Rieckher).—4. The colourless solution of the acid turns brown when heated (Winckler), and gives off sulphurous acid (Rieckher).—5. The aqueous solution of the acid is not altered by eight days' boiling, or when heated in a sealed glass tube to 250° C., not being in fact converted into malic acid. (R. Hagen.)

6. Fumaric acid enclosed with hydrochloric acid in a sealed tube, and heated to 100° C. for 140 hours, is partly converted into malic acid. On evaporating the resulting liquid to dryness, and treating the residue with a small quantity of water, to separate unaltered fumaric acid, the last mother-liquor yielded by evaporation a deliquescent syrup, which, after drying at 100° C., fused readily, and yielded fumaric acid by dry distillation. Another portion, half saturated with ammonia, yielded by evaporation, first crystals of acid fumarate of ammonium, which gave a precipitate with ferric chloride, then transparent prisms of a salt which did not precipitate ferric chloride, even after addition of ammonia, melted at 40° C. (acid fumarate of ammonium does not melt even at 200°), and was converted at 160° into fumarimide, which is the product obtained by heating acid malate of ammonium. Hence it appears that part of the fumaric acid treated as above described had been converted into malic acid. (Dessaignes, J. Pharm. [3] xxxii. 48.)

7. Fumaric acid is not decomposed by boiling with nitric acid, or with water and peroxide of lead, or acid chromate of potassium; and it does not precipitate platinum-black from solution of chloride of platinum: it exhibits therefore no great tendency to decompose under the influence of oxidising agents.—8. On the other hand, it easily takes up hydrogen, under the influence of certain reducing agents, and is converted into succinic acid:

This change takes place when aqueous fumaric acid is placed for a few hours in contact with *sodium-amalgam*, or when it is heated with *hydriodic acid*. In like manner, when heated to 120° C. in a sealed tube with *hydrobromic acid*, it is slowly transformed by addition of 1 at. HBr, into monobromosuccinic acid, $C^4H^5BrO^4$, and when heated for a few minutes to 100° in a sealed tube, with *bromine* and water, it is converted, by addition of 2 at. bromine into dibromosuccinic acid, $C^4H^4Br^2O^4$. (Kekulé, Ann. Ch. Pharm. Suppl. i. 129; Rép. Chim. pure, 1861, p. 484; Jahresber. 1861, p. 365.)

Fumarates. Fumaric acid is dibasic, forming *neutral salts*, $C^4H^2M^2O^4$ and $C^4H^2M'^2O^4$, and *monometallic or acid salts*, $C^4H^3MO^4$ and $C^4H^3M'O^4$ or $C^4H^2M^2O^4.C^4H^4O^4$. Some of the fumarates are crystalline, others pulverulent, and most of them have a mild taste. None of them, excepting the ammonium, copper, and mercury salts, become carbonised till they are heated above 250° C. They are decomposed by phosphoric, sulphuric, hydrochloric, and nitric acids; but fumaric acid expels acetic acid from the acetates. Many fumarates dissolve in water, but none in strong alcohol. Solutions of the alkaline fumarates precipitate most metallic salts, but not those of

zinc, aluminium, or chromium: fumarate of zinc is easily soluble, and fumaric acid does not appear to be capable of forming salts with aluminium or chromium.

Fumarates of Ammonium.—The neutral salt is very soluble in water, and is converted into the acid salt by evaporation.

The acid salt is obtained by saturating fumaric acid with ammonia, and leaving the solution to evaporate in a non-exhausted receiver over lime and oil of vitriol, or in vacuo over hydrate of potassium. It crystallises in oblique rhombic prisms, truncated on the lateral edges, very soluble in water and alcohol. According to Pasteur (Ann. Ch. Phys. [3] xxxi. 91), the crystals are monoclinic prisms, usually exhibiting the faces ∞P , $\infty P\infty$, oP , $-P$. Inclination of $\infty P : \infty P$ in the orthodiagonal principal section = 110° ; $oP : \infty P\infty = 86^\circ 51'$; $-P : -P = 132^\circ 52'$. The solution has no action on polarised light.

Fumarate of Barium, $C^4H^2Ba^2O^4$ (at $100^\circ C.$).—Fumaric acid does not precipitate baryta-water or chloride of barium. Fumarate of barium is obtained by dissolving fumaric acid in a hot solution of acetate of barium, or by mixing the two substances in hot concentrated solutions. It is then deposited on cooling in anhydrous crystalline grains. It may also be prepared by adding fumarate of potassium or ammonium to chloride of barium, being then deposited in small, shining, rhomboidal, hydrated prisms, which effloresce quickly in the air, giving off 15 per cent. water, and when heated to $100^\circ C.$ lose 20.81 per cent. water. It is very soluble in water and alcohol, not soluble in fumaric acid, or in any other acids in the dilute state.

There does not appear to be an acid fumarate of barium.

Fumarate of Calcium, $C^4H^2Ca^2O^4$ (at $200^\circ C.$).—This salt occurs in fumitory. Fumaric acid does not precipitate lime-water (Lassaigne), or chloride of calcium. From a hot-filtered solution of carbonate of calcium in fumaric acid, or from a mixture of fumarate of potassium with acetate of calcium, colourless shining scales separate after a while, which are tasteless, permanent in the air, and scarcely soluble in water or alcohol. An aqueous mixture of fumaric acid and acetate of calcium deposits highly lustrous crystals, which are sparingly soluble in water, insoluble in alcohol, give off the greater part of their water at $100^\circ C.$, and the whole, amounting to 25.66 per cent. (3 at.) at 200° .

Fumarate of calcium, exposed for some weeks to the heat of summer, in contact with cheese, is converted into succinate:

Fumarate of Cobalt, $C^4H^2Co^2O^4 + 3 aq.$ —A mixture of fumaric acid and acetate of cobalt does not yield crystals by evaporation; but on adding alcohol to the concentrated solution, fumarate of cobalt is deposited in the form of a rose-coloured pulverulent precipitate. It is very soluble in water and in ammonia, slightly in weak alcohol. It gives off 2 at. water at $100^\circ C.$, and 1 at. more at 200° , in all 3 at. = 23.82 per cent.

Fumarate of Copper.—Fumarate of potassium added to cupric sulphate, throws down a pale blue crystalline powder, soluble in hydrochloric or nitric acid, insoluble in water and alcohol. Aqueous cupric acetate, heated with fumaric acid till the latter dissolves, deposits a blue-green crystalline powder. This salt, after drying in the air, gives off 17.67 per cent. (rather more than 2 at.) water at $100^\circ C.$, and 23.61 (3 at.) in all at 200° ; at 230° , it suffers a total loss of 48 or 49 per cent., assuming at the same time a brown colour and being partially decomposed. It dissolves readily in nitric acid, with separation of fumaric acid; slowly in water and alcohol, and is insoluble in boiling fumaric acid. (Rieckher.)

Fumarate of Cuprammonium is deposited in shining dark blue octahedrons on evaporating a solution of fumarate of copper in ammonia. On adding alcohol to this solution, the salt is precipitated in silky blue needles.

Fumarate of Ethyl, $C^4H^{12}O^4 = C^4H^2(C^2H^5)^2O^4$. *Fumaric ether*. Hagen (Ann. Ch. Pharm. xxxviii. 274).—A solution of fumaric or of malic acid in absolute alcohol is saturated with hydrochloric acid gas, the mixture distilled, and the fumaric ether, which passes over after the hydrochloric ether, and when the heat has risen considerably, is collected in a separate receiver, and dried over chloride of calcium. It is an oily liquid, heavier than water, and having a pleasant fruity odour; slightly soluble in water.

The ether heated with potash-ley, is resolved into fumarate of potassium and alcohol. Treated with aqueous ammonia, it deposits after some time crystals of fumaramide:

Fumarate of Iron (ferrie).—Recently precipitated ferrie hydrate does not dissolve in aqueous fumaric acid, even with the aid of heat. The aqueous acid forms a brownish yellow precipitate with ferric sulphate. Fumarate of ammonium or sodium

forms with sesquichloride of iron a pale brown-red precipitate, insoluble in excess of the ammonia-salt (whereby it is distinguished from the precipitate formed by succinic acid). It is very bulky, and difficult to wash; soluble in acids but not in ammonia; and whether precipitated from cold or from hot solutions, contains after drying at 200°C . 44.08 per cent. ferric oxide.

Fumarates of Lead.—1. *Neutral or Monoplumbic salt*, $\text{C}^4\text{H}^2\text{Pb}^1\text{O}^4$ (at 200°C).—Malate of lead is converted at 200°C . into fumarate (Rieckher). The dilute potassium-salt mixed with acetate of lead acidulated with acetic acid, throws down a white crystalline powder, which dissolves on boiling, and crystallises after a while, on cooling, in white shining tufts of needles. The free acid behaves in a similar manner with neutral acetate of lead. The dried salt does not decompose at 200°C . When heated over a flame, it takes fire and burns away with a glimmering light, leaving a mixture of lead and a small quantity of protoxide. The needles, after drying in the air, contain 16.28 per cent. (3 at.) water (Pelouze); 9.31 per cent. (2 at.) according to Rieckher. The salt dissolves readily in nitric acid, with separation of fumaric acid; it is nearly insoluble in cold water, and in strong acetic acid, but dissolves with tolerable facility in boiling water, separating out again unchanged on cooling. It is insoluble in alcohol.

2. A *triplobic salt*, $\text{Pb}^3\text{O}^4\cdot 2\text{C}^4\text{H}^2\text{Pb}^1\text{O}^4$ (at 250°C), is obtained by precipitating basic acetate of lead with acid fumarate of potassium. The white precipitate, which quickly sinks down, gives off all its water of crystallisation at 130°C ., and bears a temperature of 230° without decomposition. (Rieckher.)

3. Another *triplobic salt*, $2\text{Pb}^1\text{O}^4\cdot \text{C}^4\text{H}^2\text{Pb}^1\text{O}^4$ (at 200°C), is obtained by treating the neutral salt with ammonia. (Rieckher.)

Fumarate of Magnesium, $\text{C}^4\text{H}^2\text{Mg}^1\text{O}^4$ (at 200°C).—Fumaric acid mixed with aqueous acetate of magnesium, and evaporated to a syrup, yields no crystals; but if the greater part of the acetic acid be expelled by thorough drying in the water-bath, and the residue exhausted with alcohol, fumarate of magnesium remains undissolved, in the form of a white powder, which gives off 34.48 per cent. (4 at.) water at 200°C ., but only 2 at. at 100° .

Fumarate of Manganese, $\text{C}^4\text{H}^2\text{Mn}^1\text{O}^4 + 3\text{aq}$.—Fumarate of ammonium added to a solution of manganous sulphate precipitates this salt in the form of a white powder. When fumaric acid is heated with solution of manganous acetate, a white powder is formed, containing 3 at. = 24.7 per cent. water, which it gives off at 100°C . The salt is sparingly soluble in water, insoluble in alcohol.

Fumarates of Mercury.—1. *Mercuric salt*.—The potassium-salt throws down from the solution of mercuric chloride, a mixture of yellow needles and a white crystalline salt. Free fumaric acid gives no precipitate, either with corrosive sublimate or with mercuric nitrate; it does not dissolve mercuric oxide, even with the aid of heat. (Rieckher.)

Mercurous salt.—An aqueous solution of mercurous nitrate forms with fumaric acid or alkaline fumarates, a white crystalline precipitate, which suffers no perceptible loss and no change of colour at 100°C . (Rieckher.)

Fumarate of Nickel.—Obtained like the cobalt-salt. Pale green powder, which, after drying in the air, gives off 26.49 per cent. (rather more than 3 at.) water, 30.61 per cent. (4 at.) in all at 200°C ., and at 230° suffers a total loss of 36.22 per cent. with colouring and partial decomposition. It dissolves in water, weak alcohol, and ammonia. (Rieckher.)

Fumarates of Potassium.—1. The *neutral salt*, $\text{C}^4\text{H}^2\text{K}^2\text{O}^4 + 2\text{aq}$, obtained by neutralising the acid with aqueous carbonate of potassium, and evaporating, forms large, transparent, colourless rhombic tables and four-sided prisms, often aggregated in stars, permanent in the air, and having a mild, scarcely saline taste (Winckler); or laminae united in radiating groups (Pelouze). The salt effloresces during the evaporation of its solution, but deposits shining striated prisms at the bottom of the vessel; sometimes the solution yields on evaporation a liquid which, in 12 to 24 hours, is converted into a crystalline powder. The crystals become opaque at a gentle heat, and give off 17.06 per cent. (4 at.) water at 100°C .; at a higher temperature, they melt imperfectly, blacken, swell up to ten times their original bulk, and leave a residue of charcoal and carbonate of potassium. The salt dissolves readily in water, but not in alcohol (Rieckher). From a concentrated aqueous solution, acetic acid throws down the acid potassium-salt; alcohol, the neutral salt, containing 16.61 per cent. (therefore 2 at.) water of crystallisation.

2. *Acid salt*, $\text{C}^4\text{H}^3\text{KO}^4$.—From the cold-saturated aqueous solution of the neutral salt, water saturated with fumaric acid precipitates the acid salt in needles. It forms shining, tufted needles, and oblique four-sided prisms, permanent in the air, and having a pleasant, strongly sour taste. They give off 1 at. water at 200°C ., and decompose at a higher temperature, like the neutral salt. They dissolve much less abundantly in cold water than the neutral salt, plentifully in boiling water; are nearly

insoluble in cold alcohol of 81 per cent., but dissolve sparingly therein at a boiling heat, and crystallise on cooling.

Fumarate of Silver, $C^4H^2Ag^2O^4$.—Free fumaric acid added to nitrate of silver throws down a fine white powder (Lassaigne). The acid, even when dissolved in 200,000 pts. of water, still precipitates silver-solution; and alkaline fumarates precipitate it even at higher degrees of dilution, so completely, indeed, that the filtrate shows no turbidity on the addition of hydrochloric acid (Pelouze). The powder, after being washed and dried in the dark, is white, tolerably heavy, nearly tasteless, and adheres to the fingers. It turns brown when heated, afterwards decomposes, with slight detonation and sparkling, and leaves a bulky, velvet-black mass, which leaves metallic silver when burnt. When heated, it deflagrates like gunpowder. It dissolves readily in nitric acid, with liberation of fumaric acid. It is insoluble in water, and is not decomposed by continued boiling. It dissolves readily in ammonia, and when the ammonia evaporates, yields delicate shining prisms, which give off potash when treated with ammonia.

Fumarate of Sodium, $C^4H^2Na^2O^4$.—The salt precipitated by alcohol from the aqueous solution, is a crystalline powder containing 10.03 per cent. (1 at.) water; when the solution is evaporated, the salt crystallises in needles and prisms containing 25.12 per cent. (3 at.) water. The water escapes, for the most part, at $100^{\circ}C$., completely at 200° , and the residue contains 38.77 per cent. soda. It is a crystalline mass consisting of needles, permanent in the air, having a faint silky lustre, and a warm saline taste; it behaves in the fire like the potassium-salt, dissolves readily in cold water, but is insoluble in alcohol.

It does not appear possible to prepare an acid fumarate of sodium or a fumarate of sodium and potassium, or of ammonium and potassium. (Rieckher.)

Fumarate of Strontium, $C^4H^2Sr^2O^4 + 3 \text{ aq.}$ —Aqueous fumaric acid does not precipitate strontia-water; but on adding the acid to a solution of acetate of strontium, a white crystalline powder is precipitated, consisting of fumarate of strontium with 3 at. water. It is very slightly soluble in water and in alcohol.

Fumarate of Zinc, $C^4H^2Zn^2O^4 + 3 \text{ aq.}$ —Aqueous fumaric acid, saturated at the boiling heat with oxide or carbonate of zinc, yields, on further concentration, large oblique prisms having a vitreous lustre; very soluble in water, but insoluble in alcohol, and containing 3 at. crystallisation-water; but the same solution, if left to evaporate spontaneously in a cool place, yields crystals which contain 4 at. water (29.06 per cent.) and effloresce in the air.

FUMARIC ANHYDRIDE, $C^4H^2O^3 = (C^4H^2O^2)^{\cdot}O$. (Pelouze, Ann. Ch. Phys. [2] lvi, 72.)—This body, which may also be regarded as maleic anhydride, is produced when maleic or fumaric acid is heated. To prepare it, crystallised maleic acid is rapidly distilled, with change of receiver, till nothing but crystallised fumaric acid remains behind; and the last distillate (the first being watery) is repeatedly rectified in the same manner, the first watery portion of the distillate being each time set aside, till the last distillate passes over completely, without first yielding water, and without leaving a residue of fumaric acid.

The anhydride melts at $57^{\circ}C$., and boils at 176° . When slightly heated above its boiling point, it decomposes, turning brown, and giving off gas.

FUMARIC ETHER. See FUMARATE OF ETHYL (p. 744).

FUMARIMIDE, $C^4NH^2O^2 = N \begin{Bmatrix} C^4H^2O^2 \\ H \end{Bmatrix}$. (Dessaigues, Compt. rend. xxx. 324; J. Wolff, Ann. Ch. Pharm. lxxv. 293.)—Formed by the action of heat on acid malate of ammonium. When this salt is heated in an oil-bath to 160° — $200^{\circ}C$., it melts, swells up, gives off water containing a very small quantity of ammonia, and leaves a reddish, transparent, somewhat resinous mass, very sparingly soluble in water, even at the boiling heat. This residue, after being washed with hot water, forms an amorphous powder, having a pale brick-red colour and earthy taste. When dried at 100° , it exhibits the composition of fumarimide + $\frac{1}{2}$ at. water (Dessaigues). When the residue obtained as above is exhausted with boiling water, the wash-water yields on cooling, a fine white powder, which remains suspended in the liquid, but is immediately precipitated by acids. This substance, after being several times dissolved in water and reprecipitated, exhibits nearly the composition of anhydrous fumarimide. (Wolff.)

Fumarimide is a very stable substance. It dissolves in hot concentrated acids, whence it is precipitated by water without alteration, even after boiling for some seconds. But if heated for five or six hours with hydrochloric or nitric acid, and then evaporated to dryness, it yields a crystalline residue containing a compound of hydrochloric or nitric acid with optically inactive aspartic acid:

Acid maleate and acid fumarate of ammonium yield, by dry distillation, a substance closely resembling fumarimide in most of its reactions, but not identical with it. (Dessaigues.)

FUMARINE. An organic base, contained in fumitory (*Fumaria officinalis*), first observed by Peschier (*Liebig's Organische Chemie*, p. 633); more fully examined by Hannon (*J. Chim. méd.* [3] viii. 705). The plant grown on a well-manured soil, and gathered in June or July while in full flower, contains from 5 to 6 per cent. of this base, to which it appears to owe its specific physiological action. To obtain it, the plant is beaten up to a pulp with an equal weight of water, the pulp acidulated with acetic or hydrochloric acid, then heated for some hours over the water-bath, and filtered. The filtrate evaporated to a syrup is treated with boiling alcohol, which dissolves the acetate or hydrochlorate of fumarine, and, after concentration and decolorisation with animal charcoal, deposits it in slender needles. Or the expressed and filtered juice of the plant is mixed with twice its bulk of water, and precipitated with basic acetate of lead, the excess of lead is removed from the filtrate with dilute sulphuric acid, and the liquid is evaporated; it then deposits crystalline sulphate of fumarine. (Hannon.)

Fumarine is separated from its salts by caustic alkalis or their carbonates, in the form of a curdy precipitate. It may be obtained in the crystalline form by spontaneous evaporation of its hot alcoholic solution, but not by evaporation with the aid of heat. The salts have a bitter taste. (Hannon.)

FUMAROL. See VOLCANIC EMANATIONS.

FUMARYL, CHLORIDE OF. $C^4H^2O^2.Cl^2$. (Kekulé, Ann. Ch. Pharm. Suppl. ii. 85; Rép. Chim. pure, 1863, p. 31).—Produced by the action of perchloride of phosphorus on fumaric acid:

When purified, it boils at $160^\circ C$. It unites directly with 2 at. bromine and is converted into chloride of dibromosuccinyl, $C^4H^2Br^2O^2.Cl^2$.

FUMIGATION. See the article DISINFECTANT in *Ure's Dictionary of Arts, Manufactures, and Mines*, ii. 27.

FUMING LIQUOR OF BOYLE. A mixture of two or more sulphides of ammonium, obtained by distilling sulphur with sal-ammoniac and quick lime (i. 194).

FUMING LIQUOR OF CADET. A mixture of cacodyl and oxide of cacodyl, obtained by distilling acetate of potassium with arsenious anhydride (i. 403).

FUMING LIQUOR OF LIBAVIUS. Tetrachloride of tin.

FUNGIC ACID. The name given by Braconnot to an acid which he found to exist in a considerable number of agaries (Ann. Chim. lxxix. 265; Ann. Ch. Phys. xxx. 272). According to Dessaigues, however (Compt. rend. xxxvii. 782), the acid in question is nothing but a mixture of citric, malic, and phosphoric acids.

FUNKITE. A green coccolite.

FURFURAMIDE. $C^5H^4N^2O^3 = N^2 \left\{ \begin{matrix} (C^5H^4O^3)'' \\ H^1 \end{matrix} \right.$. (Fownes, Phil. Trans. 1845, 253).—An amide, produced by the action of ammonia on furfural:

Furfural set aside with five times its volume of aqueous ammonia, is converted, partially in a few hours, and completely after a longer time, into a yellowish-white, bulky, crystalline mass of furfuramide. A mixture of aqueous furfural and ammonia yields the same compound, in a few days, purer and whiter. The resulting yellowish-white mass may be dissolved in hot alcohol, and crystallises therefrom on cooling in short needles united in tufts.

Furfuramide is fusible, nearly inodorous when dry, insoluble in cold water, but easily soluble in alcohol and ether. It burns with a smoky flame and leaves a small quantity of charcoal. When exposed to *damp air*, or heated with *water* or *alcohol*, it is slowly resolved into ammonia and furfural; *acids* produce this decomposition instantly. Furfuramide boiled with dilute *potash-ley*, is converted, without the slightest evolution of ammonia, into furfurine (Fownes). Furfuramide treated with *sulphuric acid* yields thiofurfural. (Cahours.)

FURFURINE. $C^5H^4N^2O^3$. (Fownes, Phil. Trans. 1845, 253; Stenhouse, Ann. Ch. Pharm. lxxiv. 289; Svanberg and Bergstrand, J. pr. Chem. lxxvi. 239).—An organic base, isomeric with furfuramide, and produced therefrom under the influence of caustic potash, or simply of heat.

Preparation.—1. Dried furfuramide is added to a large quantity of dilute boiling potash-ley; the liquid left to cool slowly after ten or fifteen minutes, whereupon the furfurine

which has separated in the form of a yellowish oil, solidifies, and the portion remaining in solution crystallises out; the whole of the furfurine is collected on a filter, washed with cold water, and dissolved in excess of boiling aqueous oxalic acid, from which impure acid oxalate of furfurine crystallises on cooling; this impure oxalate is washed on a filter with cold water, and dissolved in boiling water; the solution boiled for a few minutes with animal charcoal previously purified by hydrochloric acid, then filtered at the boiling heat; the pure white salt which separates on cooling is dissolved in boiling water, the solution supersaturated with ammonia, and filtered hot; and the crystals of furfurine, which form on cooling, are washed with cold water (Fownes). The crude base may also be purified by repeated solution in alcohol and precipitation with water (Svanberg and Bergstrand).—2. Furfuramide is also readily converted into furfurine by heating it for half an hour to 110° – 120° C. The resulting brown mass dissolved in alcohol, and treated with excess of oxalic acid, yields acid oxalate of furfurine, from which the base may be obtained as above. By this means furfurine may be prepared directly from furfural, viz. by passing dry ammoniacal gas into furfural heated to 110° – 120° C. The furfural then turns brown, and in the course of half an hour to an hour, is converted into furfurine. (C. Bertagnini, Ann. Ch. Pharm. lxxxviii. 128.)

Properties.—Furfurine crystallises in white, soft, silky needles, resembling those of caffeine. It melts considerably below 100° C., to a nearly colourless oil, which, on cooling, solidifies to a soft resin, and afterwards to a resinous crystalline mass. It is permanent in the air (Fownes). When perfectly dry, it remains unaltered on exposure to the air; but when moist, it quickly turns greyish-green, yellowish-brown, and often red (Svanberg and Bergstrand). It is inodorous, and has but little taste. It exhibits an alkaline reaction, which is particularly strong in the hot aqueous or alcoholic solution (Fownes). When a tolerably strong solution of neutral sulphate of furfurine is heated, the precipitated brown powder (p. 749) separated by filtration, and the filtrate treated with ammonia, furfurine is precipitated, not in the pulverulent or crystalline state, but in the form of a tough coherent mass, which, after a little kneading, becomes brittle and as hard as stone; the recently precipitated mass, when examined by the microscope, exhibits here and there crystalline groups like snow-flakes. Furfurine appears then, when heated, to pass, like quinine, into another modification (Svanberg and Bergstrand). It dissolves in 1.57 pts. of boiling water, and separates almost completely on cooling; readily in cold alcohol or ether, and crystallises when the solvent is evaporated. (Fownes.)

Furfurine, when heated in the air, burns with a red smoky flame, and leaves a trace of charcoal (Fownes). Aqueous periodic acid decomposes it, with separation of iodine. (Bödeker, Ann. Ch. Pharm. lxxi. 64.)

Furfurine-salts. Furfurine dissolves very readily in dilute acids and neutralises them completely. It expels ammonia from sal-ammoniac at a boiling heat, but at ordinary temperatures is itself precipitated from its combinations with acids, by ammonia, potash, or soda. The salts of furfurine have an extremely bitter taste. They are precipitated white by corrosive sublimate, yellow by dichloride of platinum, but give no precipitate with tincture of galls. (Fownes.)

Acetate of Furfurine is very soluble in water, and very difficult to crystallise.

Carbonate. (?)—According to Döbereiner, furfurine unites with carbonic acid. According to Davidson, on the contrary, the base dissolves in water through which carbonic acid is passed, but separates out unaltered when the solution is left to evaporate.

Chromate (acid), $2C^5H^2N^2O^3.H^2O.2Cr^2O^3$.—Orange-yellow powder, sparingly soluble in cold water, becoming brown when dry. (R. Davidson, Ed. N. Phil. J., new series, ii. 284.)

Hydrobromate, $C^5H^2N^2O^3.HBr + aq$.—Short prismatic needles soluble in 26 pts water. (Davidson.)

Hydrochlorate, $C^5H^2N^2O^3.HCl + aq$.—Dilute hydrochloric acid saturated with furfurine, yields tufts of delicate, silky, neutral needles, which retain their lustre when dried in vacuo over sulphuric acid. They dissolve readily in water, less easily in hydrochloric acid. (Fownes.)

The *chloroplatinate*, $2(C^5H^2N^2O^3.HCl).PtCl_4$, is obtained as a light-yellow precipitate, on mixing the solution of the hydrochlorate with excess of chloride of platinum (Fownes). When the chloride of platinum is poured into a hot solution of hydrochlorate of furfurine in weak alcohol, the platinum-salt of furfurine separates on cooling in long light-yellow needles resembling picroate of potassium. (Stenhouse.)

Hydrochlorate of furfurine also forms double salts with *mercuric chloride* (Fownes), and with the *chlorides of gold, palladium and iridium*. (Döbereiner.)

Hydriodate, $C^5H^2N^2O^3.HI + aq$.—Colourless, slender, oblique four-sided prism soluble in 55 pts. of cold water; soluble also in alcohol and ether. (Davidson.)

Mellate.—Aqueous mellic acid neutralised with furfurine yields the salt, after a while, in nodular groups of crystals, which by recrystallisation are obtained in beautiful monoclinic prisms. The salt gives off 5.7 per cent. water between 100° and 125° C., and begins to turn yellow at 130° . (Karmrodt, Ann. Ch. Pharm. lxxi. 171.)

Nitrate. $C^4H^2N^2O^2.HNO^3$.—Transparent, colourless, highly lustrous, hard crystals, which effloresce in vacuo over sulphuric acid, and dissolve readily in water, slowly in nitric acid. (Fownes). According to Stenhouse, it crystallises from the aqueous solution in long irregular acuminate crystals; but from the alcoholic solution, in very regular rhombic prisms of considerable size and peculiar lustre; if, however, very strong alcohol is used, the crystals, which are at first perfectly transparent, soon become opaque, whereas those obtained from weak alcohol retain their lustre and transparency.

Oxalates.—The neutral oxalate forms tufts of needles very soluble in water. The acid oxalate forms thin transparent tables, which retain their lustre in a dry vacuum, reddens litmus strongly, and dissolve very sparingly in cold, more readily in warm water. (Fownes.)

Perchlorate. $C^4H^2N^2O^2.HClO^4 + aq$.—Furfurine dissolved in warm very dilute perchloric acid, yields very long, thin, brittle prisms, having a glassy lustre and a disagreeable, saline, bitter taste; they effloresce at 60° C., melt at 150° to 160° , solidifying on cooling to a glassy brittle mass, and explode at a higher temperature. They dissolve readily in water and alcohol (Bödeker, Ann. Pharm. lxxi. 63). The crystals are right rhombic prisms, having the angles of the lateral edges = $72^{\circ} 33'$ and $107^{\circ} 27'$, the obtuse lateral edges truncated, the acute bevelled; cleavage from one obtuse lateral edge to the other. (Dauber, Ann. Ch. Pharm. lxxi. 67.)

Phosphates of Furfurine.—*a. Metaphosphate (?)*.—When strongly ignited ammonio-sodic phosphate was dissolved in water, the solution precipitated by chloride of barium, and the washed metaphosphate of barium digested for 24 hours with neutral sulphate of furfurine, a filtrate was obtained which had a neutral reaction, but did not yield any crystallisable compound. On evaporation, it left a gummy mass, which became black and glassy when heated. (Svanberg and Bergstrand.)

b. Orthophosphates.—*a.* $C^4H^2N^2O^2.H^3PO^4$.—A boiling alcoholic solution of furfurine, mixed with a large excess of ordinary phosphoric acid, deposits crystals on cooling, which gradually assume a brownish yellow colour, if left in the mother-liquor; but if quickly taken out, and pressed between paper, retain their silvery lustre on subsequent exposure to the air. They are right four-sided prisms, so short that they appear like thin laminae. The crystals do not diminish in weight or decompose at 150° C., but when more strongly heated, they assume a blackish grey colour, and between 200° and 215° , melt into a black vitreous mass, which dissolves completely in warm alcohol, and then no longer exhibits the reactions of ordinary phosphoric acid. The salt dissolves sparingly in cold, readily in hot water and alcohol, but appears to be insoluble in ether. (Svanberg and Bergstrand.)

β. $(C^4H^2N^2O^2)^2.H^3PO^4$.—Obtained by adding 1 at. furfurine dissolved in alcohol to a solution of 1 at. of the salt *c*, and heating the mixture. The filtrate on cooling deposits white, shining, oblique, four-sided, anhydrous prisms, which in the dry state are permanent in the air. They may be heated to 130° — 135° C. without decomposition, but at higher temperatures behave like the salt *a*. The neutral salt dissolves readily in boiling water and alcohol, but is nearly insoluble in ether. (Svanberg and Bergstrand.)

γ. $(C^4H^2N^2O^2)^3.H^3PO^4$.—A solution of the salt *a* mixed with a large excess of the alcoholic solution of furfurine, deposits this salt on cooling in long oblique four-sided prisms, which are white and destitute of lustre; anhydrous; permanent in the air; may be heated to 120° — 135° C. without decomposition; but at higher temperatures, behave like the two preceding salts. They dissolve readily in water and alcohol, but very sparingly in ether. The solutions have an alkaline reaction. (Svanberg and Bergstrand.)

c. Pyrophosphate. $(C^4H^2N^2O^2)^2.H^2P^2O^7 + aq$.—An alcoholic solution of furfurine, neutralised with pyrophosphoric acid, and evaporated in the drying chamber, ultimately yields a glassy crystalline crust, which dissolves readily in water and alcohol, and has a neutral reaction. The salt gives off 1.6 per cent. water at ordinary temperatures, and 2.14 per cent. more at 100° C. Hence if the 1.5 per cent. be regarded as hygroscopic, the salt may be supposed to contain 1 at. water. Between 115° and 120° , it assumes a greyish aspect, apparently from incipient decomposition. (Svanberg and Bergstrand.)

Sulphate of Furfurine.—*a. Neutral.*—Sulphuric acid saturated with furfurine, deposits when evaporated, either by heat or under the exsiccator, a black-brown powder.

When hydrochlorate of furfurine is decomposed with sulphate of silver, the crystals are deposited from the coloured and acid mother-liquor, but they contain only 0.3 per cent sulphuric acid, and therefore cannot consist of sulphate of furfurine.

b. Acid salt, $C^1H^{12}N^2O^3.H^2SO^1 + 3\frac{1}{2} aq.$ —When furfurine is dissolved in some what dilute sulphuric acid, and a slight excess of the acid added after the solution has been warmed, short four-sided prisms are soon deposited (irregular rhombic tablets according to Davidson), which dissolve readily in water, less readily in alcohol or ether, and least of all in water acidulated with sulphuric acid. The solution has a sour and bitter taste, and is coloured red by strong sulphuric acid. The salt effloresces readily at ordinary temperatures, giving off all its water of crystallisation amounting to 21.62 per cent. ($3\frac{1}{2}$ at.). Between 80° and $90^\circ C.$, it loses $\frac{1}{2}$ of its weight and appears to decompose; at a higher temperature, it cakes together, and then melt into a black mass, which no longer dissolves completely in water. (Svanberg and Bergstrand.)

Tartrate of Furfurine (acid).—This salt crystallises from a rather acid solution of furfurine in tartaric acid, in oblique four-sided prisms, which are permanent in the air, and do not give off water at $150^\circ C.$ When treated with potash, they give off ammonia. The solution mixed with ammonia does not yield any precipitate of furfurine (Svanberg and Bergstrand.)

Ethyl-Furfurine. $C^1H^8N^2O^3 = C^1H^{11}(C^2H^3)N^2O^3.$ —The hydriodate of this base is obtained by heating alcoholic furfurine with iodide of ethyl to $100^\circ C.$ in a sealed tube. It separates from a hot alcoholic solution as a gummy mass, but by spontaneous evaporation it may be obtained in fine crystals derived from a rhombic prism. It dissolves in 36 pts. of water, and more freely in alcohol and ether (Davidson, *loc. cit.*)

Hydrate of Ethyl-furfurine, $C^1H^{16}N^2O^6.HO$, according to Davidson, more probably $C^1H^{16}N^2O^6.2HO$. or $C^1H^{17}N^2O^7$ $\left\{ \begin{matrix} H \\ O \end{matrix} \right\}$, is obtained by decomposing the hydriodate with moist oxide of silver, and evaporating the filtrate. It is syrupy, easily soluble in alcohol, sparingly in water, and expels ammonia from its salts at $100^\circ C.$ The chloroplatinate has the composition $2(C^1H^{16}N^2O^6.HCl).PtCl^1$.

It does not appear possible to replace another atom of hydrogen in furfurine by ethyl or other alcohol-radicle.

Amyl-furfurine. $C^{20}H^{22}N^2O^3 = C^{15}H^{11}(C^5H^{11})N^2O^3.$ —The hydriodate, obtained by heating furfurine with iodide of amyl for four days, is a gummy mass, which dissolves but sparingly in water, but may be obtained in radio-crystalline masses. The chloroplatinate, $2(C^{20}H^{22}N^2O^3.HCl).PtCl^1$, is a yellow powder sparingly soluble in water. (Davidson.)

FURFUROL. $C^5H^4O^1$. (Döbereiner [1831], Schw. J. lxi. 368.—Ann. Ch. Pharm. iii. 141.—Stenhouse, Phil. Mag. [3] xviii. 122; xxxvii. 226.—Fownes, Phil. Trans. 1845, 253; Ann. Ch. Pharm. liv. 52; Pharm. J. Trans. viii. 113.—Cahours, Ann. Ch. Phys. [3] xxiv. 277.—Schwanert, Ann. Ch. Pharm. cxvi. 267.)—A volatile aromatic oil which may be regarded as the aldehyde of pyromucic acid ($C^5H^4O^3$), being convertible into that acid by oxidation: isomeric with fucosol (p. 718). It is produced by heating sugar, starch, bran, madder, and other vegetable substances with dilute sulphuric acid, either alone or mixed with peroxide of manganese, and appears to be a product of oxidation; thus, its formation from starch might be represented by the equation:

Döbereiner, who first obtained it as a secondary-product in preparing formic acid by distilling sugar with sulphuric acid and peroxide of manganese, called it *Artificial oil of Ants* (*künstliches Ameisenöl*). The name furfural is derived from *furfur* (bran) and *oleum* (oil).

From the experiments of Döbereiner and of Cahours, it would appear that sugar, starch, and sawdust distilled with sulphuric acid alone, do not yield furfural. According to Stenhouse, on the other hand, chips or shavings distilled with dilute sulphuric acid, yield furfural: also linseed-cake, the woody shell of the cocoa-nut, and mahogany. The furfural obtained from mahogany is very free from resin, and more easily purified than that obtained from other sources. According to Emmet (Sill. Am. J. xxxii. 140), sugar, starch, gum, and wood, distilled with sulphuric acid, so far diluted as not to exert any carbonising action, yields at $100^\circ C.$ scarcely anything but furfural; but as soon as the residue blackens, nothing but formic acid is obtained. Fownes obtained only indistinct indications of furfural by distilling starch with dilute sulphuric acid, and from recently washed linon, not a trace. He is of opinion that the source of the furfural is to be found in the matter which lines the interior of the vegetable cells, called by Payen, *matière incrustante*. Furfural is likewise obtained by heating bra

with a very strong solution of chloride of zinc. The greater the quantity of starch in the bran, the smaller is the quantity of furfural obtained. Pure starch and pectin distilled with chloride of zinc, do not yield furfural. Bran distilled with chloride of calcium does not yield furfural, but possibly might do so if heated under pressure (Babo, Ann. Ch. Pharm. lxxxv. 100). Furfural is also found among the products of the dry distillation of sugar. (VölcKel, *ibid.* 59.)

Preparation.—1. One part of sugar is distilled with 3 pts. of manganese, 3 pts. of oil of vitriol, and 6 pts. of water; the formic acid in the distillate saturated with carbonate of sodium; the liquid redistilled; the distillate saturated with chloride of calcium; and lastly, the furfural distilled off (Döbereiner).—2. One part of wheat-flour or saw-dust is distilled with 1 pt. of oil of vitriol diluted with an equal bulk of water in a copper still, which may be half filled with the mixture, the distillation being continued till the residue begins to char; the distillate, together with about as much water as was at first used, poured back into the still; the liquid redistilled nearly to dryness; the formic and sulphurous acids in the distillate—which is rendered milky by the furfural—saturated with potash, which colours the liquid yellow; one-fourth of the liquid then distilled off; the resulting distillate mixed with a large quantity of chloride of calcium and partially distilled; and this process repeated, if necessary, till the greater part of the oil, which is surmounted by an aqueous solution of itself—is obtained in the free state. By this process, 100 pts. of flour yield 0.52 pts. of furfural (Stenhouse).—3. Two parts of oatmeal are heated with 2 pts. of water and 1 pt. of oil of vitriol in a still, and the mixture stirred, till the pasty mass has become liquid from formation of dextrin; the liquid is then distilled; 1 pt. more of water added as soon as sulphurous acid begins to escape; the distillation continued till sulphurous acid comes off in larger quantity; the whole distillate poured back into the still; half of it poured off; and this half neutralised, as in 2, with potash, &c. (Fownes).—4. Two pts. of bran are distilled in a similar manner with 2 pts. of oil of vitriol and 6 pts. of water; by this process, 100 pts. of bran yield 0.3 pts. of furfural (Fownes). In subsequent experiments, Fownes obtained, by distilling 64 oz. (troy) of wheat-bran with 32 oz. sulphuric acid and an equal volume of water, 1 oz. of furfural; and from 61 oz. wheat flour, treated in the same manner, about 1½ drms. of impure furfural.—5. Six pts. of bran are distilled with 5 pts. of oil of vitriol and 12 pts. of water in a capacious still, till a strong odour of sulphurous acid is emitted, and the distillate is partially and repeatedly rectified over chloride of calcium. One hundred parts of bran yield by this process 2.6 pts. of furfural in all, part of which is held in solution in the watery distillate, but may be precipitated by ammonia in the form of furfuramide (Cahours).—6. To save the repeated rectifications, the first distillate may be immediately saturated with ammonia; the mixture set aside for 24 hours in a cool place, and shaken occasionally; the furfuramide which separates is then to be distilled with dilute hydrochloric acid not in excess, and the distillate rectified over chloride of calcium (Döbereiner).—7. According to Stenhouse, a very advantageous process for preparing furfural is to distil bran with more than half its weight of sulphuric acid previously diluted with 2 pts. of water. Hydrochloric acid may also be used, but it has the disadvantage of distilling over with the oil. To obtain furfural in large quantity, Stenhouse mixes 32 lbs. of wheat-bran with 20 lbs. of sulphuric acid, diluted as just mentioned, in a capacious three-necked glazed earthenware Woulfe's bottle (such as are used in the preparation of nitric and hydrochloric acids on the large scale); distils by passing steam into the mixture; neutralises the strongly acid distillate with chalk; rectifies the distillate repeatedly; and separates the oil by saturating the liquid with common salt and redistilling: this process yields from 12 to 13 ounces of crude furfural, containing a considerable quantity of acetone. Schwanert proceeds in a similar manner, using 100 pts. strong sulphuric acid and 300 pts. water to 100 pts. bran, and obtains 3 pts. of furfural, partly directly, partly after conversion into furfuramide by ammonia and subsequent decomposition of that compound by distillation with hydrochloric acid.—8. Bran and chloride of zinc (in the proportion of 3 to 2½ : 1), in the state of solution, strong enough to form a damp mass cohering in lumps, are distilled together, whereupon water passes over first, then furfural, then hydrochloric acid, and lastly a solid fatty mass consisting of margaric acid with a small quantity of a hydrocarbon. The distillate is strained through linen, neutralised with potash, saturated with common salt, and rectified; and the furfural, after being separated from the water which passes over with it, is dried over chloride of calcium and again rectified. The watery portion of the distillate still contains a little furfural, which may be converted into furfuramide as in (6). Six pounds of bran thus treated yielded from 1 to 2 oz. and sometimes more of furfural; bran containing a larger proportion of starch yielded less (Babo, Ann. Ch. Pharm. lxxxv. 100).—9. The most abundant and economical source of furfural is in the preparation of garancin by boiling madder with sulphuric acid. If the wooden boilers in which garancin is

manufactured were fitted with condensers, furfural might be obtained in any quantity without expense. Furfural is also produced* by boiling any kind of waste with solution of sulphate of aluminium. (Stenhouse, *Epistolary communication*.)

Crude furfural obtained from any of the preceding sources is always contaminated with another aromatic oil, *Metafurfural*, which has a higher boiling point; oxidises very readily; is for the most part converted during the distillation into a brown resin; and when mixed with a few drops of strong sulphuric, hydrochloric, or nitric acid, immediately exhibits a purple colour, a reaction formerly indicated by Stenhouse and Fownes as characteristic of furfural; pure furfural does not exhibit it. Furfural may be freed from metafurfural by repeated rectification; the latter, being less volatile and much more oxidable, remains behind. The purity of the product may be tested by boiling an aqueous solution of the furfural for a few minutes with caustic potash, and treating the dark yellow liquid with excess of sulphuric or hydrochloric acid; if metafurfural is present, a deep red colour is produced; if not, the colour remains unchanged. (Stenhouse.)

Properties.—Furfural when recently prepared is a colourless oil, but it soon turns yellow, even in the dark, and brown when exposed to light; under water these changes take place less quickly (Fownes). According to Schwanert, the first portions of furfural which distil over (in the rectification) soon become darker coloured when immersed in water, or kept in sealed tubes; but the latter portions remain nearly colourless, a fact which seems to indicate the presence of a more volatile impurity in the first portion. Pure furfural, which will not alter by keeping, can only be obtained by repeated rectification.

Furfural possesses great refracting power. It smells like a mixture of the oils of cinnamon and bitter almonds, and has an aromatic taste, like that of cinnamon oil. Specific gravity 1.1648 at 15.6° C. (Fownes). Boils at 162.8—163.3° in metallic vessels with the barometer at 29.9" (Fownes), at 166° (Stenhouse), and volatilises unchanged. Vapour-density = 3.344 (Cahours), 3.49 (Fownes), calc. (2 vol.) = 3.328. It dissolves in 12 pts. water at 15.6° C. (Fownes), in 11 pts. at 13° (Stenhouse); it is very soluble in alcohol.

Decompositions.—1. Furfural is very inflammable, and burns with a yellow, very smoky flame.—2. When its aqueous solution is boiled with recently precipitated *oxide of silver*, metallic silver is deposited, and the filtered liquid yields by evaporation crystals of pyromucate of silver, $C_5H_4AgO_3$. Hence furfural is related to pyromucic acid in the same manner as common aldehyde to acetic acid. It likewise exhibits the characters of an aldehyde in combining with acid sulphite of sodium (*vid. inf.*).—3. Hot *nitric acid* converts furfural, with violent evolution of nitrous fumes, into oxalic acid.—4. Strong *sulphuric acid* dissolves it in the cold, without colour if pure, with purple-red colour if it contains metafurfural, and water added to the solution precipitates the furfural unaltered; but if the solution is heated, the furfural is decomposed and carbonised.—5. Strong *hydrochloric acid* acts on furfural in a similar manner.—6. With *chlorine* and *bromine* it forms resinous products. *Iodine* dissolves in it abundantly, without violent action.—7. Caustic *potash* dissolves furfural slowly in the cold, forming a dark brown liquid from which acids throw down a resinous substance; the same reaction takes place more quickly on heating the liquid.—8. *Potassium* with aid of heat, decomposes furfural with violence.

9. Furfural left in contact with *ammonia* for a few hours, is completely converted into furfuramide.—10. It dissolves in *methylamine* and *ethylamine* without decomposition in the cold, but if heated it blackens, and a blackish resinous substance separates containing only traces of nitrogen; these bases do not therefore act upon furfural in the same manner as ammonia (Wurtz).—11. With *phenylamine*, furfural forms a red colouring matter (Stenhouse, Ann. Ch. Pharm. lxxiv. 282). When an aqueous solution of furfural is added, with constant agitation, to a solution of phenylamine in acetic acid of ordinary strength, the mixture turns red, and if sufficient furfural solution has been added, becomes colourless after a while, and deposits a dark-coloured viscid substance, nearly insoluble in water, but soluble in alcohol, wood-spirit, and strong acetic acid; ammonia dissolves it, forming a colourless solution, but the red colour reappears on adding acetic acid. The red substance does not unite with mordants; it imparts a fine red colour to silk and wool, but the colour is very fugitive, fading quickly even in the dark. (Persoz, Rép. Chim. app. 1860, 220.)

Compound of Furfural with acid Sulphite of Sodium, $C_5H_4NaSO_4$.—Pure furfural shaken up with a strong aqueous acid sulphite of sodium, dissolves and forms a solution, which, when evaporated over oil of vitriol, or better, when covered with an equal volume of strong alcohol and left to itself, deposits white or reddish laminae, having a fatty lustre; they may be purified by treatment with strong alcohol, and recrystallisation from water under a layer of alcohol. (Schwanert.)

Sulphuretted and Seleniuretted Derivatives of Furfural.

Thiofurfol. C^4H^4OS .—This compound, discovered by Cahours (Ann. Ch. Phys. [3] xxiv. 281), is produced by the action of sulphhydrate of ammonium on a solution of furfural, or by slowly passing sulphydric acid gas through a solution of furfuramide in a large quantity of alcohol, and washing the precipitated powder with alcohol. As thus prepared, it is a yellowish crystalline powder; but if the sulphuretted hydrogen be passed quickly through a warm concentrated alcoholic solution of furfuramide, the thiofurfol separates in the form of a resin, but with the same composition. Thiofurfol melts when heated, and yields a crystalline sublimate, having the composition $C^4H^4O^2$; probably thus:

Thiofurfol, heated in contact with the air, diffuses a strong repulsive odour, and burns with a bluish flame, somewhat smoky, and with the odour of sulphurous acid.

The compound $C^4H^4O^2$, purified by two crystallisations from alcohol, appears in colourless or yellowish, iridescent, long, hard, easily friable needles. It is violently attacked by nitric acid, and converted into oxalic acid. It is insoluble in cold water but dissolves sparingly in hot water, whence it crystallises on cooling; tolerably well in ether; also in alcohol, especially when warm, forming a solution, which slowly turns brown on exposure to the air. (Cahours.)

Seleniofurfol. C^4H^4OSe .—Selenhydric acid acts upon furfural similarly to sulphydric acid, the clear liquid becoming turbid and depositing seleniofurfol in the form of a resinous, very unstable substance. (Cahours.)

FUSCITE. See SCAPOLITE.

FUSEL-OIL. In the alcoholic fermentation of potatoes, corn, and the marc of grapes, there are always formed, together with common alcohol, volatile oily bodies, which, for the most part, boil at higher temperatures than the ethylic alcohol, and therefore pass over with the latter portions of the distillate in the process of rectification. These oily products, designated by the general name of fusel-oil, resemble each other in their taste and smell, which are nauseous and fiery, and likewise agree in composition, in so far as they all contain ethylic and amylic alcohols; but most of them contain in addition, fatty acids and ethers, and some contain other members of the alcohol-series, $(C^4H^{2n+2}O)$, the nature and quantity of these products varying considerably, according to the source from which the fusel-oil is derived, and the circumstances of the fermentation.

Potato-fusel-oil usually consists almost entirely of ethylic and amylic alcohols, the latter constituting the greater quantity; it may be freed from ethylic alcohol by agitating it with water, which dissolves the ethylic, with only a small proportion of the amylic alcohol, separating the oily liquid by a tap-funnel, and rectifying (see Amylic Alcohol, i. 203). Some samples of potato-fusel-oil, however, contain tetrylic or butylic alcohol, $C^4H^{10}O$, in addition to the preceding; in fact, it was in rectifying a sample of this kind of fusel-oil, that Wurtz made the discovery of tetrylic alcohol (Compt. rend. xxxv. 310). This alcohol has likewise been found in the fusel-oil from beet-molasses. (Wurtz, Ann. Ch. Pharm. xciii. 107.)

In fusel-oil from the brandy distilled from marc of grapes, Chancel (Compt. rend. xxvii. 410) found tritylic alcohol, $C^6H^{14}O$; and from the portion of the same kind of fusel-oil less volatile than amylic alcohol, Faget (*ibid.* 730) obtained a liquid which he supposed to be hexylic alcohol, $C^6H^{14}O$; but this result is doubtful. (See Hexylic Alcohol.)

Most kinds of fusel-oil contain several members of the series of fatty acids, $C^mH^{2m+2}O^2$.

Rowney (Chem. Soc. Qu. J. iv. 372) found in fusel-oil from the Scotch distilleries, water, ethylic alcohol, amylic alcohol, and a coloured oily residue insoluble in water, and containing capric acid in the form of caprate of amyl.

Wetherill (Chem. Gaz. 1853, p. 281) found in neutral-fusel-oil obtained as a residue in the preparation of alcohol, partly from wheat, partly from maize, acetic and propylic acids, together with (less distinctly indicated) formic, capric and amanthylic acids; also amylic and a little ethylic, but no butylic alcohol.

Fehling (J. Pharm. [3] xxv. 74) found in fusel-oil from the spirit of beet-molasses, several volatile fatty acids (capric, caprylic, &c.), and a neutral fat, answering nearly to the formula $C^{22}H^{44}O_4$, or $C^{22}H^{42}O_4$. When heated, it gave off the odour of acrolein, and when saponified, yielded capric acid.

Fusel-oil from beet-molasses has also been examined by A. Perrot (Compt. rend. liv. 309) with the following results. The portion which distilled between 80° and 110° C. contained ethylic, tetrylic and amylic alcohols, without any appreciable portion of tritylic alcohol. The liquid remaining, after the amylic alcohol had been distilled, passed over between 140° and 300° . It consisted chiefly of compound

ethers, the only substance of more simple constitution contained in it being a fetid liquid, $C^4H^{10}O$, which distilled at about $200^{\circ} C.$, floated on water, and did not exhibit the reaction of an alcohol with perchloride of phosphorus. The portion of the above-mentioned residue which passed over between 140° and 200° was heated for some time to 100° with caustic potash-solution, and the upper layer of the product distilled by itself. The greater portion, containing ethylic, tetrylic, and amylic alcohols, distilled between 94° and 135° ; the small portions which distilled between 140° and 190° did not contain hexylic or octylic alcohol, and the residue, which passed over between 190° and 202° , consisted of the above-mentioned compound, $C^4H^{10}O$. The mixture of acids, separated from combination with the potash, contained in small quantity (probably) valerianic, caproic, and α -nanthylic acids, in larger quantity, caprylic and pelargonic acids. (See also A. Müller, J. pr. Chem. lvi. 103; Jahresber. 1851, p. 498.)

Capric acid has been found in potato-fusel-oil by S. W. Johnson. (J. pr. Chem. lxvii. 262.)

In rum fusel-oil from Surinam, G. J. Mulder (Jahresber. 1858, 302) found an unsaponifiable waxy body, together with palmitic acid, α -nanthic acid, and a very small quantity of α -nanthic ether. (See *Ure's Dictionary of Arts*, &c. ii. 313.)

Defuselation of Alcohol.—As fusel-oil imparts to alcohol a very unpleasant taste and smell, it becomes a matter of great importance to the distiller to remove it from all spirit intended for drinking. The complete removal of the fusel-oil is, however, a matter of considerable difficulty, and indeed is seldom attained on the large scale. Simple distillation will not effect the object, although the boiling points of ethylic and amylic alcohols differ from one another very considerably, common alcohol boiling at $79^{\circ} C.$, and amylic alcohol at 132° . If, however, the spirit be diluted with water before rectification, and the strong spirit which comes over at first be collected apart, and this operation repeated several times, a tolerably pure spirit will at length be obtained, though at considerable expense and loss. In the modern stills constructed so that the more condensable portions of the vapour may be liquefied and flow back again, by far the greater portion of the fusel-oil is thus removed at once, together with the water, and a comparatively pure distillate is obtained. Still, however, a certain portion of the fusel-oil always diffuses into the alcohol-vapour and passes over with it.

For the complete defuselation of spirit, various methods have been devised, but that which is most generally adopted consists in absorbing the fusel-oil by *wood-charcoal*. To give the charcoal its full absorbing power, it must be recently ignited and left to cool in well-closed vessels; it is then reduced to coarse powder in rotating barrels containing a few iron balls. To effect the defuselation with the smallest possible quantity of charcoal, the spirit may be made to trickle through a number of casks filled with the charcoal and placed one above the other. According to Lüdersdorff (Dingl. pol. J. xc. 369), 2 quarts (or 2.28 litres) of spirit of 80 per cent. Trales, require for defuselation the following quantities of different kinds of charcoal:—

	Potato-spirit. Ounces.	Corn-spirit. Ounces.
Lime charcoal	14	21
Fir "	18	23
Birch "	28	34
Willow "	38	5
Oak "	48	8
Bone-black	10	14

These numbers must however be understood as merely approximate expressions of the relative defuselising power of the several kinds of charcoal, inasmuch as the detection of small quantities of fusel-oil in spirit is a matter of considerable difficulty.

In practice, however, the treatment of spirit with charcoal in the cold is seldom adopted, since a large quantity of spirit remains in the charcoal and a considerable portion of it is lost by volatilisation during the transference of the saturated charcoal to the still; moreover this operation takes a great deal of time. For this reason it is more usual to add the charcoal to the spirit in the rectifying apparatus—which, however, is a bad method, and never yields spirit free from fusel-oil, at least in the first portions of the distillate; a better method is to pass the vapour of the spirit through an apparatus filled with charcoal, before it is condensed.

Various methods of defuselation have been proposed, but for the most part with indifferent results, which consist in adding to the charcoal certain chemical reagents that will act upon the fusel-oil; or in treating the alcohol with these reagents after defuselation with charcoal, and before rectification; or in using these reagents without the charcoal.

Peters (Dingl. pol. J. cviii. 79) introduces between the charcoal in the casks used in the cold-digesting process, a layer of fine pulverised *peroxide of manga-*

ness placed between two pieces of flannel. Hourier (*ibid.* cxvi. 68) uses charcoal mixed with half its weight of *slaked lime*, also for cold digestion; Zalhau (*ibid.* c. 80) uses charcoal with *soap-boilers' lye*. A method very generally practised, is the addition of solution of *chloride of lime* before rectification to the spirit previously defuselised with charcoal (1 lb. of saturated solution of chloride of lime to 150 litres of spirit). One-third of this quantity of chloride of lime is however sufficient, if, after it has been mixed with the spirit, an equivalent quantity of *chloride of zinc* be added, hypochlorite of zinc being then formed, which is easily decomposed (Dingl. pol. J. clviii. 378). Stein (*ibid.* cxxxviii. 429) causes the vapour of the spirit to pass through a mixture of 2 pts. *chloride of calcium* and 1 pt. *charcoal*, whereby it is defuselised and dehydrated at the same time. Knop (Pharm. Centr. 1847, p. 687) mixes the spirit with a solution of *cupric sulphate* precipitated by *potash*, then adds excess of the alkali, and digests for some time, whereby cuprous oxide is formed.

The use of lime alone, or of potash, or of strong sulphuric or nitric acid is not to be recommended, inasmuch as the two former exert but little action, and the acids produce compound ethers, which give the spirit a peculiar odour not exactly that which is desired, and at the same time do not completely decompose the fusel-oil. Hünefeld (Erdmann's Journ. f. technische Chemie, xi. 527) uses manganate of potassium (*min'ral chamælcon*), which, however, acts upon the alcohol as well as upon the fusel-oil; also chloride of lime, which gives the spirit a somewhat unpleasant odour.

Milk has long been used as a defuselising agent (Erdm. Journ. f. techn. Chem. xv. 369), its action being probably due to the fat which it contains. Breton (Moniteur industr. 1858, p. 2308) states that *olive oil* shaken up with spirit containing fusel oil takes up the whole of that impurity, and when the whole is left at rest, settles down and may be separated by filtration. For operating on the large scale, he recommends that the spirit be filtered through a layer of pulverised pumice-stone slightly drenched with the oil. As soon as the oil in the pumice becomes saturated with fusel-oil, the filtration is interrupted, and steam at the pressure of 2 or 3 atmospheres is passed through the pumice; the fusel-oil then volatilises, and the oiled pumice may be again used for defuselising. According to Kletzinsky (Dingl. pol. J. cxlviii. 150), good *soda-soap* dissolved in spirit (that prepared with the oleic acid of the stearic acid manufacture answers best) is capable of retaining 20 per cent. of its weight of fusel-oil when the spirit is distilled off from it, so that a distillate is obtained quite free from fusel-oil: 4 lbs. of soap are stated to be sufficient for defuselising 1 Prussian eimer (about 69 litres or 15 gallons) of spirit, whatever may be the proportion of alcohol contained in it. The soap after being used may be completely freed from fusel-oil by distillation with steam at a temperature above 100° C., and may then be used for defuselising fresh quantities of impure spirit. Lastly, Vandevelde (Dingl. pol. J. clvii. 240) states, that brandy may be completely freed from fusel-oil by cooling it to -15° C. the fusel-oil filling to the bottom. The brandy may then be decanted or filtered and rectified. The statement, however, requires confirmation.

The best mode of detecting the presence of fusel-oil in spirit is to allow the spirit to evaporate slowly, as by rubbing it on the hand, or rinsing a glass out with it and leaving it to stand till the odour of the ethylic alcohol is no longer perceptible; the smell of the fusel-oil, being then no longer disguised by the alcohol, becomes apparent. Diluting the alcohol with warm water likewise brings out the smell of the fusel-oil. The turbidity produced in silver solution by fuselated spirit does not afford a very trustworthy indication, since a like effect may arise from the presence of many other substances. Stein (Dingl. pol. J. clv. 159) places the spirit in a large glass together with dry porous chloride of calcium, by which the ethylic alcohol is gradually absorbed, and keeps the vessel covered for some time; the odour of the fusel-oil becomes very perceptible after about two hours. (Handw. d. Chem. 2^{te} Aufl. ii. [3] 794.)

FUSIBLE METAL. An alloy of lead, tin and bismuth, which melts below the temperature of boiling water (i. 591).

FUSION. See HEAT.

FUSTIC. Two yellow dyes are known by this name, viz. *old fustic*, obtained from *Morus tinctoria*, and *young fustic* from *Rhus Cotinus*. (See DYEING, ii. 356.)

FUSTIN. The name given by Preisser to the colouring matter of *Rhus Cotinus*.

FUSYL. The radicle C^6H^5 , homologous with xylyl, CH_3 , vinyl, C^2H^3 , &c.; sometimes called *valyl*.

Disulphide of Fusyl, $C^6H^5S_2$ or $C^{10}H^8S_2$, is obtained, together with other products, by distilling disulphochloride of amylene with excess of potash. It is a clear, colourless liquid, having a not unpleasant odour, of specific gravity 0.880 at 13° C., boiling at 112° C.; insoluble in water, miscible in all proportions with alcohol and ether. (Guthrie, Chem. Soc. Qu. J. xii. 125.)

G.

GABBRO. The name given by the Italian artists, and by L. von Buch, to a rock essentially composed of felspar and diallage, called by the French geologists euphotide. Besides the essential constituents just mentioned, it contains talc, amphibole or actinote, garnets, grains of pyrites, &c. This rock is abundant in the Alps. It is found in great quantity among the rounded pebbles in the neighbourhood of the Lake of Geneva. Von Buch met with it on the elevated portions of Monte Rosa, forming considerable masses superposed on the micaceous schist, and mixed in several places with serpentine. The tops of the mountains of the territory of Genoa, which overlook the gulf of Spezzia, are composed principally of it. In Corsica it forms districts of somewhat considerable extent, whence is derived the *verde di Corsica*, a fine variety of this rock. The *nero di prato*, the *verde di prato*, the *granite di gabbro* of the Florentines, are merely diallages, habitually metalloid, and mixed sometimes with serpentine, sometimes with felspar or jade, which are brought from the mountains of Tuscany. (D'Aubisson.) U.

Gabbro is closely related to serpentine (v. Buch, *Geognostische Beobachtungen*, i. 45). G. Rose (Bull. Soc. géolog. [2] iv. 1061) observed at Zobtenberg, in Silesia, a stratified gabbro interposed between serpentine and granite, and resting on the latter. In some places it was converted into a green slate, at others into serpentine.

The gabbro, or euphotide, of Mont Genève has been examined by Delesse (Ann. Min. [4] xvi. 238). The felspar of this rock, which contains water, belongs to the triclinic system (p. 619), but does not constantly exhibit the same composition, approaching sometimes to labrador, sometimes to vösgite, sometimes to anorthite, which is also the case in some of the porphyries of the Vosges. This gabbro also contains magnetic iron ore, frequently titaniferous or chromiferous iron pyrites, talc, and serpentine, the latter often in such quantity as to make it doubtful whether the rock should be called gabbro or serpentine. It likewise contains carbonates, generally a ferrous carbonate with lime and magnesia, which occurs in the felspar and diallage crystals, as well as in the general mass of the rock. The felspar is the predominating constituent indeed, the properties of the entire formation do not differ much from those of felspar.

The composition of the entire rock is, according to Delesse, 45.00 silica, 26.83 alumina and ferric oxide, 8.49 lime, 13.90 magnesia, soda, and potash, and 5.78 carbonic anhydride.

The gabbro of Odern in the Vosges contains the same principal and subordinate constituents. At the points where it touches the transition-slate, the laminae of mica penetrate into this rock, and the gabbro passes by insensible gradations, sometimes into a kind of talcose slate, sometimes into a serpentine slate. The gabbro of Odern contains, in addition to the above constituents, amorphous quartz, calcspar, also epidote, asbestos, and small crystals of albite and axinite. (Delesse, Ann. Min. [4] xvi. 325.)

The following are analyses: *a.* Of a fine-grained gabbro at the entrance of the Radautal, in the Harz, containing about equal quantities of labrador and diallage with small quantities of magnetic iron-ore and traces of iron pyrites uniformly distributed throughout (Koibel, Jahresber. f. Chem. 1858, p. 768); *b.* Of a rock resembling gabbro, occurring on the Bahammer mountain, near Christiania, containing augite, or hornblende, and diallage, more rarely, black mica (Kjerulf, *ibid.* 1855 p. 1001):

SiO ²	Al ² O ³	FeO	Fe ² O ³	MnO	MgO	CaO	K ² O	Na ² O	CaCl ² , Water and CaF ² , and Loss by P ² O ⁵ Ignition.	0.52 = 100.96 1.29 = 98.53
49.14	15.19	6.85	8.52	0.05	6.54	10.50	0.28	2.26	1.01*	0.52 = 100.96
47.93	8.94	15.90	11.20	11.32	0.85	1.05	...	1.29 = 98.53

On the gabbro of Neurode in Silesia, see G. v. Rath (Pogg. Ann. xcv. 533; Jahresber. 1855, p. 999). On the relations between the occurrence of gabbro, greenstone hornblende-rock, and other allied rocks, on the one hand, and of metalliferous veins on the other, see Burat (Ann. Min. [4] xiii. 351; Jahresber. 1847-8, p. 1284.)

GABBRONITE. Syn. with SCAVOLITE.

GADINIC ACID. A crystalline fatty acid, obtained from cod-liver oil. A turbid residue of this oil, after being heated and then cooled to 5° C., deposited crystalline laminae of this acid, which were purified by saponifying with soda, precipitating with basic acetate of lead, washing the dried precipitate with ether, decomposing the residue with hydrochloric acid, and recrystallising from alcohol. The acid thus purified, melted between 63° and 64° C., and solidified again in a distinctly crystalline form at 60°. From the analysis of the barium- and silver-salts, the formula of the acid

* CaCl² = 0.11; CaF² = 0.09; P²O⁵ = 0.61.

was concluded to be $C^{23}H^{24}O^8.H$; which is very improbable, (Luck, Chem. Centr. 1857, 191.)

GADOLINITE. $(Y^{III})_2SiO_4$ or $3YO.SiO_2$. *Ytterbyite*. (Dana, ii. 211; Gm. iii. 409).—A black mineral, inclining to brown or green. It is generally amorphous, but is occasionally met with in monoclinic prisms of about 115° . Cleavage imperfect. Transparent at the angles. Powder, greyish-green. Harder than feldspar; readily scratches glass. Hardness = 6.5–7.0. Specific gravity = 4.0–4.35. Gadolinite is found in very small quantities only, disseminated amongst the pegmatites in the neighbourhood of Fahlun, and at Ytterby in Sweden. It is sometimes coated with carbonate of yttrium. It is a silicate of yttrium, and serves for the preparation of yttria; it likewise contains ferrous and cerous oxides, together with oxide of terbium and oxide of erbium. (?) (Mosander.)

a. Splintery Gadolinite.—Of splintery fracture. When this variety is heated before the blowpipe, it becomes suddenly incandescent, increases in density, and becomes insoluble in acids, generally evolving a little water, and swelling up to a white, cauliflower-like mass. Dissolves readily in borax, yielding a green bead (from ferric oxide). Karverfort gadolinite parts with but little water when heated, does not swell up, but fuses to a turbid, greyish, or reddish bead. Splintery gadolinite dissolves in hydrochloric acid, with separation of gelatinous silica; but after heating, it is insoluble.

b. Vitreous Gadolinite.—Of conchoidal fracture; becomes brilliantly incandescent when gradually heated, turning greyish-green, and swelling up slightly, increasing somewhat in density. Its edges blacken before the blowpipe, but it does not fuse. Behaves with borax and hydrochloric acid like *a*.

	<i>a.</i> Scherer.	<i>b</i> , from Ytterby. Berlin.

C. E. I.

GADUIN. A peculiar brown substance contained in cod liver oil. (De Jongh.)

GAGATES. The ancient name of *jet* (Dioscorides and Pliny), derived from the river Gagus in Syria, near the mouth of which it was found.

GAHNITE or *Automolite*. $(Al^2)^2Zn^2O^4$ or $ZnO.Al^2O^3$. (Dana, ii. 104; Gm. v. 46.) A greenish or greyish mineral, sometimes transparent, but generally opaque. It crystallises in large regular octahedrons, often forming beautiful twin crystals. Its cleavage is octahedral and perfect. Hardness = 8.0. Specific gravity = 4.1–4.3. Powder, pale bluish-green. Harder than quartz. Gahnite has only been found at Fahlun, in Sweden, and at Franklin, New Jersey, disseminated amongst talcose slate.

Gahnite does not melt before the blowpipe. Heated with carbonate of soda, it does not dissolve, but concretes to a dark slag, which, when heated on charcoal, yields an incrustation of oxide of zinc. Dissolves with great difficulty and very sparingly in borax and microcosmic salt; dissolves in a mixture of borax and carbonate of soda, yielding a clear bead, coloured with ferric oxide. Insoluble in aqueous acids and alkalis.

C. E. I.

GALACTIN. A gelatin-yielding substance, said by Morin (J. Pharm. [3] xxv. 423) to exist in milk.

GALACTITE. A calcareous variety of natrolite, found at Kilpatrick and Bishoptown in Scotland. (Jahresber. f. Chem. vii. 840, ix. 861.)

GALAM or SHEA BUTTER. A solid fat, much resembling palm-oil, the produce of a species of *bassia* (*Bassia Parkii*), indigenous in the interior of Africa; also of another tree, resembling the American oak, growing in West Africa. It softens at about 36° C. (95° F.), and melts completely at 43·3° C. (110° F.). It dissolves for the most part in boiling alcohol, and perfectly in cold ether, separating in crystalline needles by cooling or evaporation. By saponification, it yields margaric acid. (R. D. Thomson and E. T. Wood, Phil. Mag. [3] xxxiv. 350.)

GALANGA or GALANGAL. A name applied to several roots possessing aromatic properties. Two principal kinds are described, viz. *Galanga minor* and *Galanga major*. The former, which is most prized for its aromatic properties, is obtained from a plant of unknown species growing in China. It has a reddish colour, an aromatic odour, and very acrid taste. The greater galangal is the produce of a scitamineaceous plant, the *Alpinia Galanga*, of Willdenow, and a native of China and the Malayan archipelago. The roots are cylindrical; reddish-brown externally, and marked with whitish circular rings, lighter coloured externally; they have an agreeable aromatic odour, but less powerful than those of the lesser galangal, and a hot peppery taste. According to Bucholz, they contain in 100 parts:—0·50 volatile oil, 4·50 resin, 9·70 extractive matter, 8·20 gum, 41·50 mucilage, 21·65 woody-fibre, and 12·30 water. The root of *Kempferia Galanga*, a scitamineaceous plant, growing in the mountainous districts beyond Chittagong, and formerly supposed to be the true galanga, yields a crystallisable principle called kempferide (*q.v.*) (Pelouze et Frémy, *Traité*, vi. 368; *Penny Cyclopædia*, xi. 35.)

GALAPECTITE. See HALLOYSITE.

GALBANUM. A gum-resin, commonly supposed to be the produce of *Babon Galbanum*, an umbelliferous plant native of the Cape of Good Hope. This, however, is doubtful. It is imported from Ethiopia and other parts of Africa, and from Persia. It comes over in masses composed of white, yellowish, brownish-yellow, and brown tears, unctuous to the touch, softening betwixt the fingers; of a bitterish, somewhat acrid, disagreeable taste, and a very strong smell; generally full of bits of stalks, leaves, seeds, and other foreign matters.

Galbanum contains more resinous than gummy matter: one pound yields with alcohol upwards of nine ounces and a half of resinous extract; but the gummy extract obtained by water from the same quantity amounts only to about three ounces. The resin is hard, brittle, insipid, and inodorous. The gummy extract has somewhat of a nauseous taste. The whole smell, flavour, and specific taste of this juice reside in an essential oil, which rises in distillation both with water and spirit, and gives a strong impregnation to both. From a pound of galbanum are obtained, by distillation with water, six drachms of actual oil, besides what is retained by the water. In this respect galbanum agrees with asafetida, and differs from ammoniacum.

According to the analyses of Meissner and Pelletier, galbanum contains:—

	Meissner.	Pelletier
Resin	65·8	66·86
Gum	27·6	19·28
Vegetable mucilage	1·8	
Volatile oil	3·4	6·34
Water	2·0	
Insoluble matter	2·8	7·62
	103·4	100·00

The resin may be extracted by alcohol; it is of a dark yellow colour, transparent, and melts easily at the temperature of the water-bath. It contains, as the mean result of Johnston's analysis, 73·88 p.c. carbon, 8·45 hydrogen, and 17·67 oxygen. When heated to 120° to 130° C., it yields, amongst other products, an oil of a fine indigo-colour, and very soluble in alcohol, to which it imparts its colour. (Gerh. iv. 373.)

From the recent experiments of Mössmer (Ann. Ch. Pharm. cxix. 257), it appears that galbanum, distilled with water, yields about seven per cent. of a volatile oil, isomeric with oil of turpentine, $C^{10}H^{16}$, which, after rectification, is colourless, has a density of 0·8842 at 9° C., and boils at 160°. It turns the plane of polarisation to the left, its specific rotatory power being 0·1867. Index of refraction = 1·4542. Like other camphenes, it forms a crystallisable compound with hydrochloric acid.

The residue of the distillation consists of a resinous mass, and a turbid liquid containing gummy and extractive matters. (This liquid, distilled with sulphuric acid, yielded an acid, the silver-salt of which was intermediate in composition between acetate and propionate of silver.) On boiling the resinous mass with

milk of lime, and precipitating the filtrate with hydrochloric acid, a honey-yellow resin was obtained, soluble in alcohol and ether, containing from 71.93 to 72.06 p.c. carbon, and 8.0 to 8.2 hydrogen, agreeing nearly with Johnston's analysis above quoted. When heated to 100° with alcoholic hydrochloric acid, it yielded umbelliferone, $C^8H^6O^2$, a crystalline body previously obtained by Sommer (Arch. Pharm. [2] xcviii. 1), by the dry distillation of galbanum and other resins derived from umbelliferous plants. (See UMBELLIFERONE.)

The purified galbanum resin yields by dry distillation a small quantity of water and a greenish blue viscid aromatic oil, which, after a while, solidifies to a crystalline pulp: the oil may be separated from the crystalline matter by repeated boiling with water, and filtration through wet filters. The aqueous solution yields crystals of umbelliferone. The viscid oil, after being freed from the last traces of that substance by treatment with dilute potash, yields by repeated rectification a splendid blue oil, $C^{20}H^{20}O$, which boils at 289° C., is soluble in alcohol, insoluble in alkalis, is resinised by bromine, coloured green by alcoholic ferric chloride, and yellowish-red by nitric acid: in a freezing mixture, it quickly becomes viscid. By distillation with sodium, it yields (a) a colourless oil $C^{20}H^{20}$, boiling at 254°; and (b) by distillation with phosphoric anhydride, a yellowish oil, $C^{20}H^{20}O$, which boils between 250° and 253°. Hence the blue oil appears to be an alcohol, $C^{20}H^{20}O$, the oil b an ether, $C^{20}H^{20}O$, and the oil a a hydride, $C^{20}H^{20}.H$. (Mössmer.)

GALENA. Native sulphide of lead. See LEAD, SULPHIDE OF.

GALIPOT. See TURPENTINE.

GALITANNIC ACID. See the next article.

GALIUM. The herb of *Galium verum* and *G. Aparine* contains citric acid, precipitable by neutral acetate of lead; galitannic acid, a peculiar variety of tannic acid, precipitable from the filtrate by basic acetate of lead, and consisting, in the hypothetically anhydrous state, of $C^{16}H^8O^{10}$ (?) and rubichloric acid (q.v.), precipitated from the last filtrate (together with sexbasic acetate of lead) by ammonia. Galitannic acid is most abundant in *Galium verum*; citric acid in *G. Aparine*; and rubichloric acid occurs to about equal amount in both. (Schwarz, Ann. Ch. Pharm. lxxiii. 57.)

In *Galium Mollugo*, L. (the entire plant, excepting the root), Vielguth (Chem. Centr. 1856, 423), found a camphor-like volatile oil, chlorophyll, fixed oil, wax, resin, albumin, starch, sugar, bitter principle, oxalic acid, a tannic acid which imparted a green colour to iron-salts (aspartannic acid), citric acid, and rubichloric acid. The air-dried plant yielded 7.6 per cent. ash, containing 14.5 per cent. K^2O ; 5.6 Na^2O ; 23.4 CaO ; 7.6 MgO ; 0.3 Al^2O^3 ; 0.5 Fe^2O^3 ; trace of Mn^2O^3 ; 1.3 Cl ; 5.9 SO^2 ; 10.4 P^2O^5 ; 11.1 SiO^2 ; 4.0 sand; and 15.4 CO^2 .

GALL. See BILE.

GALLAMIC ACID. $C^7H^7NO^4$.—This acid, which has the composition of acid gallate of ammonium minus 1 at. water [$C^7H^5(NH^4)^2O^5 - H^2O$], is obtained by adding to an alcoholic solution of tannin a mixture of 1 pt. of a concentrated solution of sulphite of ammonium and 5 pts. of strong ammonia, until the whole smells strongly of ammonia. The object of adding the sulphite is to prevent the oxidising action of the air. The liquor becomes heated, and gradually deepens in colour. It is evaporated to dryness, and repeatedly exhausted with boiling alcohol. On evaporating the alcoholic liquors, gallamic acid is deposited, and is recrystallised from water slightly acidulated with hydrochloric acid.

Gallamic acid crystallises in beautiful rectangular plates, having a fatty aspect, containing $2C^7H^7NO^4 + 3 aq$. At 100° C. it loses its water (13.8 per cent.). It is very rapidly decomposed in presence of alkalis. E. A.

GALLERYTHERONIC ACID. See GALLIC ACID (p. 761).

GALLUMIC ACID. Syn. with METAGALLIC ACID.

GALLIC ACID. $C^7H^5O^5 = \left(\frac{C^7H^5O^5}{H^3} \right)^m O^2$. (Gm. xii. 396; Gerh. iii. 857.)

This acid, which was discovered by Scheele, exists, ready formed, in many plants, and is also obtained by the metamorphosis of gallotannic acid (tannin). It is contained in gallnuts, in sumach, in hellebore root, in dibidivi, in the acorns of *Quercus Aegylops*, in green and black tea, in *Uva urai* leaves, in sandalwood, in colchicum, in *strychnos* bark, and in most astringent parts of plants.

To obtain it from plants which at the same time contain tannin, an infusion of the plant is precipitated with gelatin; the liquor separated from the filtrate is evaporated to dryness, and exhausted with alcohol; the alcoholic solution is evaporated; and the residue is exhausted by boiling water, which, on cooling, deposits gallic acid in crystals. They are purified by recrystallisation and treatment with animal charcoal.

Gallic acid is, however, much more conveniently obtained by the metamorphosis of the tannin in gallnuts (gallotannic acid). The gallnuts are powdered, and exposed to the air for about a month at a temperature of 20° – 25° C., being kept continually moistened. The mass becomes covered with mould, which must be constantly removed. At the expiration of that time it is pressed. The liquor is coloured deep brown, but contains only a small quantity of gallic acid, the greater part of which remains in the residue. This is extracted by boiling water, and the crystals which deposit on cooling are redissolved in 8 times their weight of boiling water, and treated with animal charcoal. This method, though the least costly, requires a long time. The metamorphosis seems to depend on the action of a kind of nitrogenous ferment in the gallnut. If an extract of the gallnuts be employed, the metamorphosis also takes place, but much more slowly.

By the action of acids or alkalis, gallotannic acid is resolved into glucose and gallic acid:

and this is the most convenient way of obtaining gallic acid.

According to Liebig, the best mode of proceeding is to precipitate a solution of tannin by sulphuric acid, and introduce the precipitate into boiling dilute sulphuric acid. After a few minutes, gallic acid is deposited in crystals. They are purified from sulphuric acid by repeated crystallisation, dissolved in boiling water, and acetate of lead added. The precipitate is washed, diffused in boiling water, and decomposed by sulphuretted hydrogen. The mixture filtered boiling, deposits coloured crystals on cooling.

Gallic acid may be also obtained from tannin by the action of alkalis; but this process is scarcely to be recommended, from the readiness with which gallic acid is oxidised in presence of potash.

Lastly, gallic acid is produced by the action of hot concentrated potash-solution on *di-iodosalicylic acid*:

A considerable portion of the gallic acid thus formed is, however, converted during the process into pyrogallic acid. (Lautemann, Ann. Ch. Pharm. cxx. 317.)

Gallic acid crystallises in long silky needles, or in triclinic prisms. Observed combination, $\text{oP} : \text{P} : \infty\text{P} : \infty\text{P}' : \infty\text{P}''$. Inclination of the faces, $\text{P} : \infty\text{P}'' = 95^{\circ}$; $\text{P} : \infty\text{P} = 125^{\circ} 20'$; $\infty\text{P}'' : \infty\text{P} = 84^{\circ}$; $\infty\text{P} : \infty\text{P}' = 160^{\circ}$; $\text{P} : \text{oP} = 118^{\circ}$; $\infty\text{P}'' : \text{oP} = \text{about } 150^{\circ}$. Cleavage parallel to P ; less distinct parallel to $\infty\text{P}''$. The crystals are inodorous, and have an astringent slightly acid taste. They dissolve in 100 pts. of cold and in 3 pts. of boiling water, and the solution reddens litmus. They are very soluble in alcohol, less soluble in ether. They lose 2 at. = 9.5 per cent. of water at 100° C.

Pure and dry gallic acid heated to 210° or 215° C. decomposes into pyrogallic acid and carbonic anhydride:

When gallic acid is kept for some time at 230° C., a brownish, lustrous, soluble residue is obtained, which precipitates gelatin, but not the vegetable alkalis. (Berzelius's gallulmic acid.)

When gallic acid is rapidly heated to 250° C., carbonic anhydride is given off; but instead of pyrogallic acid, a black ulmic compound is obtained, lustrous, tasteless, and completely insoluble in water. This is metagallic acid (*q.v.*) It is soluble in the alkalis, and its alkaline salts precipitate the salts of the earths and metals.

An aqueous solution of gallic acid does not change if excluded from the air; but in the presence of *oxygen*, more especially in the presence of alkalis also, carbonic anhydride is disengaged, and a black substance deposited.

Pure gallic acid precipitates neither gelatin nor the vegetable alkalis, a deportment by which it is distinguished from tannin; but, when mixed with gum, it produces a precipitate with gelatin.

Boiled with an excess of *potash*, gallic acid is changed into a black acid, *tannomelanic acid*:

Solution of gallic acid, mixed with *acid-carbonate of calcium* and exposed to the air, becomes ultimately of a dark blue colour. When the solution is boiled, carbonate of calcium is deposited, and the liquid becomes colourless, but on cooling is again blue.

This coloration is said by Wackenroder to be due to the formation of a peculiar acid, called gallerythronic or cyanogallic acid.

Gently heated with concentrated *sulphuric acid*, gallic acid loses the elements of water, and becomes converted into rufigallic acid.

By the action of 4 at. of *chloride of acetyl* on gallic acid, tetracetylgallic acid is formed:

It crystallises in small lustrous needles, which are difficultly soluble in water; it is decomposed by the action of bases, forming gallates.

Triacetylgallic acid, $\text{C}^7\text{H}^3(\text{C}^2\text{H}^3\text{O})^3\text{O}^5$, dibutylgallic acid, $\text{C}^7\text{H}^4(\text{C}^4\text{H}^7\text{O})^2\text{O}^5$, and dibenzoylgallic acid, $\text{C}^7\text{H}^4(\text{C}^7\text{H}^5\text{O})^2\text{O}^5$, are similarly formed. (Nachbaur, J. pr. Chem. lxxii. 431.)

Gallic acid is decomposed by *permanganate of potassium*, with disengagement of carbonic acid; the decolorisation of the permanganate is so complete that a volumetric method for determining gallic acid has been based on this reaction. (Morin, Compt. rend. xlii. 577.)

Gallic acid reduces *gold* and *silver salts* to the metallic state.

Gallic acid expels carbonic acid from its salts; it is a tribasic acid, and forms three series of salts:

Trimetallic gallate . . .	$\text{C}^7\text{H}^3\text{M}^3\text{O}^5$
Dimetallic gallate . . .	$\text{C}^7\text{H}^4\text{M}^2\text{O}^5$
Monometallic gallate . . .	$\text{C}^7\text{H}^5\text{M}\text{O}^5$

There are also basic and acid compounds. The alkaline gallates are soluble.

Aluminium-salt. This body has no definite composition. When freshly precipitated hydrate of alumina is added to a solution of gallic acid, the latter is entirely precipitated, while the former is not altered in appearance.

An *acid ammonium-salt*, $\text{C}^7\text{H}^3(\text{NH}^4)\text{O}^5 + \text{H}^2\text{O}$, is prepared by saturating a solution of gallic acid in absolute alcohol with ammoniacal gas. The salt which deposits is washed with alcohol, and then dissolved in the smallest quantity of boiling water. It crystallises in fine needles.

The *neutral* or *triammonium gallate* is not known.

Antimony-salt.—White precipitate obtained by the double decomposition of tartar-emetic and an alkaline gallate.

Barium-salt, $\text{C}^7\text{H}^3\text{Ba}^2\text{O}^{10}$.—Freshly precipitated carbonate of barium is added to a boiling solution of gallic acid, as long as effervescence is produced: the liquor diluted, filtered, and evaporated, yields crystals, which must be removed as rapidly as they are produced. The more rapid the concentration, the purer the crystals.

The *calcium-salt*, $\text{C}^7\text{H}^3\text{Ca}^2\text{O}^{10} + 2\text{aq.}$, is prepared in like manner. Thin pale yellow crusts composed of adherent needles.

Cobalt-salt, $\text{C}^7\text{H}^3\text{Co}^2\text{O}^5 + 3\text{H}^2\text{O}$.—Deposited as a crimson powder when acetate of cobalt is boiled with excess of gallic acid solution, and the mixture evaporated.

Lead-salt, $\text{C}^7\text{H}^3\text{Pb}^2\text{O}^5 + \text{aq.}$ —Obtained as a white precipitate, which becomes crystalline, by adding acetate of lead to an excess of a boiling solution of gallic acid.

Basic lead-salt, $\text{C}^7\text{H}^3\text{Pb}^2\text{O}^{10}.\text{Pb}^2\text{O}$.—When gallic acid is added to an excess of a boiling acetate of lead solution, a white flaky precipitate is formed, which, by boiling, is converted into a yellow crystalline basic salt of the above composition.

Iron-salt.—Ferric solutions colour gallic acid of a deep blue. When the liquid is heated, it becomes decolorised, and carbonic acid is liberated, the ferric salt being reduced to the state of protoxide. According to Mahla, part of the gallic acid is converted into metagallic acid (*q.v.*)

Magnesium-salt, $\text{C}^7\text{H}^3\text{Mg}^2\text{O}^5 + 2\text{H}^2\text{O}$.—Obtained by boiling acetate of magnesium with excess of gallic acid, evaporating to dryness, and treating with alcohol to remove free gallic acid. The gallate of magnesium forms a light white powder, difficultly soluble in water.

Manganese-salt, $\text{C}^7\text{H}^3\text{Mn}^2\text{O}^5 + \text{aq.}$ —Obtained by double decomposition, as a white granular, crystalline powder, which rapidly becomes brown in the air.

Nickel-salt.—A basic nickel-salt of variable composition is prepared by treating gallic acid with carbonate of nickel.

Potassium-salt, $2\text{C}^7\text{H}^3\text{K}^2\text{O}^5.\text{C}^7\text{H}^3\text{O}^5 + \text{H}^2\text{O}$.—As this salt is rapidly changed by contact with the air, its preparation requires special precautions. An alcoholic solution of potash is gradually added to an alcoholic solution of gallic acid, until the precipitate, which at first disappears, begins to be permanent. If the liquid be then agitated, the precipitate separates in white flakes. These are filtered and washed with alcohol to remove free gallic acid, and then dissolved in water, concentrated, and precipitated by alcohol in colourless needles.

Sodium-salt, $C^1H^1NaO^1 + 3H^2O$.—Prepared in the same manner, and consists of fine needles, which lose their water of crystallisation at 100° .

Strontium-salt, $C^1H^1Sr^2O^3 + 4H^2O$.—Prepared like the barium-salt, and consists of small needles, little soluble in water and insoluble in alcohol.

Tin-salt, $C^1H^1Sn^2O^3.Sn^2O$.—White crystalline powder, obtained by adding gallic acid to a solution of dichloride of tin, previously neutralised with ammonia.

Zinc-salt, $C^1H^1Zn^2O^3.Zn^2O$.—Deposited as a bulky white precipitate when gallic acid is added to an excess of solution of acetate of zinc. E. A.

GALLICINITE. Syn. with RUTILE.

GALLNUTS, GALLS, or NUTGALLS. *Noix de galle. Galläpfel.*—Excrescences produced on the leaves and leaf-stalks of the dyer's oak (*Quercus infectoria*) by the punctures of the gall-wasp (*Cynips fulvæ quercus* s. *Diplolepis galle tinctorie*), made for the purpose of depositing the eggs. The excrescence, in its early state, forms a spongy mass, enclosing the eggs; at a later stage it hardens, and is perforated by the insects as they make their escape.

The best galls, containing the largest quantity of tannin, come from the Levant, and among these the most highly prized are the black, blue, or Aleppo galls. They are heavy, compact, prickly, of blackish or brownish colour, and not eaten or perforated. The *white galls*, which are less valued, are generally somewhat larger, of yellowish-grey colour, much lighter, spongy, and perforated by the completely developed insect.

Inferior kinds of gallnuts, called *Trieste galls*, are obtained from Dalmatia, Illyria, and Calabria, where they grow chiefly on the *Quercus Cerris*: they are smaller, prickly on the surface, and of brownish colour.

Davy found, in the best Aleppo galls, 26.0 per cent. tannic acid, precipitable by immersed animal membrane; 2.5 mucus and extractive matter; 6.0 gallic acid; 2.5 calcium- and other salts; and 63 insoluble fibre. According to Guibourt, gallnuts contain 65.0 per cent. tannic acid, 2 gallic acid, 2 ellagic and luteogallic acids, 0.7 volatile oil and chlorophyll, 2.5 brown matter, 2.5 gum, 2 starch, 10.5 woody fibre, 1.3 sugar, albumin, and inorganic salts, and 11 water.

The galls, or oak-apples, of the common English oak are similarly constituted, but contain only a small proportion of tannic acid.

Galls are extensively used for the preparation of ink, for the production of black and grey tints in dyeing, for turkey-red dyeing, and in calico printing. The galls of the common oak and *Quercus Cerris* are used for tanning in Hungary, Dalmatia and the southern provinces of Austria. (See *Ure's Dictionary of Arts, &c.*, ii. 320.)

GALLOTANNIC ACID. $C^{27}H^{22}O^{17} = \left(C^{27}H^{19}O^{14} \right)^{3-} O^3$. *Tannic acid. Tannin.* *Tanning principle.* (Devreux, J. Phys. xlii. 401.—Séguin, Ann. Chim. xx. 15.—Braconnot, *ibid.* l. 376.—Pelletier, *ibid.* lxxxvii. 103.—Berzelius, *ibid.* xciv. 318.—Pelouze, Ann. Ch. Phys. liv. 337.—Liebig, Ann. Ch. Pharm. x. 172.—Büchner, *ibid.* liii. 175, 349.—Stenhouse, Phil. Mag. [3] xxii. 417; xxiii. 331; Proc. Roy. Soc. xi. 401.—Wetherill, J. Pharm. [3] xii. 107.—Mulder, Ann. Ch. Pharm. xxxi. 124.—Wackenroder, J. pr. Chem. xxiv. 28.—Strecker, Ann. Ch. Pharm. lxxxi. 248; xc. 328; Chem. Soc. Qu. J. v. 102; Phil. Mag. [4], viii. 157.—Rochleder and Kawalier, J. pr. Chem. lxxiv. 28 and 399.—Gm. xv. 449.—Gerh. iii. 847.)

This acid is contained in the gallnuts of *Quercus infectoria* and other species of oak, in the various species of sumach (Stenhouse), and in Chinese gallnuts, the excrescences formed on the branches of a tree growing in Japan, which, according to Schenck (N. Rept. Pharm. v. 26 and 306), is also a species of sumach (*Rhus semialata*, or *Rh. Chincensis*).

Many other plants contain substances which resemble gallotannic acid in many respects, viz. in having a slight acid reaction, and an astringent but not acid taste; in precipitating albumin and gelatin from solution, and uniting with animal membrane into a substance which resists putrefaction, namely leather, the skin then becoming *tanned*. All these substances, called tannic acids, or tannins, were originally supposed to be identical with gallotannic acid, or to differ from it only in consequence of the admixture of foreign matters; but the more exact investigation to which they have been submitted of late years, has shown that most of them differ in some essential properties from gallotannic acid, this acid, indeed, existing only in the plants above mentioned.

The various species of tannin may be divided into two genera—those which give black or blue, and those which give olive-green precipitates, with ferric salts; and Stenhouse has shown that most of the tannins which give bluish-black precipitates with ferric salts are glucosides, that is to say, they are resolved, by boiling with dilute acids, into glucose and another substance—a property first pointed out in the case of gallotannic acid, which yields glucose and gallic acid, by Strecker; whereas, among those which give green precipitates with ferric salts, only one, viz. the tannin

of willow-bark, appears to be a glucoside. Among the tannins of the first division, gallotannic acid is especially distinguished by yielding pyrogallie acid when heated, whereas the other tannins yield different products. (See TANNIN.)

Preparation of Gallotannic acid.—1. A percolating apparatus is half filled with finely pulverised gallnuts, and commercial ether, containing water and alcohol, is poured in. The liquid which runs away separates into two layers, the lower of which is a heavy, syrupy, amber-coloured solution of tannic acid, water, and ether; while the upper is mobile, consisting of ether, water, gallic acid, and a small quantity of tannic acid. Ether is poured into the apparatus as long as the lower stratum continues to increase: the upper layer is then removed; and the lower is repeatedly washed with ether, and dried in vacuo or by heat. Gallnuts thus treated yield from 35 to 40 per cent. tannic acid. (Pelouze, *Ann. Ch. Pharm.* x. 145, 210.)

2. 100 pts. of powdered gallnuts are treated in the percolating apparatus with a mixture of 300 pts. ether, 15 pts. alcohol of 90 per cent., and 5 pts. water (or 20 pts. alcohol of 69 per cent.); the residue, after the liquid has run off, is twice treated with the same mixture, then three times with pure ether; and the whole of the extracts are shaken up together, and left to settle for a week. The upper of the two layers thus formed is decanted from the syrup below, the latter is evaporated over the water-bath, and the residue is dried between 100° and 110° C. To purify the tannic acid thus obtained, or by the first process, from admixed gallic acid, ellagic acid, volatile oil, and chlorophyll, 100 pts. of it are shaken up with 100 pts. water and 200 pts. ether, whereby three layers are formed, the upper consisting of ether, the middle of aqueous gallic acid and impure tannic acid, while the lowest, which is syrupy, and amounts to 215 pts., leaves, on evaporation, 90 pts. of pure tannic acid (Guibourt, *Ann. Ch. Pharm.* xlviii. 359). Mohr employs for the extraction a mixture of equal volumes of ether and alcohol of 90 per cent. The filtrate is syrupy, but thinner than that obtained by the first method, and forms only one layer, exhibits but little turbidity on the addition of a large quantity of ether, and if 7 fluid ounces of ether are used to 2 ounces of galls, yields a quantity of tannic acid amounting to 72 per cent. of the galls. If a mixture of 4 vols. ether and 1 vol. alcohol of 90 per cent. is used, the extract has the same constitution (Mohr, Sandrock). With Chinese galls, hydrated ether acts better than ether-alcohol. (E. Riegel, *N. Jahrb. Pharm.* iii. 252.)

According to Strecker, tannic acid, prepared and purified as above, cannot be further resolved into different substances by repeatedly treating its ethereal solution with water, but exhibits the same composition before and after this treatment. Rochleder and Kavalier, on the other hand, regard the tannic acid obtained from gallnuts by exhaustion with ether and water, as a mixture still containing gallic and ellagic acids; to separate these substances they proceed as follows:—

The solution of tannic acid in the smallest possible quantity of water, is shaken up with a small quantity of solution of neutral acetate of lead; the filtrate is mixed with water, and filtered again from the very impure tannate of lead thereby precipitated; and the new filtrate is precipitated by neutral acetate of lead in three portions. By decomposing the first and third of these precipitates with sulphydric acid, and expelling the excess of that acid by a stream of carbonic acid, solutions are obtained which, when boiled with sulphydric acid out of contact with the air, yield a large portion of ellagic acid. If the tannic acid solution, obtained in like manner from the middle portion, be precipitated by tartar-emetic, with addition of a little carbonate of ammonia, the precipitate washed with hot water, and decomposed under water with sulphydric acid,—and the excess of that acid expelled by passing carbonic acid into the hot liquid, the filtrate, when left to itself in vacuo, becomes turbid, and deposits a brown substance. The solution, separated from this substance by filtration and evaporation in vacuo, leaves colourless amorphous tannic acid, which, when boiled with hydrochloric acid, no longer leaves any residue of ellagic acid.

Properties.—Gallotannic acid is a colourless, amorphous mass, remaining, when its aqueous solution is evaporated, in transparent, vitreous, shining, fissured, easily friable lumps. It is inodorous; has a strongly astringent taste, not at all bitter; reddens litmus strongly; does not soften between the fingers. It acquires a yellow colour by exposure to light, even in closed vessels. It does not act on polarised light.

Gallotannic acid dissolves readily in water, forming a colourless frothing liquid. The following table exhibits the specific gravity of aqueous gallotannic acid at 16° C according to Hammer (*J. pr. Chem.* lxxxi. 169):

Per cent.	Sp. gr.	Per cent.	Sp. gr.
1	1·0040	6	1·0242
2	1·0080	7	1·0283
3	1·0120	8	1·0325
4	1·0160	9	1·0367
5	1·0210	10	1·0409

Gallotannic acid is precipitated from its aqueous solution by several salts, as by sal-ammoniac, common salt, sulphate and acetate of potassium (not by nitre or Glauber's salts, according to Strecker); by *sulphuric acid* and *hydrochloric acid* (Berzelius); from very concentrated solution by *phosphoric, oxalic, and tartaric acid* (Wackenroder), and by *arsenic acid* (Berzelius). When *boric acid* is dissolved, with aid of heat, in aqueous tannic acid, the mass solidifies on cooling to a white jelly, which dries up to a bulky, snow-white mass (Berzelius). These precipitates were regarded by Berzelius as compounds of tannic acid with mineral acids; but the precipitate thrown down by sulphuric acid retains, after pressure, only a small and variable quantity of sulphuric acid; that produced by hydrochloric acid gives off all its hydrochloric acid in vacuo over quicklime: hence the precipitates can be regarded only as mixtures of tannic acid with mineral acids, produced because tannic acid is less soluble in acidulated than in pure water. (Strecker.)

Gallotannic acid dissolves in *hydrated* more abundantly than in *absolute alcohol* (Pelouze). According to Pelouze, Bolley, and Luboldt, it dissolves but sparingly in *anhydrous ether*, and, when covered with it, remains perfectly pulverulent, according to Strecker and others, while, according to Mohr, it dissolves in considerable quantity. With *ether containing water*, it forms, after some seconds, a very heavy liquid, like that which separates in the preparation of tannic acid (p. 763). Of the two layers thus formed, the lower consists of tannic acid, which has taken up the water of the ether and only a very small quantity of ether, while the upper layer contains ether, a small quantity of tannic acid, and the foreign substances taken up with it (Pelouze). When tannic acid, dried at 110°C ., is covered with anhydrous ether, the solution standing above the excess of pulverised tannic acid, after being agitated for a considerable time, contains in solution only 0.206 per cent. at 5°C ., and 0.384 per cent. at ordinary temperatures. On adding to the ether half a volume per cent. of water, the tannic acid, which has hitherto been greyish yellow and pulverulent, deliquesces to brownish lumps, and on addition of a few drops more water, to a syrup. After addition of 1 vol. per cent. of water, the supernatant ether contains 1.2 per cent. tannic acid in solution. On continuously dropping water into the mixture and agitating, three layers are formed, the lowest of which is syrupy, and contains 0.297 grms. tannic acid in a cubic centimetre. The middle layer is somewhat lighter than the lowest, and contains in a cubic centimetre 0.082 grms. tannic acid dissolved in a large quantity of water and a small quantity of ether. The syrupy layer contains both ether and water, and is perhaps a tannate of ethyl and hydrogen, analogous to ethylsulphuric acid. (Bolley, Chem. Soc. Qu. J. xiii. 295; Ann. Ch. Pharm. cxv. 63.)

Gallotannic acid (crude) dried at 150°C . remains pulverulent when covered with 10 pts of anhydrous ether, while the supernatant ether takes up 2 or 3 per cent. of solid constituents, chiefly the foreign substances mixed with the tannic acid. Water, either present in the ether, or subsequently added, is greedily absorbed by the tannic acid, and causes it to deliquesce to a viscid mass or a syrup, which does not mix with the excess of ether. When a solution of 100 pts. tannic acid in 100 pts. water is mixed with 150 pts. ether, the liquid, if agitated and left at rest at a temperature of 18°C ., separates into three layers, the lowest of which has a specific gravity of 1.07, takes up half the total space, and contains 40.5 per cent. tannic acid, 42.2 ether, and 17.3 water. The middle layer, which has a density of 1.02, contains 14.15 per cent. tannic acid, 10.09 ether, and 75.76 water; the uppermost, of density 0.752, is chiefly ether, containing in solution small quantities of foreign matters and water. Also, when 20 grms. tannic acid, 39 grms. ether, and 20 grms. water are shaken up together and then left at rest, three layers are formed, the lowest of which increases by continual agitation at 14.5° , at the expense of the upper, till it occupies 36.5, and the upper 17.5 pts. of the entire space, the middle layer, which remains unaltered, occupying 20 pts. The bottom layer, when removed with the pipette, is found to be soluble in 4.5 to 5.5 pts of water, more abundantly in lukewarm than in cold water. But if water be added to the mixture as it stands, divided into three layers, a quantity equal to 11 times the volume of the bottom layer will be required to dissolve it (the top layer at the same time diminishing to $\frac{2}{3}$) because the water dissolves the bottom layer only so far as it can take up ether. Water saturated with ether dissolves only $\frac{1}{4}$ of the bottom layer. The bottom layer is therefore hydrated *tannic acid*, containing ether in solution; the middle layer is *water* containing ether and tannic acid; and the top layer is *ether* which has taken up water, tannic acid, and the foreign constituents (Lubolt, J. pr. Chem. lxxvii. 357). According to Mohr, on the contrary (Ann. Pharm. lxi. 352), the lowest of the three layers contains tannic acid dissolved in water; the middle layer tannic acid dissolved in ether. This statement, and another made by Mohr to the effect that tannic acid deliquesces to a syrup in anhydrous ether, and that by addition of more tannic acid, the ether may be completely converted into this syrup, are not reconcilable with the experiments above described.

The viscid syrup, which separates at the bottom of the mixture of gallotannic acid, water, and ether, unites with the supernatant ether, on addition of alcohol, to a thin filterable liquid. (Mohr.)

Gallotannic acid dissolves in *acetone*, with evolution of heat, the solution drying up to a jelly and leaving a powder which has the aspect of gallotannic acid. (Knop.)

Gallotannic acid does not unite with *urea* (Hlasiwetz, Wein. Akad. Ber. xx. 208). It does not dissolve in *picamar* (p. 162) even at the boiling heat (Reichenbach, Schw. J. lxviii. 356). It dissolves in 6 pts. *glycerin* (Cap and Garot, J. Pharm. [3] xxvi. 81); in *bitter almond* oil, in almost all proportions, the solution, which turns brown in contact with the air, slowly depositing crystals of benzoic acid (Knop). It dissolves in other oils, both *fixed* and *volatile*.

Detection and Estimation of Gallotannic Acid.—This acid is precipitated from its aqueous solution by *mineral acids*, as a gelatinous mass insoluble in excess of the acid. With *ferric salts* it forms a bluish-black precipitate; with *ferrous salts*, this precipitate forms only as the solution is gradually oxidised by exposure to the air. With *tartar-entic* it forms a white gelatinous precipitate. With solution of *gelatin*, it forms a white precipitate, not absolutely insoluble in water, unless the tannic acid is in excess, in which case the precipitate is greyish, and aggregated to an elastic mass. It is owing to this property that tannic acid combines with animal skin, forming leather. It is entirely removed from a solution by immersing in it a piece of skin; and the acid may be estimated by determining the increase in weight of the skin. With most *organic alkaloids*, gallotannic acid forms white compounds, insoluble in water, soluble in acetic acid.

Estimation of Gallotannic Acid in Gall-nuts, &c.—1. The aqueous extract is mixed with solution of gelatin, as long as a precipitate is thereby produced, the quantity of tannic acid which the same solution of gelatin (or another of known strength) is capable of precipitating having been determined by a previous experiment (Wheeler, Mem. Chem. Soc. iii. 319.—Fehling, Pharm. Centr. 1853, 872.—G. Müller, Chem. Centr. 1859, 42). Müller mixes the gelatin-solution with $\frac{1}{4}$ pt. alum to accelerate the clarification of the liquid. To obviate the necessity of filtering, or waiting for the slow deposition of the precipitate towards the end of the experiment, Wheeler dips into the solution a glass tube loosely closed at the bottom with sponge, and tries whether the gelatin solution which enters the tube still gives a cloud with solution of gelatin. —2. Stein mixes the aqueous extract with a known volume of a standard solution of neutral acetate of lead, dilutes the mixture to a given volume, and determines the quantity of lead remaining in a measured portion of the filtrate (Schweiz. polyt. Zeitschr. ii. 169.). —3. Monier (Compt. rend. xvi. 577; Dingl. exlviii. 209) mixes the aqueous extract with solution of permanganate of potassium, which rapidly decomposes tannic acid, the quantity of tannic acid which this solution is capable of decomposing having been previously determined. —4. Hammer (J. pr. Chem. lxxxi. 159) determines the specific gravity of the solution (p. 763), both before and after the removal of the tannic acid by addition of about a fourfold quantity of animal skin which has been softened in water, pressed between linen, then washed, dried, and pulverised.

On the estimation of tannic acid see also Fr. Müller (N. Br. Arch. xxxviii. 147), Löwenthal, J. pr. Chem. lxxxi. 150; Handtke (*ibid.* lxxxii. 345); H. Sackur (*Ueber den Gerbprocess, Dissertat.* Berlin, 1860).

Decompositions.—1. Gallo-tannic acid heated to 150° or 160° C. becomes darker from incipient decomposition (Strecker); at 215° it is resolved into water, carbonic anhydride, and pyrogallic acid, which volatilise, and metagallic acid, which remains. At 250° only metagallic acid is formed, without pyrogallic acid (Pelouze):

Metagallic
acid.

Pyrogallic Metagallic
acid. acid.

The two decompositions may go on simultaneously. (Strecker.)

2. Gallotannic acid, heated in a platinum spoon, decrepitates, undergoes semifusion, swells up, carbonises, takes fire, and burns with a bright flame, leaving an easily combustible cinder (Berzelius). —3. Exposed on a watch-glass to strongly *ozone*d air, it acquires a yellow or yellow-brown colour, becomes glutinous and fluid, strongly acid, from formation of oxalic acid, and if the action be continued long enough, disappears completely, being converted into water and carbonic acid (Schönbein, J. pr. Chem. lxxxi. 12). Aqueous gallotannic acid, through which *ozone*d air is passed, absorbs it quickly and completely, becomes dark brown-red, then again lighter, and forms oxalic acid and a substance which reduces cupric oxide, these products being decomposed by the further action of the ozone, so that the liquid ultimately leaves

but little residue when evaporated (Gorup-Besanez, Ann. Ch. Pharm. ex. 108). When a very dilute aqueous solution of gallotannic acid is exposed to the air, it becomes turbid, from separation of grey crystalline gallic acid; oxygen is absorbed at the same time, and an equal volume of carbonic anhydride is produced (Pelouze). Aqueous gallotannic acid, evaporated with aid of heat in open vessels, leaves a brown, translucent mass, which, when treated with water, leaves a dark-brown residue; and by repeated evaporation and re-solution, a further quantity of the same substance is obtained (Berzelius). This residue is the *oxidised tannic acid* of the older chemists. *Peroxide of hydrogen*, and oxygenated oil of turpentine, do not produce any perceptible alteration in gallotannic acid. (Schönbein.)

4. Aqueous gallotannic acid dissolves finely divided *iodine*.—5. Aqueous *iodic acid* eliminates from gallotannic acid, even in the cold, carbonic anhydride mixed with a small quantity of carbonic oxide (Millon, Compt. rend. xix. 272).—6. *Bromine* acts violently on gallotannate of potassium, and forms a brown resin (Cahours, Ann. Ch. Phys. xix. 507).—7. By a small quantity of *chlorine*, aqueous gallotannic acid is clouded, coloured brown, and altered in the same manner as by evaporation in contact with the air; a larger quantity of chlorine decomposes it completely (Berzelius). Chlorate of potassium scarcely exerts any action upon it. (Simon.)

8. Strong *sulphuric acid* dissolves gallotannic acid with lemon-yellow or brown-yellow colour, becomes purple-red, and gives off sulphurous acid when moderately heated; and at a stronger heat becomes pitch-black, and forms humic acid (Wackenroder). By boiling, or by continued digestion at a moderate heat, with *dilute sulphuric acid*, gallotannic acid is resolved into gallic acid (Liebig), and dextroglucose (Strecker, see p. 762). Small quantities of ellagic acid and humous substances are likewise formed, probably as secondary products (Strecker). Acetic acid is not produced in this reaction. (Liebig.)

9. When gallotannic acid is boiled with aqueous *hydrochloric acid* out of contact with the air, ellagic acid and sugar are almost always obtained, their quantities, however, not bearing any definite proportion to one another. (Rochleder and Kawaller.)

10. *Nitric acid* does not precipitate aqueous gallotannic acid, or with difficulty only, but colours it yellow, then red, and decomposes it quickly with formation of oxalic acid (Stenhouse).—11. When aqueous gallotannic acid is mixed with aqueous *osmic acid* of the strength of 3 per cent., an inodorous deep blue liquid is formed, transparent only in thin films, and leaving on evaporation a black-blue, amorphous, insoluble layer. On dissolving this residue in aqueous osmic acid, osmic oxide is separated, the reaction being accelerated by heat; and the red-brown filtrate obtained after heating the liquid with ammonia yields, by evaporation, brown crystalline needles and a humous substance. The needles contain oxalic acid, and an acid very much like suberic acid. (Buttlerow, J. pr. Chem. lvi. 207.)

12. Gallotannic acid, boiled with excess of weak *potash-ley*, yields gallic acid (Liebig, xii. 398). The solution separated from the gallic acid does not contain acetic acid. By prolonged boiling, the gallic acid is resolved into carbonic and pyrogallic acids. (Liebig.)

When gallotannic acid is treated with *alkalis* in a current of hydrogen, gallic acid and a gum, $C^{12}H^{22}O^{11}$, are produced (Rochleder and Kawaller, Wien. Akad. Ber. xxv. 558).—13. Gallotannic acid boiled with *hydrate of barium*, yields gallic acid and glucate of barium (Rochleder and Kawaller). Baryta or limewater in excess quickly colours gallotannic acid green, blue, red, and yellowish-brown; acids decolorise the solution. (Wackenroder.)

14. When gallotannic acid is boiled for several hours with an equal weight of *neutral sulphite of sodium or potassium* and 12 pts. of water, or when the solution is evaporated till it froths up in viscid bladders, a quantity of gallotannic acid is obtained, equal to 75—79 per cent., and 5 or 6 per cent. of a second body, which has the composition, but not the properties, of sugar. (Knop.)

15. *Chromic acid*, heated with an aqueous solution of gallotannic acid, quickly decomposes it, with evolution of carbonic anhydride (Hünefeld, J. pr. Chem. xvi. 361). Acid chromate of potassium produces a yellow-brown precipitate, which quickly turns black (Wackenroder).—16. *Peroxide of manganese* heated with aqueous gallotannic acid, with or without sulphuric acid, decomposes it, with evolution of carbonic anhydride and formation of brown extractive matter. No gallic acid is produced in this reaction (Hünefeld). By *permanganate of potassium*, aqueous gallotannic acid is rapidly oxidised, the solution, if concentrated, giving off carbonic anhydride. In this reaction, a body of undetermined constitution is produced, besides carbonic acid and water (Monier, Compt. rend. xlv. 577). One milligramme of gallotannic acid, dissolved in a litre of water, is sufficient to decolorise the acid solution of the permanganate (Monier). When permanganate of potassium is added to a strongly acid solution of gallotannic acid, the colour of the permanganate disappears quickly at first (the

liquid becoming yellow and then colourless); more slowly, if a portion of the gallotannic acid has been decomposed, so that the instant at which the last portion of the gallotannic acid disappears cannot be recognised with certainty; 100 pts. gallotannic acid take up about 60 pts. oxygen from the permanganate. (Mohr, *Titrimbuch*, 2 Aufl. Braunsch. 521.)

17. Gallotannic acid reduces *ferrie solutions*, partially at common temperatures, completely at the boiling heat, to ferrous solutions (Wackenroder; see p. 768).—
18. From *cupric salts*, it reduces cuprous oxide; from *mercuric chloride*, mercurous chloride; from solutions of *mercurous* or *mercuric oxide*, it gradually throws down metallic mercury (Wackenroder). *Carbonate of silver* is reduced by gallotannic acid, even in the cold. (Schiff. Ann. Ch. Pharm. cix. 65.)

19. Aqueous gallotannic acid, which remains unaltered when not exposed to the air, decomposes, with evolution of carbonic anhydride and formation of gallic acid—if it remains in contact with the nitrogenous constituents of the gall-nuts; therefore, in infusion of galls, and more quickly in gall-nuts moistened with water (Robiquet, Pelouze). Ellagic acid is formed at the same time (Erdmann, Mulder). The formation of mould, which commonly takes place, has no influence on the transformation (Winckler, Répert. 53, 401). The decomposition takes place even in closed vessels (Nesenbeck, Br. Arch. xxxi. 129), and more quickly in proportion as the solution of tannic acid is more dilute (Robiquet). The transformation may be regarded as a fermentation process, inasmuch as it is stopped or retarded by antiseptic substances, as alcohol, wood-vinegar, creosote, mercuric oxide, and corrosive sublimate, and gall-nuts freed from tannic acid excite vinous fermentation in solution of sugar (Laroque). The pectase of the gall-nuts is the ferment which excites the gallous fermentation, and the simultaneous conversion of the pectose into pectin. The pectase of gall-nuts is also capable of converting the pectin of fruits into pectic acid; and pectase from turnips can excite the gallous fermentation. Gallotannic acid prepared with ether, but not purified, still contains sufficient pectase to give rise to its decomposition when dissolved in water. Emulsin, yeast, vegetable or animal albumin, and legumin retard rather than promote the gallous fermentation. (Robiquet.)

Gallotannates or Tannates. Gallotannic acid is tribasic, forming *neutral* or *trimetallic salts*, having the composition $C^{27}H^{18}M^3O^{17}$; likewise *acid* and *basic salts*. All these salts, however, alter quickly in contact with the air, and are difficult to obtain pure; hence but few of them have been analysed. The acid expels carbonic acid from carbonates, and forms precipitates with the solutions of most metallic salts.

Tannate of Aluminium.—Hydrate of aluminium shaken up with aqueous gallotannic acid, quickly unites with it, forming a compound which is insoluble in water, but soluble in excess of tannic acid.

Tannate of Ammonium, $C^{27}H^{21}(NH^4)O^{17}$ (?)—Carbonate of ammonia added to aqueous tannic acid, throws down a white precipitate, which changes to a white powder in vacuo (Berzelius). An excess of carbonate of ammonia causes the white precipitate produced at first to disappear immediately, and the liquid, after standing for some time, acquires a red-brown colour, and deposits light white flocks (Buchner). Ammonia gas passed to saturation into a solution of tannic acid in absolute alcohol, throws down white flocks, or, if the solution is very strong, a white resin, which becomes friable when repeatedly treated with absolute alcohol. This substance, dried between filtering paper, and then over oil of vitriol, forms a resin having a faint brown tint, and very soluble in water. (Buchner.)

The salt dried over sulphuric acid, gives by analysis 51·3 per cent. carbon, 4·5 hydrogen, and 3·3 nitrogen, agreeing approximately with the formula above given.

Tannate of Antimony is a white, gelatinous, sparingly soluble precipitate, obtained by mixing solution of tartar-emetic with gallotannic acid. Its composition resembles that of the ferric salt. (Pelouze.)

Tannates of Barium.—*a.* Baryta-water, added to aqueous gallotannic acid, throws down a basic salt (Berzelius). The precipitate dissolves in aqueous gallotannic acid, not in excess of baryta-water; it turns green when left to stand, or washed in contact with the air, also if it has been prepared with baryta-water not in excess.

b. When carbonate of barium is added to aqueous gallotannic acid as long as effervescence takes place, the liquid then filtered, and the filtrate concentrated, only small quantities of flocks separate on cooling, but alcohol added to the brown solution throws down a white light powder, which, after washing with alcohol, turns brown in drying.

c. From warm aqueous solutions of alkaline tannates, chloride of barium throws down a white precipitate, sparingly soluble in cold water, more soluble in boiling water (Berzelius). The light flocculent precipitate assumes a very faint reddish colour when washed, and after drying at 100° C. contains 39·7 per cent. C, 28 H, 36·8 O, and 10·7 BaO (Buchner). Strecker regards the salt as a mixture of tribarytic and libarytic tannate.

Tannate of Cadmium.—Hot aqueous gallotannic acid throws down from cadmium-salts a white precipitate, which assumes a yellow-green colour when dry becomes anhydrous at 100° , and contains 21.4 per cent. CdO . Insoluble in water and in alcohol. (Schiff.)

Tannate of Calcium is obtained as a white precipitate, on mixing the concentrated solutions of tannate of ammonium and chloride of calcium; the precipitate is soluble in pure water. When a solution of gallotannic acid is mixed with excess of hydrate of lime, a nearly insoluble *basic salt* is produced, the solution retaining only traces of gallotannic acid.

Tannate of Chromium. (?)—Chromic hydrate forms with aqueous gallotannic acid, an insoluble compound, which is likewise precipitated on mixing a solution of a chromic salt with gallotannic acid (Berzelius). According to H. Rose, chromic salts are not precipitated by infusion of galls.

Tannate of Cobalt.—Cobalt-salts form a yellowish precipitate with infusion of galls.

Tannate of Copper is precipitated in bulky yellow flocks on adding gallotannic acid to a solution of cupric acetate. If, on the other hand, the copper-salt be added by drops to solution of tannin, a reddish white precipitate is formed, completely soluble in ammonia. According to Wackenroder, the ammoniacal solution is not precipitated by sulphydric acid.

Tannates of Iron.—**Ferrous Tannate** is a white gelatinous precipitate, formed on mixing the concentrated solutions of ferrous sulphate and gallotannic acid. Dilute solutions give no precipitate.

Ferric Tannate.—When a mixture of gallotannic acid and a ferrous salt is exposed to the air, the precipitate quickly acquires a bluish-black colour, being oxidised to ferric tannate. This black precipitate, which forms the colouring matter of common ink, is produced immediately on mixing a ferric salt with excess of gallotannic acid. The reaction is very delicate, indicating the presence of the smallest traces of tannic acid. If, on the other hand, the tannin solution is added drop by drop to an excess of the ferric salt, no precipitate is formed, the liquid not even becoming coloured; but the gallotannic acid is oxidised, and the ferric salt reduced to ferrous salt. The same reduction takes place when the black precipitate of ferric tannate is boiled with excess of tannic acid, carbonic acid being then evolved, and the mixture becoming colourless. The black precipitate dried in the air contains 12.02 per cent. ferric oxide, agreeing nearly with the formula $\text{C}^{27}\text{H}^{18}\text{Fe}^{\text{III}}\text{O}^{17}$, which requires 11.92 per cent. Wittstein, on the other hand, found the quantity of iron in the precipitate obtained by mixing tannic acid with ferric salts, very variable; the only way in which he obtained a constant compound was by precipitating ferrous sulphate with gallotannic acid, and exposing the precipitate to the air.

Tannates of Lead.—These salts vary in composition according to the proportions of the solutions used for precipitation; the variation extending from 3 to 10 atoms of lead for 27 atoms of carbon (Strecker). *a.* On mixing a solution of gallotannic acid with a quantity of lead-acetate not sufficient for complete precipitation, a white precipitate is obtained, which becomes slightly brown on exposure to the air. When boiled with water, it loses part of its acid, and leaves a compound containing 34.21 per cent. lead-oxide (Berzelius). This salt probably contains $\text{C}^{27}\text{H}^{18}\text{Pb}^{\text{II}}\text{O}^{17}$ (calculation 36.2 per cent. lead-oxide).

Gallotannic acid heated with lead-oxide gives off 4.4 per cent. water, which is equivalent to the substitution of 3 at. lead for 3 at. hydrogen; the salt thus produced is, therefore, also the neutral salt, $\text{C}^{27}\text{H}^{18}\text{Pb}^{\text{II}}\text{O}^{17}$.

b. Another tannate of lead is obtained on pouring a solution of gallotannic acid into a boiling solution of acetate of lead. A yellow pulverulent precipitate is then formed, which may be obtained of constant composition, by boiling it for about a quarter of an hour in the liquid, in presence of excess of the lead-acetate and free acetic acid. It is nearly insoluble, and when dried at 100°C . contains 20.2 per cent. carbon, 1.1 hydrogen, and 63.0 to 63.8 per cent. protoxide of lead, answering to the formula $\text{C}^{27}\text{H}^{18}\text{Pb}^{\text{II}}\text{O}^{14.6}\text{PbO}$, which requires 20.2 C, 1.1 H, and 63.0 PbO (Liebig, Ann. Ch. Pharm. xxvi. 128).—*c.* The precipitate formed by adding dilute aqueous tannic acid to excess of lead-acetate, if collected after a few minutes' boiling, and dried in vacuo, contains 68.2 per cent. C, 1.0 H, 17.1 O, and 63.7 PbO, answering to the formula $\text{C}^{27}\text{H}^{18}\text{Pb}^{\text{II}}\text{O}^{14.7}\text{PbO} + 3\text{H}^{\text{O}}$ (calculation, 18.6 C, 1.3 H, 15.65 O, and 64.45 PbO). When heated to 120°C ., it gives off its water (15.64 per cent.), and then contains 64.7 per cent. PbO, answering to the formula $\text{C}^{27}\text{H}^{18}\text{Pb}^{\text{II}}\text{O}^{14.7}\text{PbO}$ (Strecker).—*d.* When a lukewarm aqueous solution of gallotannic acid is precipitated with excess of acetate of lead, and the precipitate washed with boiling water, it contains 24.85 per cent. C, 1.40 H, and 52.80 PbO, agreeing nearly with

the formula $C^{32}H^{12}Pb^{3}O^{34}.3PbO + 3H^2O$ (calculation 25.11 C, 1.71 H, 21.09 O, and 62.09 PbO). At $120^{\circ}C$. it gives off its 3 atoms of water, amounting to 2.2 per cent. (Strecker.)

Tannate of Magnesium is obtained as a sparingly soluble basic salt, by digesting the aqueous acid with hydrate or carbonate of magnesium; if the magnesia is used in excess, the liquid retains only traces of tannic acid.

Tannates of Mercury.—The mercuric salt is a brick-red precipitate, insoluble in excess of mercuric nitrate, but soluble in hydrochloric acid, the solution gradually becoming turbid, from formation of mercurous chloride. The mercurous salt is obtained, on mixing the solutions of mercurous nitrate and gallotannate of potassium, as a yellow precipitate, which dissolves in excess of mercurous nitrate, the solution gradually depositing metallic mercury.

Tannate of Nickel.—Greenish white precipitate.

Tannate of Platinum. (?)—Tincture of galls added to solution of platonic chloride throws down pale yellow flocks.

Tannates of Potassium.—On adding alcoholic potash to a moderately concentrated alcoholic solution of gallotannic acid, till red veins become visible on the surface of the liquid, white-crystalline flakes are produced, which when washed with alcohol, pressed and dried, are converted into an earthy salt, very soluble in water, and containing 45.0 per cent. C, 3.0 to 3.1 H, and 13.2 to 13.3 K^2O , agreeing approximately with the formula $C^{27}H^{20}K^2O^{17}$ (calculation, 46.9 C, 2.8 H, and 13.5 K^2O).

Another potassium-salt, white, pulverulent, and less soluble, is obtained by dropping a moderately concentrated aqueous solution of gallotannic acid into a solution of carbonate of potassium.

Tannate of Silver.—Aqueous gallotannic acid forms a brown precipitate with oxide or with nitrate of silver.

Tannate of Sodium, which appears to contain $C^{27}H^{20}Na^2O^{17}$ (at $100^{\circ}C$.), is obtained in the same manner as the corresponding potassium-salt. After drying over the water-bath, it forms a light, earthy mass, which, when suspended in water, becomes glutinous like gum-water, and dissolves easily in a larger quantity of water. It contains on the average 46.6 per cent. carbon, 3.3 hydrogen, and 10.6 anhydrous soda, the above formula requiring 48.9 C, 3.0 H, and 9.3 Na^2O .

Tannate of Tantalum. (?)—Infusion of galls colours tantalic acid yellow, and precipitates tantalic anhydride of the same colour, from its acid and alkaline solutions. The light yellow precipitate is soluble in alkalis. (Rose.)

Tannates of Tin. (?)—Both stannic and stannous hydrate digested with infusion of galls decolorise it, and appear to abstract all the tannic acid. Infusion of galls precipitates stannic chloride, also stannous salts.

Tannate of Titanium. (?)—From hydrochlorate of titanate oxide neutralised as nearly as possible with ammonia, aqueous tannic acid throws down yellow-red flocks (Pfaff). From acid solutions of titanate acid, infusion of galls throws down a thick chocolate-coloured precipitate. Tannic acid colours alkaline molybdates deep blood-red, and on addition of hydrochloric acid, a blood-red precipitate is formed which dissolves in a large quantity of water. (Rose.)

Tannate of Tungsten. (?)—Infusion of galls produces no alteration in the solution of an alkaline tungstate, but acids, added to the mixture throw down a thick chocolate-coloured precipitate. (Rose.)

Tannate of Uranium.—Tincture of galls forms with uranic salts a red-brown precipitate. (Rose.)

Tannate of Vanadium. (?)—With salts of vanadic oxide, aqueous gallo-tannic acid forms a bluish inky mixture, which, when left to stand quietly, deposits a black precipitate. With alkaline vanadates, infusion of galls first gives a green, then an inky-black colouring; the mixture diluted with a large quantity of water forms a clear dark blue liquid, which gradually turns green in contact with the air. The concentrated mixture may be used as an ink, but changes in contact with the air, the black-blue colour passing into green. The writing is durable and withstands the action of hydrochloric acid, of chlorine, or of alkalis, but is destroyed by successive treatment with chlorine and alkalis (Berzelius), or by nitric acid (Kraut).

Tannate of Zinc is a white precipitate obtained by adding an alkaline tannate to sulphate of zinc.

GALLS. See GALLNUTS (p. 762).

GALLSTONES. The general composition of these concretions in man and in the ox, as determined by Dr. Thudichum, has been already stated in the article BILIARY CALCULI (i. 588). The same analyst has recently made a more minute examination of a specimen of ox-gallstones, in which he has found the following constituents:

Glycocholate of sodium.

Cholonate of sodium.

Salt of resinous acid related to the preceding.

Cholic acid, partly combined with lime.

Choloidic acid.

Cholochrome, free and combined.

Traces of cholesterin and fatty acids.

A new organic compound soluble in ether.

A sulphide emitting sulphuretted hydrogen with acids.

Lime and magnesia as carbonate, phos-

phate, and in combination with cholochrome and cholic acid.

Chloride of sodium.

Chloride of ammonium.

A compound ammonia-base.

A matter having a very repulsive odour, and another having the flavour of musk.

Iron in the form of oxide and phosphate.

Alumina.

Manganese.

Copper, a trace.

Zinc, in considerable quantity.

The bulk of the calculi was made up of cholochrome; next in amount were the biliary acids and their salts; then came lime and zinc and the new organic compound; the other ingredients were present in small quantity only.

The presence of zinc is certainly remarkable; its presence was probably due to some accidental cause, as from the animal having licked wood coated with zinc-paint.

For the method of analysis, see the original memoir (Chem. Soc. J. xiv. 34).

GALLULMIC ACID. See **GALLIC ACID** (p. 760).

GALVANISM. See **ELECTRICITY** (p. 412).

GALVANOMETER. An instrument for measuring the force of a galvanic current. It is often applied, however, to instruments which merely indicate the presence of a current (p. 460).

GALVANOPLASTY. Syn. with **ELECTRO-METALLURGY** (see *Ure's Dictionary of Arts, &c.*, ii. 88).

GALVANOSCOPE. The proper name for instruments which indicate the existence of galvanic currents without measuring them exactly (p. 443).

GAMBIR. See **CATECHU** (i. 816).

GAMBOGE or **CAMBOGE.**—*Gomme-gutte, Gummigutt.*—This gum-resin appears to be produced from the *Stalagmites cambogioides*, a tree belonging to the tribe of the *Guttiferae*, and growing in the peninsula of Cambogia, in Siam. From the bruised leaves and yellow branches of this tree, there flows a yellow juice, which is received in cocoa-nut shells or earthen vessels, then allowed to thicken, and afterwards formed into rolls. This is the finest sort, called the *pipe gamboge of Siam*. A portion is also formed into round cakes, either entire, or having a hole in the middle. Gamboge is also produced in Ceylon; and an inferior sort is said to be obtained from the *Gambogia gutta*, a tree growing wild on the Malabar coast.

Gamboge occurs in pieces of various sizes, of a dirty yellowish colour externally, and covered with a yellow powder. When broken, it exhibits a vitreous or conchoidal fracture, with brown or saffron-yellow colour. Its powder is of a brilliant yellow, and forms an emulsion with water. It is nearly inodorous at ordinary temperatures, but gives out a very peculiar odour when heated. When simply taken into the mouth, it has scarcely any perceptible taste, but if chewed for some time, it causes a sharp somewhat acrid feeling, ending in a sweet sensation, accompanied by dryness in the mouth. It afterwards excites a flow of saliva, which is coloured yellow. It is a drastic purgative.

Gamboge dissolves in alcohol, in resins, and in ammonia. The ammoniacal solution forms a red precipitate with salts of *barium*, yellow with *zinc* salts, reddish-yellow with acetate of *lead*, and brownish yellow with nitrate of *silver*.

The following analyses of gamboge are by Dr. Christison:

	Pipe-gamboge from Siam.		Cake-gamboge from Siam.		Ceylon gamboge.			
Resin . . .	74.2	71.6	64.3	65.0	68.8	71.5	72.9	75.5
Gum . . .	21.8	24.0	20.7	19.7	20.7	18.8	19.4	18.4
Amylaceous matter	6.2	5.0				
Woody fibre	4.4	6.2	6.8	5.7	4.3	0.6
Moisture . . .	4.8	4.8	4.0	4.6	4.6	4.8
	100.8	100.4	99.6	100.6	100.0	96.0	96.6	99.3

Cake gamboge is not entirely a natural product, but a manufactured article. The resin contained in gamboge is easily separated by means of ether; it is hyacinth-red, and yields a powder of a very fine yellow colour. It possesses marked acid properties, decomposing alkaline carbonates at the boiling heat, and forming with

the alkalis red salts, which may be separated from their solutions by common salt, like soaps.

According to Buchner's analysis, the resin contains 72.04 per cent. carbon, 7.23 hydrogen, and 20.73 oxygen (mean), and its silver-salt, 18.7 per cent. oxide of silver, whence Buchner deduces for the resin the formula $C^{60}H^{23}O^{12}$; and for the silver-salt the formula $C^{60}H^{23}O^{12}.AgO$. Johnston assigns to the resin the formula $C^{60}H^{23}O^{12}$.

Chlorine turns the resin white, and decomposes it. Nitric acid decomposes it at the boiling heat, forming oxalic and picric acids.

Gamboge is sometimes used in medicine as a purgative, but its administration requires great caution. Its principal use is as a pigment in water-colour painting.

Yellow juices, which, when inspissated, form a substance resembling gamboge, are obtained from several trees of the guttiferous and hypericaceous tribes. Some of them give good colours, but less permanent than that of real gamboge. An artificial gamboge is sometimes manufactured with turmeric and other materials. This should be rejected. (Gerh. iv. 474.—*Penny Cyclopædia*, vi. 176.)

GAMSIGRADITE. (Breithaupt, Jahresber. 1861, p. 986).—A black amphibole from the timazite (*q.v.*) of Gamsigrad in Servia, where it occurs in crystals exhibiting the usual combinations of hornblende. Hardness = 5–6 (on the ordinary scale, 7 on that of Breithaupt); specific gravity = 3.119. It is velvet-black, with a glassy lustre, opaque, and yields a greenish-grey streak. According to R. Müller, it melts very easily and quietly before the blow-pipe, to a greenish black, strongly magnetic glass. It is but slightly attacked by hydrochloric acid. It contains:

SiO ^a	Al ^b O ³	FeO	MnO	MgO	CaO	Na ^c O	K ^d O
46.58	13.68	12.29	6.00	8.44	8.83	3.17	1.00 = 99.94

GANGUE. The stones which fill the cavities forming the veins of metals, are called the gangue or matrix of the ore.

GANOMATITE. Syn. with CHENOCOPROLITE (i. 867).

GARANCEUX. A product obtained by treating the waste madder of the dye-houses, which still contains a certain quantity of alizarin and other colouring matters, with sulphuric acid, to remove lime, magnesia, &c. It is adapted for dyeing red and black, but does not afford a good purple. (See Madder.)

GARANCIN. The product obtained by treating pulverised madder, previously exhausted with water, with concentrated sulphuric acid at 100° C., and again washing with water. The residue thus obtained, is found to yield better results in dyeing than madder itself, the colours produced by it being more brilliant, and requiring less after-treatment, while the white portions of the fabric remain unsullied. (See Madder.)

GARBENSTILBITE. Syn. with STILBITE.

GARCINIA MANGOSTANA (Resin of). The crude resin contains 87.9 per cent. pure resin soluble in alcohol, 8.3 per cent. gum soluble in water, and 3.8 per cent. insoluble matter, consisting of woody fibre and earthy substances. The residue obtained by evaporating the alcoholic solution is a transparent amorphous mass, having a lemon-yellow colour when pulverised, easily soluble in alcohol and in ether, only partially soluble in alkalis. It melts at 110° C., and consists of $C^{36}H^{22}O^{10}$. The ammoniacal solution of the purified resin, forms with neutral acetate of lead, an egg-yellow, gummy precipitate, which when dried at 110°, is said to contain $5PhO.C^{36}H^{22}O^{10}$. The residue obtained by evaporating the ammoniacal solution is greenish, melts at 80° C., and consists of $C^{36}H^{22}O^{10}$. The portion insoluble in ammonia is pale yellow, melts at 115°, and consists of $C^{36}H^{22}O^{10}$. (N. Reitler, Chem. Centr. 1858, pp. 510 and 575; Jahresber. 1858, p. 449.)

The rind of the fruit of this tree is used in the East Indian Islands as a remedy against fever; it contains a substance called mangostin (*q.v.*)

GARDENIA GRANDIFLORA. A Chinese plant, the pods of which yield crocin (p. 108.)

GARNET. *Grenat.* *Granat.*—This name comprehends a variety of minerals, all crystallising in the monometric or regular system, and represented by the general formula $3MO.M^2O^2.2SiO^2$ (Berzelius), $3MO.M^2O^2.3SiO^2$ (Gmelin), or $M^mM^nSiO^4$ (Odling); wherein M = Ca, Mg, Fe, or Mn, and $m = fe, al, \text{ or } mn$.^{*} Thus a variety of substances are met with differing in composition, but identical as to their constitution, known generally as garnets, but having each a distinctive name. According to Trolle Wachtmeister, all garnets may be considered as mixtures of the following kinds of garnet in varying proportions. The names inclosed in brackets after each formula designate the varieties of garnet in which that particular compound predominates:

1. $CaalSiO^4$ (*Cinnamon-stone, Grossularia* and *white garnet*).
2. $MgaSiO^4$ (*Black garnet* from Arendal).

^{*} $al = \frac{1}{2} Al : fe = \frac{1}{2} Fe : mn = \frac{1}{2} Mn$.

3. MnAlSiO_4 (Garnet from North America and from Broddbo).
4. FeAlSiO_4 (Oriental *Almandine* and other red precious garnets).
5. CaFeSiO_4 (Common yellow, brown and black garnet; also *Melanite*).
6. MgFeSiO_4
7. MnFeSiO_4
8. FeFeSiO_4 } (These compounds do not predominate in any known species of garnet).

Pyrope, which consists principally of the compounds 1, 2, and 5, is characterised by containing chromium, which probably replaces part of the aluminium.

Garnet crystallises in rhombic dodecahedrons ∞O (fig. 178) or trapezohedrons 202 (fig. 180), more frequently, however, in the combinations $\infty O . \infty O \infty$ (fig. 201), and $\infty O . 202$ (fig. 206). Cleavage imperfect parallel to ∞O . (Kopp.)

The formula CaAlSiO_4 , where Ca is partly replaced by Mg, Mn, and Fe, and *al* by *fc*, likewise belongs to vesuvian, which, however, crystallises in forms of the dimetric system; hence the chemical compound represented by this formula is dimorphous. When grossularia from Wilui is melted, it becomes undistinguishable, both physically and chemically, from fused vesuvian from the same locality.

Garnets are generally transparent or translucent, rarely quite opaque; their colours vary from red or red-brown to yellow, white, green, and black, according to the metallic oxides which they contain. They have a vitreous or resinous lustre. Specific gravity = 3.15 to 4.3. Hardness = 6.5 to 7.5, or rather greater than that of quartz.

Garnet melts readily before the blow-pipe to a transparent glass; behaves with fluxes like vesuvian. The fused glass has a lower specific gravity than garnet. Garnet from Greenland has a specific gravity of 3.9; after fusion, only 3.05. Garnet is generally not attacked by hydrochloric acid, unless it contains a large proportion of lime, and then only partially; but, after fusion, it may be entirely decomposed by hydrochloric acid, with separation of gelatinous silica; a red heat is sufficient for this purpose when the garnet is rich in lime. (Kobell.)

The following are analyses of garnets:—1. C. Gmelin (Berz. Jahresb. v. 224).—2. Klaproth (*Beiträge*, v. 188).—3. Tr. Wachtmeister (Kongl. Vetensk. Vörh. 1823).—4. Croft (*G. Rose, Reise nach dem Ural*, p. 132).—5. Wachtmeister (*loc. cit.*).—6. Hisinger (Schw. J. xxi. 258).—7. Kobell (*ibid.* lxiv. 283).—8. Seybert (Sill. Am. J. vi. 155).—9. Hisinger (Berz. Jahresb. ii. 101).—10. Kersten (Karst. Arch. f. Min. iv. 388).—11. Wachtmeister, (*loc. cit.*).—12. Vauquelin (J. Phys. l. 94).—13. Damour (Institut. 1856, p. 1198).—14. Wachtmeister (Pogg. Ann. ii. 1).

Lime-garnet.

Garnets are almost always found crystallised, and disseminated amongst various rocks, especially mica-schist, gneiss, pegmatite, clay-schist, serpentine rocks, and cal-

careous rocks in the neighbourhood of crystalline deposits. They are also found in trachytic, basaltic, and volcanic earths of recent formation; and are then generally of that class known as *Melanite*, which contains ferric oxide. Garnet has also been found in small granular masses, and sometimes in small strata in mica-schist. (Beudant.)

Altered Forms.—Garnets containing ferrous oxide, often become rusty and disintegrated from oxidation of the iron, and are sometimes altered to red iron ore. The lime in lime-garnets may be taken up by the carbonic acid in waters, and if magnesia is combined with the carbonic acid (as acid carbonate), it may take the place of the lime, and thus give rise to a steatitic pseudomorph, or to a chlorite, if the iron partly remains. Quartz also occurs with the form of garnet. (Dana, ii. 194.) C. E. L.

GAS. The term gas, now commonly applied to aeriform substances, was introduced about the middle of the seventeenth century by Van Helmont; but its general use, even in scientific language, is of much more recent date. Strictly speaking, a gas is a substance possessing the condition of perfect fluid elasticity, and presenting, under a constant pressure, a uniform rate of expansion for equal increments of temperature, whereas vapour, which may be regarded as corresponding to gas near a state of maximum density, does not, under constant pressure, present a rate of expansion that is uniform for equal increments of temperature.

Since the liquefaction of several gases that were considered to be permanent, has been effected, the distinction between gas and vapour, originally established by Van Helmont, and since generally adopted, viz. that vapours could be reduced to a liquid or solid condition by increase of pressure and reduction of temperature, while gas could not be so altered, is no longer tenable, or, at most, it applies only to the ordinarily prevailing conditions of atmospheric pressure and temperature. Under great pressure, gases appear to approximate to the condition of vapour, and vapours, at high temperatures, assume the characters of gas.

Prior to the middle of the seventeenth century, the substantial nature of aeriform substances was almost unknown. It was considered that air, like fire, was an element of extreme subtilty, with a natural tendency to rise from the earth. Still it was held that air contributed to the formation of some substances, and even that it was a constituent part of them, but there was no decided opinion as to the material nature and ponderability of air.

A still greater vagueness prevailed with regard to the appreciation of the chemical characteristics and functions of air. It was known to be in some way necessary for the support of fire and of animal life; but its influence in regard to these phenomena seems to have been regarded more as analogous to the influence of light in vegetation than of that nature which it is now known to be.

As regards the existence of aeriform substances distinct from atmospheric air, it is very doubtful whether anything was known either by the ancients or by the alchemists. The suffocating or inflammable nature of the air evolved from the earth in various localities was early observed, and, under the terms *spiritus* or *flatus*, aeriform substances produced artificially appear to be referred to by some of the writers from the fourteenth to the seventeenth century. It seems, however, to have been generally considered that aeriform substances, differing in their characters from atmospheric air, were not essentially distinct, but that they differed from it only in consequence of admixtures. Thus, Basil Valentin, describing the inflammable air and suffocating air of mines, says, 'It must be remembered that choke-damp is so called because it is not pure air like that above ground, but always carries with it something that is thicker and more detrimental to man than the air above ground.'

The aeriform substances generated during chemical operations were, as a rule, but little regarded at this period. Paracelsus (1493–1541) mentions the evolution of gas in the solution of iron by sulphuric acid, as an eruption of air, but without attaching any significance to it. The knowledge of Libavius (1527–1616) respecting aeriform substances, appears to have been limited to the inflammable and suffocating gases of mines.

Van Helmont (1577–1644) was the first to undertake the study of aeriform substances whose characters were different from those of atmospheric air, and to show that they could be produced artificially. He distinguished between gases and vapours, as being respectively permanent and condensable—"Gas est spiritus non coagulabilis." He showed that the conditions under which gases are generated are chiefly combustion, fermentation, putrefaction, and the reaction of acids with metals, calcareous substances, &c. But, at the same time, he was far from having any true conception of the relations between air, gas, and vapours, nor did he arrive at any knowledge of the distinctions between different kinds of gases.

Under the name of *gas sylvestre*, and more rarely *gas carbonum*, he described carbonic acid as being a product of the combustion of fuel, of fermentation, &c., and as existing

in mineral waters, in caverns, and in the stomachs of animals. He showed that it could be obtained from limestone by means of acids, that it would not support life, and that it extinguished flame. But he confounded under this term several other gases quite distinct from carbonic acid, such as nitric oxide, sulphurous acid, &c. The only distinction he appears to have drawn between gases was between what he termed *gas sylvestre* and the inflammable gases produced by the destructive distillation of organic substances and in putrefactive decomposition. Van Helmont also observed that when a light was burnt under a bell-jar over water, the air which remains after a time extinguishes the flame; but he gives no further account of this air, nor did he make any advance towards a knowledge of the part played by the atmosphere in combustion and animal respiration.

In the early part of the seventeenth century, even previously to the demonstration of the ponderability of air by Torricelli, in 1643, the influence and functions of atmospheric air began to attract the attention of chemists. One of the earliest and most remarkable inquiries into this subject was instituted by Jean Rey, a French physician, in consequence of a communication from an apothecary named Brun, that he had observed, in the calcination of tin and lead, an augmentation of weight in the calx obtained, which he was unable to account for. In 1630, Rey published a treatise on this subject, entitled "*Essays sur la recherche de la cause, pour laquelle l'étain et le plomb augmentent de poids, quand on les calcine,*" which, though chiefly of a speculative character, distinctly puts forward the opinion that the augmentation of weight observed in the calcination of metals was due to the absorption of air. At the same time, however, Rey, adopting the prevailing opinion of his period, that metals were compound substances, considered that the absorbed air combined with the calx pre-existing in the metal, and made it heavier than the metal from which it was obtained, in the same way that sand is made heavier by water adhering to it. He also pointed out that the augmentation of weight in the calcination of metals was limited and definite. "*L'air espaisi s'attache à la chaux, et va adhérent peu à peu aux plus minces de ses parties; ainsi son poids augmente du commencement jusqu'à la fin. Mais quand tout est affublé, elle n'en saurait prendre davantage.*" This essay of Rey's was the first attempt to elucidate a phenomenon which, nearly a century and a half later, served as the key to a knowledge of gaseous substances, and furnished the basis of the present system of chemical science. It attracted, however, but little attention, and did not lead to any experimental investigation of the subject. Meanwhile the facts of the augmentation of weight in the calcination of metals, of the necessity of air for respiration and combustion, of its alteration by those processes, and, at a later period, the fact of the absorption of air in the calcination of metals, though perfectly well known and established, floated through the chemistry of the intervening period, unexplained and unappreciated, much as the facts of isomerism, allotropy, and catalysis remain, amidst the chemistry of the present day, without explanation or apparent connection with other facts.

But though the tendency of chemical investigation prior to the latter part of the eighteenth century, did not lead to the experimental study of these important phenomena in any degree commensurate with their actual value, their consideration in a more speculative manner was not neglected, nor was it without useful results. The direct study of aeriform substances was also prosecuted with some success. The inflammability of the air produced by the reaction of iron with dilute sulphuric acid, was made known by Turquet de Mayerne, in 1650, which may be regarded as the date of the recognition of hydrogen as a distinct substance.

In 1665 Hooke propounded in his "*Micrographia*" a theory of combustion, which was designed to afford an explanation of the necessity for the presence of air for its support. He considered that atmospheric air contained a substance analogous to, if not identical with that fixed in nitre, and possessing the property of dissolving all combustible substances, provided their temperature was raised sufficiently high. This solution he supposed to take place with such violence, that fire was produced, which in his opinion was simply a phenomenon of motion. The product of this solution might be aeriform, liquid, or solid. Combustion in a limited quantity of air was considered by him to cease, in consequence of the solvent becoming saturated with the combustible substance, and could be revived only by a fresh supply of air. The constituent of air which he regarded as thus taking part in combustion, existed in a highly fixed condition in nitre, so that a given bulk of nitre contained incomparably more of it than an equal bulk of air. Hooke's views were, however, put forward in such general terms as to be destitute of any scientific value, and are of interest rather as showing the absence, at that period, of true principles of chemical investigation, which might have led to discoveries of the highest importance, had they been applied under the influence of opinions which, in their general tendency, were so much allied to the more advanced knowledge of the present.

Hooke's views were subsequently developed by Mayow in his "*Tractatus de aëre nitro et spiritu nitro-aëreo*," published in 1669. His *spiritus nitro-aëreus*, existing both in air and in nitre, was the solvent which Hooke had assumed to be active in combustion. A similar theory was also propounded in reference to respiration an animal heat by Willis, in his "*Exercitatio de Sanguinis incalescentia sive accensione*," published in 1671, with the difference that he regarded combustion as consisting, not only in the reaction of the combustible with a constituent of atmospheric air but also in the simultaneous elimination of a combustible principle from the former.

Far more in accordance with the spirit of experimental investigation were the labours of Boyle, with regard to aeriform substances, and the related phenomena of combustion, respiration, &c. In his "Continuation of new experiments physico-mechanical touching the spring and weight of air and their effects, wherein are contained divers experiments, made both in compressed and also in factitious air," &c., published in 1680 he showed that air could be produced artificially, and he was the first to collect the air thus produced, without mixture with atmospheric air. His examination of factitious air was, however, more physical than chemical. In his "Tract containing suspicions about some hidden qualities of the air" (1674), and in his "General history of the air" (1692), he frequently refers to the alteration of air in combustion, but his conclusions are more guarded than those of his predecessors. He was satisfied that, by respiration and by combustion, something was abstracted from the air, but he defines this only as "some vital substance diffused through the air, whether it be a volatile nitre, or (rather) some yet anonymous substance, sidereal or subterranean;" and referring to the views of Hooke and Mayow, he says, "though I agree with them in thinking that the air is in many places impregnated with corpuscles of a nitrous nature, yet, I confess, that I have not been hitherto convinced of all that is wont to be delivered about the plenty and quality of the nitre in the air; for I have not found that those that build so much upon this volatile nitre have made out, by any competent experiment, that there is such a volatile nitre abounding in the air."

In reference to combustion, and the calcination of metals, Boyle opposed the prevailing opinion that calcination was due to the separation of moisture or some other constituent of the metal calcined. The increased weight of the calx he ascribed to the combination of ponderable heat-substance, and this preconceived opinion led him to disregard many of his most important observations. In the course of his experiments, he clearly showed that in calcination, air is absorbed; but he made no attempt to connect this fact with the augmentation of weight. He heated tin and lead in sealed retorts containing air, and found that, after maintaining the heat for a considerable time, on opening the retort, air rushed in to supply the place of what had been absorbed by the metal. But he regarded this merely as a proof that the retorts had been hermetically closed. Nor did Boyle arrive at any knowledge of the mode in which air took part in, and was essential to combustion, though he showed, in his "New experiments touching the relation betwixt flame and air" (1672), that in a vacuum combustion could not take place, and that lead was converted into a calx only when in contact with air.

Simultaneously with Boyle, a similar explanation of the increase of weight in the calcination of metals was given by N. Lemery. In his "*Cours de chymie*" (1675), he says, "although by the action of fire, some sulphurous or volatile portions of lead are separated which ought to diminish the weight, nevertheless, after a long calcination, it is found that, in place of weighing less, as it should do, it weighs more;" and he ascribes this fact to the penetration of the fire-corpuscles into the pores of the lead.

In this respect, the views of Becher, Boyle, and N. Lemery, as to the increase of weight in calcination of metals, were identical; they were also accepted by the majority of chemists at the time, and were retained up to the commencement of the eighteenth century.

One of the earliest objectors to the opinion that glass vessels were permeable by the fire-corpuscles, as assumed by Boyle, was Cherubin D'Orleans, Capucin of the province of Touraine, who in 1679 published a dissertation "*Sur l'impenetrabilité du verre, . . . sur la cause de l'augmentation du poids de l'Etain et du Plomb par la calcination*." Referring to Boyle's experiment with lead in a sealed retort, he says, "these chemical observations do not at all convince me; they rather prove the impermeability of the glass than its permeability. . . . For to show the alleged permeability of glass by that experiment, he should, before opening the retort, have weighed it together with its contents; then having exactly ascertained the weight, he should have weighed it again with its contents, after having opened it, in order to ascertain whether the external air, which he says rushed in with noise when the retort was opened, did not cause an alteration of the weight that had been observed before opening the retort; . . . without doubt he would then have found that the retort weighed more

after it was opened than it did before." This criticism of Boyle's experiment and conclusion noway affects the main object he had in view, viz. to establish the absorption of air in the calcination of metals; but it is highly interesting as illustrative of the growing sense of the importance of quantitative observations in chemical investigation, and more especially since the deficiency pointed out in Boyle's experiment was precisely that which, when subsequently supplied by Lavoisier, contributed so largely to the establishment of correct views of the calcination of metals.

About the commencement of the 18th century, the belief in the ponderable nature of heat became considerably shaken, and with its abandonment, the previous explanation of the increased weight of metallic calces fell to the ground. Those chemists who noticed it at all, put forward various hypotheses to account for it; some regarded it as accidental, and Stahl disregarded it altogether, as quite unimportant.

The next step of any importance in the chemical history of aeriform substances, was made by Hales, who published in 1727 his "Vegetable Staticks; . . . also a specimen of an attempt to analyse the air, by a great variety of chemico-statical experiments." His investigation of this subject was distinguished from those of his predecessors, chiefly by his adopting a quantitative method, and by his employing improved apparatus for preparing and collecting gases. Hales was the first to use an apparatus which was the germ of the pneumatic trough now employed. A globular vessel, filled with water, and inverted with its mouth under the surface of water in a large pan, served for the collection of the gas, which was generated in a retort, with a long neck extending up into the globular vessel serving as a receiver. The various aeriform substances he obtained, were examined only as to their inflammability, or their power of supporting combustion. He first observed the diminution of volume of atmospheric air, when mixed with nitric oxide, which afterwards, in the hands of Cavendish and Priestley afforded, such important results; but generally, Hales' experiments contributed little to the existing knowledge of aeriform substances, and he appears to have regarded the different substances of this kind which he obtained, as mere modifications of atmospheric air. His own conclusion from these "experiments, which show in how great proportion air is wrought into the composition of animal, vegetable, and mineral substances, and withal, how readily it resumes its elastic state, when, in the dissolution of those substances, it is disengaged from them," was in the following words: "Since, then, air is found so manifestly to abound in almost all natural bodies; since we find it so operative and active a principle in every chemical operation; since its constituent parts are of so durable a nature, that the most violent action of fire or fermentation cannot induce such an alteration of its texture, as thereby to disqualify it from resuming, either by means of fire or fermentation, its former elastic state; unless in the case of vitrification, when, with the vegetable salt and nitre in which it is incorporated, it may perhaps, some of it, with other chemical principles, be immutably fixed; since, then, this is the case, may we not with good reason adopt this now fixed, now volatile Proteus, among the chemical principles, and that a very active one, as well as acid sulphur, notwithstanding it has hitherto been overlooked and rejected by chemists as no way entitled to that denomination?"

Hales' main result, therefore, like many more of the results of scientific labours at that period, consisted more in the proposition of a problem than in its solution, either wholly or in part; and in this light, the general conclusion at which he arrived had the merit of being the first comprehensive indication of an important and fertile path of research, which before his time had been little pursued, but soon afterwards became the means of entirely remodelling chemical science.

Of the writers, contemporaneous with and immediately following Hales, little need be said, as their treatment of the subjects of aeriform substances, combustion, &c., was mostly argumentative and prolix rather than experimental, without adding anything to the existing state of knowledge. Thus, for instance, a lengthy section of Boerhaave's "Elementa Chemiæ," 1732, was devoted to criticisms of opinions and speculations as to the nature of air as an element. But by this time the speculative vein of chemical study had pretty well run out; the establishment of the phlogistic theory served to give a more systematic and comprehensive character to the science, and admitted of its being cultivated in a manner more calculated to secure progress than the desultory inquiries hitherto undertaken, under the influence either of alchemistic or of metaphysical doctrines.

Chief among the achievements of this epoch was the investigation of the difference between caustic and mild alkalis by Black, and the consequent demonstration of the existence of carbonic acid gas, or as he termed it, fixed air, this being the first instance of a gas being proved to be essentially distinct from atmospheric air.

This investigation is, perhaps, the most remarkable in the whole history of chemistry, whether it be considered in regard to its special character, or to its subsequent influence on the development of the science. Undertaken, in the first instance, merely to furnish

subject-matter for a medical thesis, it nevertheless stands out far above any other chemical research of that or any previous period; pre-eminent in its completeness and accuracy, it served as the inauguration of pneumatic chemistry, as the first decided step in that path of research which had been suggested by Hales, and as the corner-stone of modern chemistry.

Having, in the first instance, ascertained that caustic lime, exposed for some time to the atmosphere, became heavier, at the same time that it lost its causticity, instead of becoming lighter, as might have been expected if that change were really due to the escape of a ponderable heat-substance, Black perceived in this fact sufficient ground for rejecting the received doctrine of ponderable caloric. He next ascertained that the loss of causticity and the increase of weight were accompanied by a considerable absorption of air. On extending his observations to magnesia, he found that it effervesced with acids, that it lost weight by ignition, and then no longer effervesced with acids, though it still yielded the same salts with acids, as the magnesia that had not been ignited. He then sought to ascertain what was separated from magnesia by ignition, causing the loss of weight; and, with that view, heated a weighed quantity in a retort. Some water was thus obtained, but not sufficient to account for the whole loss of weight by the magnesia. This led him to suspect that air was disengaged from the magnesia by ignition; and to determine this point, he dissolved a known quantity of ignited magnesia in sulphuric acid, then precipitated it by means of a mild alkali (carbonate of potash), and found that it had increased in weight as much as the magnesia had lost in weight by ignition, and that it had recovered all the qualities which the magnesia lost by ignition. Hence he concluded that the loss of weight and alteration of qualities presented by magnesia on ignition, were due to the separation of air, and that the restitution of those qualities, and the increase of weight, when ignited magnesia was dissolved by acid and precipitated by a mild alkali, were due to its recovering from the alkali the air that had been expelled by ignition: in this latter conclusion he was guided by Hales's observation, that fixed alkali contained abundance of air. His own statement of these conclusions is very simple and clear. "*Quid ergo magnesia hoc experimento amisit, quid demum recuperavit, quod, quum adesset, tam multas qualitates dabat, eum abesset, tollebat? Aërem forte: experimenti enim vigesimi consideratione, verisimile admodum videtur, ponderis, ustione amissi, partem maximam aëre evanido constare: et hoc quidem corroboratur, quod aërem nullam, post ustionem, in acido injecta emittat. Nonne etiam verisimile, aërem iterum magnesiæ ab alkali restitui, quo tempore illam hoc de acido depellebat: alkali fixum aëre certe abundare, ex ingeniosi Hales experimentis constat, ejus quidem magnam vim eructat, ubi acido puro conjungitur; hac occasione, quamvis non puro, acido tamen certe conjungitur, et sal etiam medius ex horum conjunctione fit, copîâ, dotibus, omni denique modo idem, ac si acidum purum additum fuisset; sed neque tamen vel minimum aëris erumpit; nonne igitur ex alkali ab acido excutitur, et magnesiæ sese unit aër?*"—*Dissert. med. inaug. de Humore acido a cibis orto, et magnesiæ alba*, 1754, p. 37.

Black then examined the air evolved from magnesia and alkalis by means of acids, and found that it was identical with that given off in fermentation. He gave it the name of fixed air, and explained the difference between caustic and mild alkalis and alkaline earths as being due to the presence or absence of this substance. He showed that fixed air was essentially distinct from atmospheric air, in regard to its chemical character, and in regard to respiration and combustion; that it was produced by the combustion of fuel and by respiration, its chief characteristic being the power of combining with caustic alkalis, and to some extent neutralising them after the manner of an acid.

In his inaugural dissertation, published in 1754, he also suggested that the explosion of fulminating gold might be due to its containing air in a fixed state, and that the increase of weight observed when metals were dissolved by an acid and then precipitated by an alkali, might also be due to air furnished by the alkali.

Shortly afterwards Macbride published his *Experimental Essays* (1764), in which he gave the results of a more minute examination of the conditions under which fixed air or carbonic acid is produced in fermentation, putrefaction, &c.

Pneumatic chemistry received a further important development at the hands of Cavendish, who published in 1766 his "*Experiments on Factitious Air*" in which he gave the results of his examination of fixed air (carbonic acid) and inflammable air (hydrogen), describing their physical and chemical characters, mode of preparation, and the apparatus by which they were to be submitted to experiment. He showed that hydrogen, mixed with various proportions of atmospheric air, exploded with different degrees of violence; that equal weights of different metals gave different quantities of hydrogen with dilute sulphuric acid; that the concentrated acid did not furnish hydrogen with metals, and that when they were heated with it, another gas (sulphurous acid) was evolved.

Fixed air (carbonic acid) was shown by Cavendish to precipitate lime and magnesia from their solution in water, and again to redissolve these precipitates; he connected

with this fact the precipitation of earthy carbonates from water when boiled, and showed that potash combined with fixed air, producing a more easily crystallisable salt. He also made some advance towards the determination of the quantitative composition of the earthy and alkaline carbonates.

In 1769, Lane showed that chalybeate water contained fixed air as the solvent of the iron; in 1771, Priestley observed that fixed air kept in contact with growing plants, acquired the capability of supporting combustion and respiration, and that this change was effected only in daylight; in 1774, Bergmann published a long memoir on carbonic acid, under the name of *Acidum ærcum*, showing its existence in the atmosphere, that in its chemical functions it possessed the characters of an acid, and, in short, developing more minutely many of the details of its history, which had been previously more or less incompletely made known. Lavoisier's description of this gas, published in his *Opuscules Physiques et Chymiques* (1774), was simply a confirmation of Black's experiments.

Shortly before this time (1772), a very important discovery with regard to the constitution of the atmosphere was made by Rutherford, who showed that, in respiration, air was not, as Hales had supposed, rendered unfit for supporting combustion or respiration, by being impregnated with admixtures, but that it naturally contained a substance (nitrogen) which was incapable of supporting combustion or respiration. He obtained nitrogen by absorbing the carbonic acid from air which animals had breathed, and showed that it extinguished flame and was suffocating. In the same year, the calcination of metals again became the subject of inquiry by Priestley and Lavoisier. The former referred, in his "Observations on different kinds of Air," to the absorption of air when lead or tin was calcined in closed vessels; but, under the influence of the phlogistic theory, he failed to connect this fact with the augmentation of weight of the calces. Lavoisier, in the same year, communicated to the Académie, as the result of his experiments, his opinion, that in the calcination of metals, as well as in the combustion of phosphorus and sulphur, the increase of weight that took place was due to the absorption of air, which was again liberated in the gaseous state when metallic calces were reduced. In 1774, he made known the experiments upon which this opinion was based. One was essentially a repetition of Boyle's experiment with lead; but Lavoisier determined the weight of the retort and its contents before opening it, and thus ascertained how much air entered the retort when it was opened. This quantity was found to be exactly as much as the increase of weight in the calcined metal. In the same work (*Opuscules*), Lavoisier also showed that the augmentation of weight taking place when mercury or iron was dissolved by acids and precipitated by lime, was probably due to the combination of the metals with a gas derived from the precipitant, and although the experiments on which he based this conclusion were mixed up with the production of metallic carbonates, as well as mere oxides, the evidence they furnished of the part played by gaseous substances in chemical changes was not less important than if they had referred only to the production of true calces or oxides in the wet way. These experiments were, both in their form and significance, an exact extension of those by which Black arrived at a knowledge of the chemical nature of alkalis and their carbonates.

In the same year, Bayen showed that oxide of mercury was decomposed by heat, without any addition of phlogistic substance, that a gas was evolved in the process, and that the reduced mercury weighed less than the oxide from which it was obtained. To Priestley, however, belongs the honour of the discovery of oxygen, and of recognising its distinct nature, in August, 1774. He had, indeed, obtained it in 1771 from nitre, as Hales had obtained it in 1727 from red lead, but in both cases its true nature does not appear to have been noticed. It is, however, more questionable to whom is to be ascribed the credit of having first arrived at the conclusion that the oxygen which Priestley obtained from oxide of mercury and from red lead, was that gaseous constituent of the atmosphere which was active in the phenomena of combustion, calcination of metals, and respiration. It is at least certain that Priestley communicated to Lavoisier his discovery of oxygen very shortly after making it; but considering how much further advanced Lavoisier was at that time, in true appreciation of the phenomena with which this gas was so closely connected, than Priestley was, there seems but narrow ground for imputing to Lavoisier unfairness towards Priestley in claiming to be, jointly with him, a discoverer of oxygen.

In November, 1774, Lavoisier, in his memoir "*Sur la calcination de l'étain dans les vaisseaux fermés*," first put forward the opinion that atmospheric air consisted of two gases, but he did not express any decided view with regard to the nature of these gases, except that one was capable of supporting combustion and respiration, while the other could not. It was not until the end of 1775, in his memoir "*Sur la nature du principe qui se combine avec les métaux pendant leur calcination*," that Lavoisier stated his conclusion that the gas obtained from oxide of mercury by heat, was the

me as the constituent of atmospheric air which supported combustion and respiration, and combined with metals in calcination. In this memoir, he made known his view of the composition of carbonic acid, which he showed was formed when oxide of mercury was heated with carbon, and was therefore to be regarded as a compound of carbon with that constituent of atmospheric air which supported combustion.

Scheele's investigation on the constitution of the atmosphere,—made in 1774-75, it not published until 1777, in his essay on "Air and Fire,"—comprised another dependent discovery of oxygen gas, obtained by heating nitre or metallic oxides, but he was content with the fact, there was no dispute as to the priority of the discovery. His essay also contained many valuable results connected with the composition of the atmosphere, the phenomena of combustion, and other details relating to pneumatic chemistry, especially the quantitative composition of the atmosphere, which, since the discovery of its nature, had been a more definite object of investigation than it had formerly been. As contributors to the attainment of this result, were Fontana, Andriani, Lavoisier, Ingenhous, Sigaud de la Fond and Davidson. It was, however, by Cavendish's "Experiments on Air," published in 1784-85, that the true quantitative composition of the atmosphere was first established, and the use of the discrepancies which had been observed in eudiometrical experiments made known.

In the early part of 1783, which was a period of great importance in the history of chemistry, the knowledge of *aëriiform* substances had made very considerable progress, so far as concerned the establishment of facts as to the existence of different gases, the part played by atmospheric air in combustion and respiration, and by gaseous substances generally in most chemical phenomena. A passage in the "Histoire de l'Académie Roy. des Sciences," for 1776, published in 1779, will serve to show the range which had taken place with regard to this subject. "Les substances *aëriiformes* auxquelles nous n'avions que des observations isolées, sont devenues, depuis quelques années, l'objet des recherches des chimistes; et elles ont jeté un grand désordre dans les théories les mieux établies et les plus fermement adoptées. En effet, on a connu que ces substances, qui, au degré de chaleur de l'atmosphère, sont dans l'état de fluides expansibles, entrent dans la composition de la plupart des corps solides et élastiques; c'étoit donc un nouvel ordre de substances auxquelles il falloit avoir égard dans l'analyse de ces corps." In the same volume, the increase of weight in calcination of metals was also referred to: "Ainsi l'on a observé dans les calcinations des métaux, et leur réduction, que l'explication de Stael n'étoit suffisante; que les substances métalliques s'unissoient, par la calcination, avec une espèce d'air, qui s'en dégageroit ensuite dans leur réduction," while not longer back than 1766, the same subject was referred to in the "Histoire de l'Académie" for 1763, in the notice of a memoir by Hellot, Tillet, and Macquer, "Sur les Essais des Matières d'Or et d'Argent," in very different terms: "L'augmentation observée dans le bouton d'argent fin n'est . . . qu'apparente, et il ne se fait aucune transmutation du plomb en argent; mais ce premier métal, qui sembleroit devoir considérablement diminuer de poids par l'action du feu et par les fumées continuelles qu'il exhale en se convertissant en litharge, augmente au contraire de poids. . . . Le fait n'est point équivoque, . . . c'est un vrai paradoxe chimique, que l'expérience met cependant hors de doute. Mais s'il est facile de constater ce fait, il ne l'est pas autant d'en rendre une raison satisfaisante; il échappe à toutes les idées physiques que nous avons, et ce n'est qu'un temps, qu'on peut attendre la solution de cette difficulté." Tillet, who had studied this fact very carefully, remarks in his memoir, "Nous sommes donc forcés de convenir que cette augmentation de poids étant constante et bien décidée . . . devient par là le sujet d'une recherche curieuse, s'il est possible de saisir un point de physique aussi délicat."

Besides the gases already mentioned, Priestley had discovered hydrochloric acid gas, ammonia, fluosilicic gas, sulphurous acid, and nitrous oxide. He had also devised the use of mercury in place of water for the pneumatic trough. Scheele had discovered chlorine. Volta had pointed out, in 1776, the peculiarity of the inflammable air of marshes, in yielding carbonic acid when burnt, and had made a comparative examination of it and other inflammable gases, as regarded the proportions of oxygen requisite for their combustion. He also showed that a mixture of atmospheric air and inflammable air could be exploded by the electric spark, and Kirwan had endeavoured, in support of the phlogistic theory, to identify phlogiston with the inflammable air obtained by dissolving metals with dilute acids. But, in general, there was an absence of any connected interpretation of the facts which had been ascertained. Lavoisier had given, in his *Opuscules*, a comprehensive historical statement of the views which had been entertained with regard to *aëriiform* substances, and at the same time put forward his own views with regard to combustion. In his paper on the combustion of diamond, phosphorus, and organic substances, he showed that only a part of the

atmospheric air was concerned in the process, and that fixed air was the only gas remaining after the combustion of organic substances when vital air was substituted for atmospheric air. He showed that sulphuric acid contained vital air and sulphur that the production of a salt by the exposure of pyrites to the atmosphere, consisted in a simultaneous absorption of the same air by the sulphur and iron; that nitric acid contained this air; and that phosphorus was convertible into phosphoric acid by nitric acid. In 1781, he published an approximate analysis of carbonic acid, and showed that it, in common with all other acids as he maintained, contained oxygen. His attempts, in 1782, to explain the precipitation of one metal by another, as consisting in a transfer of oxygen from one to the other, in opposition to Bergmann's view, that it consisted in a transfer of phlogiston, were less successful than some of his other investigations; and just at this time his attention was directed to an objection urged against his views, that they did not account for the evolution of hydrogen when metals were dissolved by dilute acids, nor explain whence they derived the oxygen, which he maintained it was necessary they should combine with, to form oxides, before they could form salts with the acids.

About the end of 1781, Cavendish commenced some experiments, which "were made principally with a view to find out the cause of the diminution which common air is well known to suffer, by all the various ways in which it is phlogisticated, and to discover what becomes of the air thus lost or condensed" (Phil. Trans., 1783, p. 119): "Having now mentioned the unsuccessful attempts I made to find out what becomes of the air lost by phlogistication, I proceed to some experiments which serve really to explain the matter. In Dr. Priestley's last volume of experiments, is related an experiment of Mr. Warltire's, in which it is said, that on firing a mixture of common and inflammable air by electricity . . . in glass vessels, the inside of the glass, though clean and dry before, immediately became dewy; which confirmed an opinion he had long entertained, that common air deposits moisture by phlogistication" (*ibid.* p. 126). In studying this fact, Cavendish met with a difficulty, consisting in the production of an acid in some instances; and the examination of the conditions under which this took place delayed the publication of his experiments until 1783; but so early as the summer of 1781, he had ascertained that, "when a mixture of inflammable and dephlogisticated air is exploded in such proportions that the burnt (i.e. residual) air is not much phlogisticated, the condensed liquor contains a little acid, which is always of the nitrous kind, whatever substance the dephlogisticated air is procured from; but if the proportions be such that the burnt air is almost entirely phlogisticated, the condensed liquor is not at all acid, but seems pure water, without any addition whatever; and as, when they are mixed in that proportion, very little air remains after the explosion, almost the whole being condensed, it follows that almost the whole of the inflammable and dephlogisticated air is converted into pure water." The weight of the water so produced was also shown to be equal to the joint weight of the two gases. Cavendish adds, "Last summer (1783), a friend of mine gave some account of these experiments to M. Lavoisier, as well as of the conclusion drawn from them, that dephlogisticated air is only water deprived of its phlogiston."

These experiments, which furnished evidence of the compound nature of water—the only point that was wanting to render Lavoisier's theory complete, and to overthrow the phlogistic theory—were interpreted by Cavendish in perfect accordance with older views, to which he uniformly adhered. The water obtained by exploding a mixture of inflammable and dephlogisticated air, was never regarded by him as the result of a chemical combination of two distinct substances, but, strictly in accordance with the spirit of the phlogistic theory, merely as being the result of a mutual and compensating alteration of the two kinds of air, both of which he supposed to be, at the same time, equally air and also equally water, the difference between the two kinds of air, and between either of them and water, consisting solely in their condition with regard to the unknown principle, phlogiston. His own language in reference to this point is so clear and explicit, that it is remarkable this fact should have been entirely overlooked in the long controversy which has been maintained as to the discovery of the compound nature of water, or the originator of the view that water is a compound of the two gases.

It is somewhat questionable what was the exact nature of Cavendish's views with regard to phlogiston; so far as may be inferred from his writings, he appears to have regarded it as imponderable. Certainly he did not, as has been frequently asserted, regard hydrogen as phlogiston; and, though he mentions that opinion, as put forward by Kirwan and Priestley, he expressly states his dissent from it. With regard to his view of the nature of dephlogisticated and inflammable air, however, there is no room for doubt or uncertainty:—"dephlogisticated air is only water deprived of its phlogiston," and inflammable air "is either phlogisticated water or else pure phlogiston, but in all probability the former" (Phil. Trans. 1784, p. 140). Again, after discuss-

ing the probable source of the acid produced in some of his experiments, he says:—"We must allow that dephlogisticated air is, in reality, nothing but dephlogisticated water, or water deprived of its phlogiston; or, in other words, that water consists of dephlogisticated air united to phlogiston; and that inflammable air is either pure phlogiston . . . or else water united to phlogiston, since, according to this supposition, these two substances united together form pure water." His account of the nature of phlogistication of pure air renders his opinion still more clear: "adding dephlogisticated air to a body is equivalent to depriving it of phlogiston, and adding water to it." "In the detonation of nitre with inflammable substances, the acid unites to phlogiston and forms phlogisticated air" (nitrogen); but in the production of nitric acid from a mixture of oxygen and nitrogen, "the reverse of this process was carried on, namely, the phlogisticated air united to the dephlogisticated air, which is equivalent to its being deprived of its phlogiston, and was reduced to nitrous acid" (Phil. Trans. 1785, p. 380). As illustrative of this process he mentions the oxidation of mercury in his first paper, and, even in 1785, the formation of nitric acid. He had formerly come to the conclusion that phlogisticated air (nitrogen) was "nothing else than nitrous acid united to phlogiston. According to this conclusion, phlogisticated air ought to be reduced to nitrous acid by being deprived of its phlogiston. But as dephlogisticated air is only water deprived of its phlogiston, . . . therefore phlogisticated air ought also to be reduced to nitrous acid by being made to unite to, or form a chemical combination with, dephlogisticated air, only the acid formed this way will be more dilute than if the phlogisticated air was simply deprived of its phlogiston" (Phil. Trans. 1785, p. 379). This assumed dilution of the acid shows that he considered water to be produced by the transfer of phlogiston from nitrogen to oxygen, as well as by the transfer of phlogiston from hydrogen to oxygen, just as he considered it to be produced also, by the transfer of phlogiston from mercury to oxygen, and to remain as a constituent of the oxide of mercury.

The argument that Cavendish regarded water as a compound, rests solely upon the assumption that he considered inflammable air to be phlogiston, an assumption not only quite gratuitous, but directly opposed to his own statements as to this point. "I know of no experiment," he says, "which shows inflammable air to be pure phlogiston, rather than a union of it with water, unless it be Dr. Priestley's experiment of expelling inflammable air from iron by heat alone;" and, he adds, it is "more likely that the inflammable air was formed by the union of the phlogiston of the iron filings with the water dispersed among them" (Phil. Trans. 1784, p. 137). Even the fact that the water, produced by exploding a mixture of inflammable and dephlogisticated air, was equal to the joint weight of the two gases, was not interpreted by Cavendish as indicating the formation of a compound, according to present ideas, but merely as showing that both kinds of air were, as he expresses it, "turned into water." The change, in his estimation, was of much such a nature as that in the production of water by mixing ice and steam; or in the contact of a negatively electric body with another positively electric. He even expressed his dissent from Lavoisier's view of the fact, while admitting that it could be as well expressed according to that view, as according to the phlogistic theory; and he speaks of Lavoisier's view as an "hypothesis," according to which "we must suppose that water consists of inflammable air united to dephlogisticated air." The difference between Cavendish's real view and this expression of Lavoisier's, will appear trivial or nothing if they are considered in the manner which has now become habitual; but the fact that Cavendish took the pains to refer to the difference between his view and that of Lavoisier, is sufficient proof that, in his own estimation, the difference was not slight; and if the tendencies and spirit of the phlogistic theory are fairly considered, it will be evident even now that it was no slight difference.

It is only to the disregard of the point of view from which this and similar phenomena were considered, according to the phlogistic theory, that the spurious argument and signal misconception, characteristic of much of the water controversy, can be ascribed—misconception so great, that the late Dr. Wilson, in his biography, has asserted it to be "undeniable" that Cavendish considered every oxidisable body contained hydrogen! "Inconceivable" would be a more correct term to apply to the notion that any such opinion was ever thought of by Cavendish, and more consistent with that high estimation of his philosophical character which has always been so generally entertained, and which rests on so solid a foundation. It is only by such a disregard of the phlogistic point of view, that it is possible to account for the attempt to claim for Cavendish any further share in the discovery of the composition of water, than that of having been the first to recognise the fact that it was the sole product of the explosion of oxygen and hydrogen in certain proportions: with regard to this having been done by Cavendish it seems hardly possible that there should be any dispute. It is equally impossible to perceive any ground for the assertion that he did anything

more than supply the evidence of the composition of water, without, however, forming any conception of its compound nature, or, in other words, adopting the true interpretation of his experimental results. If the mere recognition of the fact that hydrogen and oxygen yielded water by explosion, be held to constitute the discovery of its composition, both Warltire and Priestley should be allowed to participate in the credit of having made it, and, to some extent also, Macquer and De la Moth rie, who, in 1776, had observed that water was the product of combustion of inflammable air. But the view that water was a compound, was incompatible with the system of chemical philosophy then prevailing, and was, in fact, the means of subverting it. The credit of having first given the true interpretation of the facts observed by Cavendish, is certainly due to Lavoisier; and to that extent he may be regarded as the discoverer of the composition of water, inasmuch as the advancement of chemical science, at that time, and in this case especially, consisted more essentially in the correct interpretation of known facts, than in the observation of new facts.

It would be improper not to mention here the claim which has been made for James Watt, as having been the discoverer of the composition of water, a claim which appears to involve a disregard of what really constitutes a title to be considered as a discoverer. Watt certainly was the first to put forward, in 1783, the opinion that water was a compound of inflammable and dephlogisticated air; but that opinion was merely an hypothesis, based upon data furnished to him by Priestley, and unsupported by any experimental observation of his own. In fact, he never appears to have laid claim to anything more than having put forward this view as a speculation; and though, for a time, he believed he had been unfairly treated, his only complaint was that his "ideas" had been pirated, and that no mention had been made of his "theory," either by Cavendish or Lavoisier, to whom it had been communicated.

The communication of Cavendish's results to Lavoisier, by Blagden in 1783, appears to have been received by him with doubt as to their accuracy. The combustion of inflammable air had already occupied his attention, about the end of 1781, under the belief that, like sulphur and phosphorus, it would yield an acid. In his memoir on this subject, read in 1783, he says, "*L'analogie m'avoit port e invinciblement   conclure que la combustion de l'air inflammable devoit  galement produire un acide.*" At the time of Blagden's communication, however, the evolution of hydrogen when metals were dissolved by dilute acids, and the reduction of metallic oxides by inflammable air, were inexplicable according to Lavoisier's views; and he appears to have thought Cavendish's experiment sufficiently important to repeat it. The result which he obtained, at once showed him that his preconceived opinion as to the combustion of inflammable air was wrong, and it furnished him with the key to the explanation of those difficulties which were then being urged against the correctness of his views by Kirwan and other supporters of the phlogistic theory. He followed up the subject by decomposing water, and contributed to establishing its quantitative composition. Berthollet and other chemists soon afterwards adopted his views; before the end of the 18th century the antiphlogistic theory was generally established; and with its establishment, the chemical importance of gaseous substances was fully recognised.

Since that time, the knowledge of the chemical and physical characters of gases has been largely extended by the investigations of numerous chemists. The relations of volume obtaining in the combination of gases, first definitely pointed out by Gay-Lussac and Humboldt in 1805, and subsequently developed by the former in 1809, have but recently been fully brought to bear upon the theory of chemical constitution, and, like the phenomena of diffusion investigated by Dalton and Graham, belong so entirely to the chemistry of the present time, that they will require to be treated in separate articles.

B. H. P.

GAS BURNERS AND FURNACES. The forms of gas-burner used for illumination, are described in *Ure's Dictionary of Arts, Manufactures, and Mines*, art. COAL-GAS, i. 733. In these burners, the main condition to be fulfilled is, to supply the flame with just so much air as to burn the whole of the hydrogen in the gas, and a sufficient quantity of the carbon to prevent the formation of visible smoke, but, at the same time, to separate a certain quantity of the carbon within the flame in the form of minute solid particles, which, being rendered incandescent by the flame, impart to it a high degree of luminosity; perfect combustion is not desirable, as all the products would then be gaseous, and very little light would be emitted. (See COMBUSTION, i. 1094, and FLAME, ii. 654.) But when coal-gas is used as a source of heat, it is desirable to make the combustion as complete as possible, as this condition insures the production of a high temperature and the absence of smoke. This object is attained by mixing the combustible gas, before it reaches the burning point, with the quantity of air required to burn it completely. A simple and effective contrivance for this purpose is to fix on the top of the chimney of an ordinary argand gas-burner a piece of wire-gauze, then turn on the gas, and light it above the gauze. The gas then becomes

mixed with air in passing up the chimney, and this mixture, when set on fire above the wire-gauze, burns with a pale blue, perfectly smokeless flame, producing a very intense heat, and well adapted for heating basins, small crucibles, or other vessels. If the wire-gauze is of the proper degree of fineness, and fits closely on to the top of the chimney, the flame will not extend to the mixture of air and gas below the wire-gauze, because in passing through the meshes, it would be cooled below the burning temperature, as in the miner's safety-lamp (i. 1101).

But the form of gas-burner now most generally used in chemical laboratories, as a source of heat, is that contrived by Professor Bunsen, and represented in *fig. 496*. The gas, supplied by a flexible tube attached at *t*, passes through a set of small holes into the box *a*, in which it mixes with atmospheric air entering freely by a number of holes as shown in the figure. The gaseous mixture passes up the tube *b*, and is inflamed at the top, where it burns with a single tall blue flame, which gives no smoke and very little light, but much heat. The flame may be made large or small at pleasure by regulating the supply of gas; and by arranging two or more such tubes, together with an air-box containing a sufficient number of holes, a very powerful burner may be constructed.

This form of burner is, however, subject to two defects; sometimes the flame burns white and smoky, and sometimes it blows down, the gaseous mixture exploding, and the gas then burning with a smoky flame in the air-box *a*. The remedies for these defects are as follows:—If the flame is white only when the gas is turned on very full, the remedy is to lessen the supply of gas; but if the flame continues to burn white at the top, when the gas is gradually turned off and the mass of flame slowly sinks, then the holes which deliver the gas from the supply pipe into the air-box are too large, and are placed too directly under the centre of the vertical tube *b*: these defects must be corrected in the instrument. Finally, when the flame blows down, it is because the supply of atmospheric air is too large in proportion to the supply of gas, and their relative proportions must be altered. To effect this alteration, Mr. Griffin (to whose kindness the editor is indebted for the following descriptions of gas burners and furnaces) places over the air-box *a* a thin brass cap, *c*, perforated with holes, and capable of turning round so as partially to close the holes, and thus lessen the supply of air. If, when the gas is alight, the flame needs to be lowered, first the supply of air is to be lessened, then the supply of gas. If the flame is to be enlarged, first the supply of gas must be increased, and then the supply of air. In short, to prevent the flame blowing down, the gas must always be first placed in excess, and then have the proper quantity of air adjusted to suit it, by means of the regulator *c*.

To produce a spreading flame, and render the burner better adapted for heating an evaporating basin, Mr. Griffin places over the mouth of the vertical tube *b* (*fig. 496*), a flat cast-iron box, *d*, with many holes round its margin, and a few small ones on the top. The flame thus produced consists of a series of radiating jets, forming a horizontal circular flame. *Fig. 497* represents a variety of this rose burner in which the head is not removable, but the efflux of the mixed gases is regulated by a sliding valve *b*. When the slide is pushed over the central hole, the burner gives a number of small flames in a circle suitable for boiling and evaporation; when it is pushed aside, the burner gives a single tall flame adapted for ignition and fusion.

Gas Furnaces. The power of the burner just described, and, indeed, of every kind of gas-burner, may be greatly increased by surrounding the flame with a jacket of fire-clay, or some other substance of small conducting power, which will prevent the dissipation of the heat by radiation. In this manner gas furnaces may be constructed capable of producing very high temperatures with but a small expenditure of gas.

Fig. 498 represents a gas furnace arranged for boiling and evaporation. *a* is the gas burner, like that represented in *fig. 496*: it is 12 inches high, the bore of the tube *d* is 1 inch, and the diameter of the fire-box *c* is 4 inches: *b* is an iron stool with three legs; *c*, a furnace-body, or iron jacket, lined with plumbago or fire-clay. *Fig. 499* shows the jacket and lining in section, and marks the position of the fire-box, *c*, of the gas-burner. This furnace is 14 inches high and 9 inches in diameter. The three

Fig. 496.*Fig. 497.*

brackets fixed on the upper part of the jacket serve to support the vessel containing the liquid to be boiled or evaporated. A porcelain basin 18 or 18 inches in diameter can be thus supported. It is important to allow, between the jacket *c* and the evaporating basin, plenty of space for the escape of the heated air which ascends from the interior of the furnace. When the evaporating basin is of small diameter, it may be supported on triangles placed within the furnace *c*. Round the vertical tube of the gas-burner *a*, there is in the bottom of the furnace *c* (fig. 499) a circular opening 2 inches in diameter, through which the air passes

Fig. 498.

Fig. 499.

freely, partly to feed the flame and partly to be heated by the flame, and directed upwards in a continuous current upon the lower surface of the basin that is to be heated. The flame within the furnace burns steadily. No side currents of air agitate it. No part of it touches, or must be permitted to touch, the basin, which should receive its heat solely from the mass of ascending hot air. The gas-burner thus arranged, and supplied by a gas-pipe of $\frac{1}{4}$ inch bore, burns about 33 cubic feet of gas in an hour, and the flame which it produces, acting upon water contained in an open porcelain evaporating basin, will heat from 60° to 212° F.:

1 quart in 5 minutes | 1 gallon in 15 minutes | 2 gallons in 30 minutes

When the water boils, it is driven off in steam at the rate of more than a gallon of water per hour.

By increasing the draught and confining the heat still more, the same gas burner

Fig. 500.

may be made to give heat enough for the fusion of silicates with carbonate of soda. Fig. 500 represents a gas furnace contrived by Mr. Griffin for this purpose. *a* is the gas-burner; *b*, a tall iron stool; *c*, a chimney which collects atmospheric air to feed the flame, and leads it up close to the vertical tube of the gas-burner, by which contrivance the air is warmed and the tube cooled; *d* is a sole or plate of fire-clay; *i* is a cylinder of fire-clay, $\frac{1}{4}$ inches high, and $4\frac{1}{2}$ inches diameter; *k* is a plumbago or fire-clay furnace, in which is placed a small cast iron ring, the form of which is shown in fig. 501, and on this ring the platinum crucible is adjusted; *l* is a fire-clay or plumbago reverberatory dome; and *g* is the chimney, 24 inches long and $3\frac{1}{2}$ inches wide. The crucible being adjusted, the gas lighted, and the dome and chimney put on, the lapse of 12 or 15 minutes, according to the quality and pressure of the gas, suffices for the fusion of 1000 grains of carbonate of soda in a platinum crucible.*

Fig. 501.

The crucible is placed very high above the orifice of the tube *a* at which the gas is inflamed. The distance is, in fact, about 10 inches, the point of maximum heat in the flame being at nearly that distance from the burner, more or less according to the pressure and the quality of the gas. The gas which rises from the burner *a*, though mixed with as much air as it will bear without becoming explosive when lighted, does not contain sufficient oxygen to burn all the carbon present in it. The flame produced is, consequently, quite superficial. The gaseous mixture burns only on the surface, where it is in contact with fresh atmospheric air, and it requires time to take up the requisite amount of oxygen. The draught produced by the joint action

* If this quantity of fused carbonate of soda is permitted to cool and consolidate in a platinum crucible, the salt is liable to expand and burst the crucible.

of the two chimneys *c* and *g* carries the flame rapidly to a great height before the point of complete combustion is attained.

When the highest degree of heat is not required, the reverberatory dome *l* may be omitted. It must also be dispensed with when the crucible to be heated is of comparatively large size, because it is then liable to lower the temperature of the furnace by impeding the draught.

Fig. 502 shows a form of the furnace adapted for igniting a large fire-clay crucible, as when oxide of copper is to be dried for use in organic analysis. The crucible is enclosed within a reverberatory dome *f*. The chimney is provided with a damper to lessen the draught when small crucibles are to be heated.

The action of these furnaces may be judged of by a peculiar roaring noise which they produce. If the gas and air are mixed in due proportions, the roar is regular and continuous. If there is too much gas, the roar is lessened; if too much air, the roar is increased, but is rendered irregular and intermittent. The greater the noise, the greater the heat in the furnace: but when the roar becomes spasmodic, the flame is on the point of blowing down. To prevent that occurrence, the proportion of air must be lessened or that of gas increased.

The effects ascribed to the various arrangements of this gas-furnace, can be produced with gas supplied by a pipe of a $\frac{1}{2}$ -inch bore, and at a moderate pressure, giving from 30 to 40 cubic feet per hour.

The principles of heating by gas, which have led to the construction of this furnace, may be summed up as follows:—When a crucible or other solid body is to be heated, it is to be wrapped in a single flame at the point of maximum heat, and loss of heat by radiation and conduction is to be prevented by the interposition of non-conducting materials (plumbago or fire-clay); and when liquids are to be boiled or evaporated, particularly when they are contained in vessels of glass or porcelain, the flame is to be broken up into numerous horizontal jets, and these are to be made to supply a large and regular current of highly heated air, by which alone, and not by the direct application of the flame, the vessel containing the liquid is to be heated. In both cases, provision must be made to secure a sufficient draught of air through the furnace, because every cubic foot of gas requires for combustion 10 or 12 cubic feet of air, and the gases which have done their duty must be rapidly carried away from the focus of heat. If the steam, the carbonic acid gas, and the free nitrogen, which constitute the used-up gases, are not promptly expelled, fresh gaseous mixture, in the act of producing additional heat by combustion, cannot get near the object that is to be heated, and the heat so produced out of place is wasted.

Griffin's Blast Gas Furnace. This is a more powerful apparatus adapted for metallurgic operations, such as fusing considerable masses of metal, assaying, roasting, &c. It consists of two parts: first, of a particular form of gas-burner, which is supplied with gas at the usual pressure, and with a blast of common air, supplied by bellows or a blowing machine, at about ten times the pressure at which the gas is supplied; and secondly, of a furnace, which is built up in a particular manner, round the flame produced by the gas-burner, and the crucible exposed to ignition. The object of this particular construction is to accumulate and concentrate in a focus the heat produced by the gas flame, and to make it expend its entire power upon any object placed in that focus. This apparatus can be made of various sizes, according to the amount of work required from it.

The gas-burner is a cylindrical iron reservoir, shown in section in fig. 503, which is drawn on a scale of one-third the full size. It contains two chambers, not in communication with one another. Into the upper chamber, gas is allowed to pass by the tube marked GAS. Into the lower chamber, air is forced by the tube marked AIR. The upper part of the burner is an inch thick in the metal. Through this solid roof, holes from 6 to 26 in number are bored for the escape of the gas. The number of holes, depends, of course, upon the heating power required from the burners. The air passes from the lower chamber, through

Fig. 502.

Fig. 503.

a series of metal tubes, placed in the centre of the gas-holes, and continued to the surface of the burner, so that the gas and air do not mix until both have left the gas-burner, and then a current of air is blown through the middle of each jet of gas. The bottom of the gas-burner is made to unscrew, and the division between the two chambers, which carries the air-tubes, is easily removable for the purpose of being cleaned. The gas and air pipes generally used in the inventor's experiments were both half an inch in the bore, and ten inches long; the gas had usually a pressure of half an inch of water, and the blast of air about ten times that pressure. The quantity of gas used in an hour was about 100 cubic feet. The stopcock which supplied it had a bore of half an inch. The round rod represented at the bottom of the burner, *fig. 503*, is intended to fit it to the support, shown by *b*, in *figs. 505 and 506*.

When the gas is lighted and the blast of air is put on, the flame produced by the gas-burner is quite blue, and free from smoke. It is two inches in diameter, and three inches high, and the point of greatest heat is about two inches above the flat face of the gas-burner. Above this steady blue flame there rises a flickering ragged flame, several inches in height, varying with the pressure of the gas. In the blue flame, thin platinum wires fuse readily.

When the gas is burning in this manner, and the apparatus is attached to flexible tubes, the burner may be inverted or held sideways, without disturbing the force or regularity of the flame, so that the flame may be directed into a furnace at the bottom, the top, or the side, as circumstances may require.

The following articles are used in building up the gas furnace for different experiments. They vary in size according to the volume of the crucible, or the weight of the metal to be heated.

1. A circular plate of fire-clay, two inches thick, with a hole in the centre, exactly fitting the upper part of the gas-burner, which is made to enter into the hole three-quarters of an inch. In external diameter, this clay plate agrees with each size of furnace.

2. A cylinder of fire-clay, of which two pieces are required to constitute the body of each furnace. In the middle of each cylinder, a trial-hole is made, one inch in diameter, to which a fire-clay stopper is adapted.

3. A fire-clay cylinder, closed at one end, and pierced near the open end with six holes of half an inch in diameter. The thickness of the clay is immaterial. This cylinder is three inches high and three inches in diameter.

4. A circular plate of fire-clay, two and a half inches or three inches in diameter, and one inch thick. Similar pieces $\frac{1}{2}$ inch thick are useful.

5. A cylinder of plumbago, to be used as a crucible support. It is three inches in inside diameter, one inch in height, and pierced with twelve holes of three-eighths of an inch bore.

6. A similar cylinder of plumbago, two or three inches high, pierced with 24 holes of three-eighths of an inch bore.

7. A thin plate of plumbago, three inches in diameter, viz. of the same diameter as the cylinders 5 and 6. It has a small hole in the middle, and being of soft material, the hole can be easily cut or filed to suit crucibles of any desired size.

To suit the larger kind of crucibles and furnaces, cylinders are made resembling the above in form, but of greater diameter.

As in all cases the heating power of the gas furnace spreads laterally and does not rise vertically, the most advisable form of the crucibles required for use in it, is *short and broad*, not tall and narrow, and the supporting cylinders must be shaped accordingly. No fire-bars or grates must be used to support the crucibles in this gas furnace, because no material formed into narrow bars can sufficiently withstand its power of fusion and combustion.

8. A plumbago cylinder, or crucible-jacket, two and a half inches high, two and a half inches in diameter, and a quarter of an inch thick in the walls. It has six holes of three-eighths of an inch diameter near one end.

9. A circular cover or dome (*fig. 504*) flanged at the bottom, and having a knob or handle at the top. It is pierced with 24 holes of a quarter of an inch in diameter, arranged in two rows near the bottom. This dome, when of small size, is made of plumbago; when large, of fire-clay.

Fig. 504.

10. Plumbago crucibles made with a solid overhanging rim, the use of which is to suspend the crucibles over the gas-burner, by means of the cylinders, Nos. 5 and 6. When the crucibles are too small to fit the cylinders, the flat plate, No. 7, is filed to fit the crucible, and is then placed on the cylinder, to whose diameter it is adapted.

Besides these pieces of fire-clay and plumbago, it is necessary to be provided with a strong iron tripod, to sustain the furnace, as represented by *c*, in *figs. 505, 506*; an

iron pan, in which to place the furnace; and a quantity of gravel, or rounded flints, not less than half an inch, nor more than one inch in diameter. These pebbles form an essential part of the gas-furnace.

Gas-furnace heated at the top, exhibited in section by Fig. 505.—*a* is the gas-burner, (fig. 503); *b* is the support for it, when used below the furnace; *c* is the iron tripod support for the furnace; *d*, *d'*, are two perforated clay plates, like No. 1, adapted to the gas-burner *a*; *c*, *e*, are two clay cylinders, like No. 2. These pieces *a* to *e*, are similar in all the furnaces represented by figs. 505 and 506.

The interior of the furnace is built up as follows:—The clay plate *d*, is put upon the tripod *c*. Over the central hole in *d*, the clay cylinder (No. 3) is placed, and upon that cylinder two or three of the clay plates (No. 4). Upon these a porcelain or platinum crucible is placed. If it is of platinum, a piece of platinum foil may be put between the crucible and the uppermost clay plate, to protect the crucible from contact with particles of iron, or against fusion with the clay. The crucible is to be covered by the plumbago jacket (No. 8). The space between this pile in the centre of the furnace and the two cylinders *c*, *e*, which form the walls of the furnace, is to be filled with flint-stones, or gravel, washed clean and dried. The stones which answer best are rounded, water-worn pebbles, of half an inch to one inch diameter. These may be piled up to the top edge of the jacket (No. 8). The number of clay plates (No. 4) must be such as to bring the top of the crucible, to the distance of two inches, or two and a half inches at the utmost, from the flat face of the gas-burner *a*. In some cases, merely one of the furnace cylinders, *e*, is necessary, in which case the crucible and its jacket is placed directly upon the cylinder (No. 3), and when only a moderate heat is required, even the packing with pebbles may be dispensed with. Another means of diminishing the heat is to increase the distance between the gas-burner and the crucible.

The apparatus being thus arranged, the gas is to be turned on, and lighted; the blowing-machine is to be put into action; and the nozzle of the gas-burner is to be depressed into the central hole of the clay plate *d'*, as shown in fig. 505. The whole force of the blue flame then strikes the crucible; part of it forces its way through the holes in the jacket (No. 8), and part of it rises and passes over the upper edge of the jacket; after which it forces its way downwards between the pebbles. The carbonic acid gas and the vapour of water which result from the combustion of the gas, together with the nitrogen of the air, and any uncombined oxygen, accompany it. No space being left open for the escape of these gases at the upper end of the furnace, they go downwards through the interstices among the pebbles, and passing through the holes in the cylinder (No. 3), and through the central hole in the lower plate *d*, fig. 506, escape finally into the air. In this progress, the hot gases give up nearly all their heat to the flint-stones. Water and gases escape below at a very moderate temperature, water even running down in the liquid state, while the stones rapidly acquire a white heat, and if the blast and the supply of gas is continued, they retain that white heat for any desired length of time—for hours.

At the end of ten minutes after lighting the gas, the crucible, placed in the described circumstances, and exposed to the full action of the heat of the gas, and surrounded by substances which are bad conductors of heat, is raised, with the jacket and pebbles around it, to a white heat. The consequence is, that the full power of the gas jet is then exerted upon the crucible and its contents.

If it is desired to inspect the substance subjected to the action of heat in this furnace, the gas-burner is lifted out, and the crucible is examined through the hole in the clay plate. To make it possible to inspect substances at a white heat, the view is taken through a piece of dark cobalt-blue glass. If the substances submitted to heat suffer no harm from the action of oxygen, it is better to dispense with a crucible cover, and throw the jet flame directly down upon the substance to be heated. The

Fig. 505.

action is then more rapid. When the burner is taken out, the substance in the crucible can be stirred, if it is considered necessary.

The following experiment will give an idea of the power of a furnace of this description. A common clay crucible, three inches high and three inches diameter at the mouth, was filled with about twenty-four ounces of cast iron. It was mounted like *fig. 505*, in a furnace of four inches internal diameter, and eight inches deep. The pebbles were filled in to the edge of the crucible. No crucible cover and no jacket were used. The flame was thrown directly upon the iron. In a short time the iron melted; the oxygen then converted some of the cast iron into magnetic oxide of iron, which formed a thin, infusible mass on the surface of the cast iron. At twenty minutes from the lighting of the gas, the furnace was dismantled. The crucible was taken out. A hole was broken by an iron rod in the infusible surface of oxidised iron, and the fused cast iron below it was decanted into a mould, and made a clear casting weighing twenty ounces.

In the same small furnace 32 ounces of copper can be fused in fifteen minutes. When the furnace is hot, that quantity of copper or cast iron can be fused in ten minutes.

In a furnace of the same dimensions, but with a gas-burner having only six, instead of sixteen jets, 16 ounces of copper or of cast iron can be completely fused, in ten minutes if the furnace is cold, and in seven minutes if the furnace is hot.

These experiments show that within twenty minutes a heat is producible in this furnace, which is more than sufficient for the decomposition of silicates by fusion with the carbonates of potash, soda, or baryta.

Gas-furnace heated at the bottom, exhibited in section by fig. 506.—In this furnace the parts marked *a, b, c, d, e, e*, are the same as those similarly marked in *fig. 505*;

Fig. 506.

but the gas-burner is in this case put into the bottom of the furnace, instead of the top, and the arrangement of the crucible and its support is altered in the manner shown by the figure. Upon the centre of the clay plate *d*, the perforated plumbago cylinder and cover (Nos. 5 and 6) are placed; and upon them a flanged plumbago crucible. The size of the crucible, and the height of the perforated cylinder, are to be so adjusted that the bottom of the crucible shall be struck by the hottest part of the gas flame; that is to say, the space left between the face of the gas-burner and the bottom of the crucible must not exceed $2\frac{1}{2}$ inches. The crucible is provided with a closely fitting cover, and pebbles are then filled in between the crucible jacket and the furnace cylinder *e*, and are covered over the crucible until both the pieces of the furnace *e, e*, are filled. The gas is then lighted, the blast of air is set on, the gas-burner is forced up into the hole in the clay plate *d*, and the operation proceeds. In from ten to twenty minutes after the gas is lighted—this difference of time depending upon the size of the furnace and the weight of the metal contained in the crucible—the interior of the lower cylinder *e* acquires a white heat. The progress of the operation can be watched by occasionally removing the stone peg in the trial hole of the furnace cylinder *e*. The heat very slowly ascends into the upper cylinder, and it never becomes so great in the upper as in the lower cylinder. The greatest fusing power of the furnace is confined within a vertical space of about six inches, reckoning from the bottom. The power of flint pebbles to abstract heat from the gases which pass through this apparatus is quite remarkable. When about six inches of pebbles lie above the crucible, and the crucible and the pebbles about it have been white-hot for half an hour, the hand can be held over the top of the furnace, within a few inches of the pebbles, without inconvenience. It becomes wetted with the vapour which rises from the furnace, but feels only a moderate degree of heat.

This form of furnace is attended with the inconvenience that the condition of the matter contained in the crucible cannot be examined, so as to ascertain when the heat has been continued long enough. In cases where the fusion is performed repeatedly on the same weight of metal, this would be of no importance, because the power of the furnace is so steady and regular, that the time of firing which has been found to answer once will answer the same purpose again.

When it is supposed that the fusion of the metal submitted to trial is completed, the

gas is first to be turned off, and then the supply of air stopped. The furnace may either be allowed to remain intact till it is cold, or it may be lifted off the cylinders *c c* with tongs, and the hot stones allowed to fall into the iron pan placed below the furnace to receive them. A few bricks should be laid between the pan and the table or stool on which it rests, if the latter is made of wood; because the heat given off by the pebbles is very great. The pebbles being raked away from the crucible, the contents of the latter can be examined.

Mr. Griffin has also contrived forms of the gas-furnace provided with a lifting apparatus to afford access to the crucible during the progress of the operation. For figures and descriptions of these, see *Griffin's Chemical Recreations*, 10th edition; also *Griffin's Scientific Circular*, December 1859.

Gore's Gas Furnace. This furnace, invented by Mr. G. Gore, of Birmingham (who has kindly communicated the description), is similar in principle to the furnace represented in figure 500, and is well adapted for heating small crucibles to high temperatures.

A (*fig. 507*) is a cylinder of fire-clay about 9 inches high and 6 inches diameter, open at both ends, and with a hole in its side near the bottom to lead into the chimney; it is covered by a movable plate of fire-clay, *b*, with a hole in its centre for introduction of the crucible or of substances to be melted: this hole is closed by a perforated plug of fire-clay, *c*, for access to the contents of the crucible; and that again is closed by another stopper of clay, *d*. *n* is a chimney of sheet iron about 5 or 6 feet high, kept upright by a ring of iron, *r*, attached to the top of the furnace.

The fireclay cylinder is enclosed in a sheet iron casing with a bottom of iron, to which are fixed three iron legs, *g*. An iron tube, *h*, with a prolongation, *i*, supports, by means of the screw, the burner *k* and its tube *l*, which is open at both ends. Gas is supplied to the burner by means of the tap *m*, which has a small index *n*, attached to it for assistance in adjusting the gas.

Inside the larger cylinder is another fire-clay cylinder or cupola, *o*, with open ends, and with three projections of fire-clay, *p*, for supporting the crucible *q*; it is kept steady by means of three clay marbles, *r*.

The gas-burner is a thin metal cylinder deeply corrugated at its upper end, with the corrugations diminishing to nothing at its lower end.

The action of this furnace is as follows:—Gas is admitted to the open tube *l* by the tap *m*; it there mixes with air to form a nearly explosive mixture, which ascends through the burner and burns in the clay cylinder, *o*, being supplied with the remainder of air necessary to complete combustion through the tube *h*, to the outer surface of the flame by means of the spaces between the corrugations. The flame and products of combustion pass up through the cylinder *o*, and then downwards outside it to the chimney, the point of greatest heat being at *q*. It is important in using this furnace that the burner be placed quite in the centre of the bottom of the tube *o*; also that a crucible of not too large nor too small dimensions be selected. The most suitable way of supporting a smaller crucible is by placing it in a larger one that has had its upper parts broken off. If desirable, a little clay luting may be placed round the top edge of the iron casing to exclude air entering between it and the cylinder; also a little thin clay luting upon the part of the bottom of the furnace where the inner cylinder rests.

In lighting the furnace, the plugs *c* and *d* are removed, a light held within the opening, and the gas turned on full; should the flame blow down to the bottom of the tube *l* on lighting (which, however, rarely occurs unless the furnace is already hot), the gas must be turned off and the bottom end of *l* momentarily closed whilst lighting the gas as before. Should the flame not burn down to the burner, but only burn at the orifice in the clay plate *b*, it must at once be extinguished and relighted, otherwise some of the gaseous mixture will pass into the chimney unburned, and subsequently ignite and cause an explosion. A large flame now issues from the top orifice, and is white if too much gas is on, and violet or red with the proper quantity. This flame generally diminishes and nearly disappears into the body of the furnace in the course of one minute: whether it does or not, the annular plug *c* should now be inserted, which

Fig. 507.

will compel it to pass downwards to the chimney; and as soon as the small remaining flame disappears or nearly disappears, as it will in a few seconds, the small stopper *d* should also be inserted; instead of this, the large flame may be deflected against the chimney by means of a shoot or bent piece of sheet iron, until it withdraws inwards; the plugs *c* and *d* may then be reinserted, and the gas-tap partly adjusted. The crucible may be placed in the furnace either before or some time after the act of lighting, but not immediately after (if the furnace is cold), or explosions may occur by unburned gaseous mixture passing the crucible into the chimney and igniting afterwards.

After about five minutes, the gas should be adjusted until a sound is heard inside like a series of small explosions. This sound is sometimes not very distinct, especially at high temperatures, and therefore requires a little experience in the use of the furnace in order to be detected; it is, however, a chief guide in determining the proper amount of gas, and should therefore be carefully studied. To assist in adjusting the gas, it will be found very useful to place a small piece of looking-glass beneath the tube *z*, and to adjust the gas-tap until the flame between the burner and the crucible appears wholly violet or slightly white; but this test is liable to fallacy if employed when the gas is just lighted, because the coldness of the parts makes the flame much whiter than it otherwise would be; it is also fallacious when the flame is very hot, the flame appearing whiter than it really is; it is, however, of great assistance at intermediate temperatures. A rough deposit of carbon upon the outer edge of the crucible indicates an excess of gas.

Less gas is required with a crucible in the furnace than without one; also less is necessary when the small hole at the top of the furnace is open than when it is closed; and less is also required when the furnace is cold than after it has been lighted some time, because the draught gradually increases and draws in more air. After having accurately adjusted the gas, no further attention to the furnace is requisite.

Having once found the proper adjustment of gas under certain known circumstances, it is well to notice the position of the index *x*, in order to be able at once to adjust it to the right point on other occasions. The gas should be supplied by a pipe of not less than $\frac{3}{16}$ of an inch bore, with a main pipe of half an inch; but all depends upon the pressure of gas at the particular locality, which is very variable. The consumption of gas varies from 30 to 40 cubic feet per hour.

The top of the chimney should be placed in a position where the products of combustion can pass freely away; if it is placed in an opening or pipe leading to another chimney, care must be taken not to have the draught too powerful, otherwise the heat will be drawn more into the chimney, and the supply of gas in the daytime may be found rather deficient. The furnace will act satisfactorily, though less powerfully, with the chimney standing in an open room, without any special outlet for the products of combustion, provided the full height (6 feet) of chimney is employed; under other circumstances a chimney $4\frac{1}{2}$ or 5 feet in height may be used.

This furnace will readily melt half a pound of copper, or six ounces of cast iron. It requires from 20 to 30 minutes to acquire its highest temperature; and then the entrance part of the chimney exhibits a faint red heat in daylight; if it exhibits much more than this, the draught is too powerful.

When the small hole *d* is open, some air is drawn in that way, and less air passes up with the gas through the tube *o*; but this cold air does not much diminish the temperature of the crucible, because it combines with the excess of gas now passing over the edge of the inner cylinder; it however renders the flame round the crucible white by deficiency of air, and this should be partly corrected by lessening the amount of gas. An excess either of air or gas renders the surface of melted copper dull.

When it is desirable to avoid entirely the contact of air with the fused substance during manipulation, a thin and narrow ring of fireclay should be placed upon the top of the tube *o*, to contract its opening; the flame then completely closes over the top of the crucible and prevents access of air. A proper adjustment of gas, together with exclusion of air in this manner, enables a perfectly bright surface of melted copper, or even tin, to be continuously maintained, from which the images of the parts above are clearly reflected. The clay ring may be withdrawn by lifting the plate *b*. A less perfect exclusion of air may be obtained by employing a narrow crucible placed rather low down in its support. A small iron dish should be placed beneath the tube *z*, to receive any melted substance that may fall.

For descriptions of gas-furnaces for organic analysis, see vol. i. p. 229.

GASES, ABSORPTION OF, BY LIQUIDS AND SOLIDS. All solid and liquid substances absorb, or condense in their pores, or on their surfaces, certain definite quantities of every gaseous body with which they are placed in contact. The amount of gas thus absorbed depends, in the first place, on the properties, both chemical and physical, of the bodies brought together, and, secondly, on the temperature and pressure under which the absorption occurs.

As a general rule solids absorb less gas than the same volume of liquid bodies; and in the case of solids, those of which a given weight contains the largest surface or which are most porous take up the largest quantity of gas. We are as yet altogether unacquainted with the law which regulates the amount of gas absorbed by any solid or liquid substance under any condition whatever; any knowledge which we possess concerning the absorptive powers of bodies for gases must therefore be entirely empirical. The volume of a gas which, under certain fixed conditions of temperature and pressure, is absorbed by the unit-volume of any solid or liquid, is a fixed and definite quantity, and is called the "Coefficient of Absorption" of the body for that particular gas. These coefficients of absorption have been determined with accuracy for various liquid and gaseous bodies, and certain relations existing between the volume of gas and the temperature and pressure under which it is absorbed have been satisfactorily established. In the case of solid bodies, on the other hand, the coefficients of absorption are not capable of such easy and accurate determination, partly owing to the impossibility of obtaining the solid matter always under like conditions as regards its state of aggregation, and partly because the amount of gas absorbed by solid bodies is in general extremely small.

1. *Absorption of Gases by Liquids.*—Gases are absorbed by liquids under two distinct sets of laws, according as the gas enters into chemical combination with the liquid or not. Absorptions of the one class are simple chemical combinations, in which the gas is absorbed in fixed proportions, regulated by the known laws of chemical action, independent of alterations of pressure or temperature; examples of this class of phenomena are found in the absorption of carbonic acid or chlorine gas by a solution of caustic soda, or that of chlorine or hydrochloric acid gas by alcohol. The second class of absorptions includes the cases in which the absorbed gas does not enter into any definite chemical combination with the absorbing liquid, and its amount is variable with the temperature and pressure under which the saturation occurs. The one class we may term chemical, the other physical absorptions. Of the phenomena of chemical absorptions we shall not here treat, except in a few cases in which a gas enters into chemical combination with a liquid, by which, at the same time, it is absorbed physically. It is the phenomena of, and the laws relating to, the physical absorption of gases, which here more immediately concern us.

The amount of a gas absorbed by a liquid upon which it exerts no direct chemical action, is dependent: (1.) on the specific nature of the gas and of the liquid; (2.) on the temperature at which the absorption takes place; (3.) on the pressure under which the absorption takes place. That the amount of absorbed gas depends in the first place upon the chemical nature of the gas and of the liquid, is seen from the fact that the solubility of different gases in the same liquid and of the same gas in different liquids, varies extremely. Thus, for example, 1 volume of water at 0°C . absorbs 0.00193 volumes of hydrogen, 1.7967 volumes of carbonic acid, and 1180.0 volumes of ammonia; thus, too, whilst 1 volume of water at 0°C . absorbs only 0.2563 volumes of olefiant gas, 1 volume of alcohol at the same temperature, absorbs 3.695 volumes.

The law which expresses the relation existing between the quantity of any absorbed gas and the temperature, appears to be an extremely complicated one, to the nearer acquaintance with which we have at present but little clue; so that the variation of the amount of absorbed gas with the temperature must in every case be determined by direct experiment. As a general rule, the volume of gas absorbed decreases with increase of temperature, and *vice versa*; thus 1 volume of water at 0°C . dissolves 68.61 volumes of sulphurous acid, but the same volume of water at 24° dissolves only 31.8 volumes; thus also, 1 volume of alcohol at 0° absorbs 17.891 volumes of sulphuretted hydrogen gas, whereas at 24° the quantity absorbed is only 6.955 volumes. This rule is, however, not without its exceptions; thus, for example, hydrogen is equally soluble in water between the temperatures of 0° and 25° , 1 volume of water between these temperatures dissolving 0.0193 volume of this gas; and thus also, for temperatures varying from 0° to 20° , 1 volume of alcohol dissolves a constant amount of oxygen, namely, 0.284 volume. In the case of many of the less soluble gases, the alteration in the absorbed volume effected by changes of temperature lying within the range of easy experimentation is so small, that it can only be detected by accurate observation; indeed, the earlier chemists, especially Dalton, believed that the amount of gas absorbed was entirely independent of the temperature.

A simple relation has, however, been found to exist between the amount of absorbed gas and the pressure under which the absorption takes place. Within certain limits, which we shall presently more nearly define, the quantity or weight of gas absorbed varies directly as the pressure. The general fact that under increased pressure the amount of absorbed gas is greater, has been known for a long time, and was pointed out by Cavendish and Priestley; but the exact law was first enunciated by William

Henry, in the Philosophical Transactions for 1803, in the following words:—"Under equal circumstances of temperature, water takes up, in all cases, the same volume of condensed gas as of gas under ordinary pressure. But as the spaces occupied by every gas are inversely as the compressing force, it follows that water takes up of gas condensed by one, two, or more additional atmospheres, a quantity which, ordinarily compressed, would be equal to twice, thrice, &c. the volume absorbed under the common pressure of the atmosphere." Thus, for instance, water at 15° C. absorbs its own bulk of carbonic acid under whatever pressure the absorption may take place; and if the pressure in the one case be 1, and in the other 2, 3, 4, &c., the quantity or weight of gas absorbed under the various pressures is as 1 to 2, 3, 4, &c.

This simple relation holds good within certain limits only, because Boyle's law (that the volume of a gas is inversely proportional to the pressure to which it is subjected), upon which this relation is based, is strictly correct for all gases only within a certain range of pressure, and in the case of the more condensable gases, as carbonic acid and ammonia, this range does not diverge far beyond the ordinary pressure of the atmosphere. The exact limit above and below the normal atmospheric pressure at which this relation of the absorbed quantity of gas to the pressure ceases to be exact, has as yet been experimentally determined in one or two cases only.

When a mixture of two or more gases is allowed to remain in contact with a liquid with which none of the gases enter into chemical combination, a portion of each gas is absorbed; but the liquid does not dissolve so much of any one gas as it would have done if that gas alone had been present. The quantity of each gas absorbed, is in this case also dependent upon the pressure which each gas exerts on the liquid. When two or more gases having the volumes v , v_1 , v_2 , &c. each measured under the pressure P , are brought together, they diffuse into each other until the particles of each are extended equally throughout the total space. If the pressure which the gas v exerts before mixing was P , the pressure after mixing, P_1 , is, according to Boyle's law, equal to $\frac{v}{v + v_1 + v_2} \cdot P$; that on v_1 is $\frac{v_1}{v + v_1 + v_2} \cdot P$; and that on v_2 is $\frac{v_2}{v + v_1 + v_2} \cdot P$,

the sum of these pressures being equal to the original pressure P . This pressure exerted by one of a mixture of gases on the inclosing space may be termed "partial pressure," in contradistinction to the sum of these or the "total pressure." As the amount of a single gas absorbed by a liquid is proportional to the total pressure of the experiment, so, in a mixture of gases, is the absorbed amount of each proportional to the partial pressure on that gas. This law regulating the absorption of mixed gases by liquids (which, in fact, includes Henry's law for total pressures), was first stated by Dalton in a paper on the absorption of gases in liquids, published in the Manchester Memoirs for 1805, containing a masterly theoretical treatment of the whole subject. In this paper, Dalton discusses all the cases of the absorption of gases by liquids, and develops the law which regulates the absorption of two or more gases when their volume is infinitely large as compared with that of the absorbing liquid, as also the law regulating the absorption when the volume of the gases has a finite relation to the liquid, showing in this last case, that the absorptiometric equilibrium occurs when the pressure of each gas dissolved in the liquid is equal to that of the portion of the gas which remains unabsorbed above the liquid. Although, as we shall see, these theoretical results are correct, still many of Dalton's ideas regarding absorption, being founded on incomplete and inaccurate data, have since proved false; thus for instance, he pictured to himself the act of absorption as nothing else than an infiltration of the liquid by the molecules of the gas, and hence assumed, his experiments not teaching him otherwise, that all non-viscous liquids absorb a like quantity of the same gas, and that temperature does not affect the absorption; and he expresses the difficulty which he has to account for the fact, too evident to be overlooked, that different gases are absorbed by the same liquid in such very various quantities.

Hence, owing to the incomplete nature of Dalton's experiments, and notwithstanding the fact that Saussure afterwards occupied himself with the subject, the law of pressures must be considered as having remained without a sound experimental basis, until the recent exact determinations of Bunsen and his pupils * placed the question beyond a doubt, proving that, within the limits before mentioned, the laws of Dalton and Henry are founded on fact.

In order to be able to compare the solubility of the various gases in liquids, it is usual to determine the volume of gas, measured at the standard temperature and pressure (0° C. and 0.76m. pressure of mercury), which is absorbed under a pressure of 0.76m. of mercury in 1 volume of liquid at the temperature of observation, and this volume is called the "Coefficient of Absorption" of the gas in the liquid.

* See Bunsen's Gasometric Analysis, London: Walton and Maberly, 1857, article, Absorption; also Phil. Mag. [4] ix. 116 and 181; also Ann. Ch. Pharm. xlv. 129; xcv. 1; xcix. 129; also Chem. Soc. Qu. J. viii. 16.

The methods adopted by Bunsen and his pupils for the determination of the coefficients of absorption of gases by water and alcohol,—for these are the only liquids which have as yet been employed,—varied according to the solubility of the gas in the liquid used. In the case of the very soluble gases, the amount of the absorbed gas was determined chemically; in the case of the less soluble gases, a peculiar eudiometric process was adopted.

The gases whose solubility has been determined by chemical methods are, *sulphuretted hydrogen, sulphurous acid, ammonia, and chlorine*; these gases, evolved in state of purity, were passed for a long time through a large volume of liquid, which had been freed from air by long continued boiling, and was kept at a constant temperature during the experiment. After the gas had passed so long through the liquid that the latter was completely saturated, the barometric pressure was read off and a known volume of the liquid was withdrawn, special precautions to avoid possible loss of gas being observed, and the gas contained in this liquid quantitatively determined either by means of volumetric analysis or by the other ordinary processes of analytical chemistry.

If the volume of the liquid does not undergo any appreciable increase in bulk, owing to the absorption of the gas, we are able easily to calculate the coefficients of absorption from the data obtained by this process. If, however, as is the case with all the more soluble gases, the volume of the saturated liquid is considerably larger than that of the liquid before saturation, it is necessary, either to determine the amount of its increase of bulk, or, what is the same thing, the specific gravity of the saturated solution, or else, by a modification of the process, to saturate only a small volume of liquid, and to determine the absolute quantity of gas absorbed, by weighing before and after the saturation. As an example of this calculation, we may choose an actual experiment of the determination of the solubility of sulphurous acid in absolute alcohol at 20° . It was found that 4 volumes of the alcohol saturated with sulphurous acid at 20° C. and under a pressure of 3.7438 m. of mercury, contained 1.092 grms. of sulphurous acid:—required the volume of gas at 0° and 0.76 contained in the unit-volume of pure alcohol, when the specific gravity of the saturated solution at 20° is 0.9404, and that of the pure alcohol 0.792? From these data we find that the weight of the measured volume is 3.7616 grms.; and 2.6696 grms. is the weight, or 3.371 c.c. the volume of alcohol which absorbed 1.092 grms. of sulphurous acid at 20° , and under the pressure of 3.7438 m.; so that, according to Henry's law, the quantity which would have been absorbed under a pressure of 0.760 m. is 1.115 grms.; and as one cubic centimetre of sulphurous acid gas at 0° and 0.76 weighs 0.002861 grms., the volume of gas at 0° and 0.76 absorbed by 3.371 c.c. alcohol is 389.8 c.c.; or the coefficient of absorption of sulphurous acid in alcohol at 20° is 115.7.

For the determination of the coefficients of absorption of gases less soluble in the liquid employed, Bunsen has constructed an instrument termed an "Absorptionmeter," represented in *figs. 508 and 509*, which he thus describes:—The absorption tube *e*, *fig. 508*, divided into millimetres and calibrated, has a small iron band *b*, *fig. 509*, furnished with a screw luted on to its lower and open end; this fits into another screw attached to the small iron stand *a*. By means of this arrangement, the open end of the tube can be screwed down against a plate of caoutchouc covering the bottom of the stand, and the tube thus completely closed. On each side of the stand are fixed two steel springs, *c c*, which fit into two vertical grooves inside the wooden foot of the apparatus *f*, *fig. 508*, so that the little iron stand *a*, *fig. 509*, can be raised or depressed, but not turned on its axis horizontally. The outer cylinder, *g g*, *fig. 508*, is not cemented into the wooden foot *f*, or into the iron rim *A*, but the ground glass edges of the cylinder are pressed against caoutchouc rings, inserted in the foot and in the rim by means of the screws *i i*. The tubes *r r* serve to pour in mercury, so that any desired pressure is obtained in the absorption tube by

Fig. 508.

Fig. 509.

raising or depressing the level of the mercury in the inner glass cylinder. The temperature of the surrounding water is determined by the small thermometer *k*. The upper end of the outer cylinder is closed by an iron lid having a hinge at one side, and fastened down by means of a nut and screw attached to the iron rim *h*, fitting into a groove *p*, in the side of the lid. In the inside of the lid there is a raised rim of iron, over which a thick sheet of caoutchouc is extended and fastened by a screwed ring *s*. This distended caoutchouc serves as a spring against which the top of the tube can be pressed, keeping it in a fixed position during the violent agitation necessary for the process of absorption.

The mode of using this apparatus, and the method of calculation employed in these experiments, is best explained by an actual example. We select for this purpose the determination of the coefficient of absorption of nitrogen in water at 19°C . A certain quantity of the gas under examination is placed in the absorption tube, over mercury in the mercurial trough, and its volume determined, the usual precautions as to reading off pressure, temperature, &c. being taken, as in the ordinary process of gas analysis. The following observations are made:

Lower surface of mercury in outer cylinder	$a = 423.6$ mm.
Upper surface of mercury in absorption tube	$b = 124.1$ "
Barometric pressure	$p = 746.9$ "
Temperature of the absorptiometer	$t = 19.2^{\circ}\text{C}$.
Temperature of the barometer	$\tau = 19.0^{\circ}$ "

A quantity of water perfectly freed from air is next introduced under mercury into the tube, which is then screwed tightly against the caoutchouc plate, and the tube thus closed, is placed in the cylinder *g g*, containing some mercury, and over that a quantity of water. As soon as the pressure within and without has been equalised by slightly turning the tube, it is again closed, and the whole apparatus rapidly agitated for about a minute. This agitation, with opening and closing of the tube, is continued many times, until no further change of volume is perceptible. The observations necessary for the measurement and reduction of the residual gas are thus made:

Level of mercury in outer cylinder	$a' = 352.2$ mm.
Level of mercury in absorption tube	$b' = 350.7$ "
Upper level of water in absorption tube	$c' = 65.5$ "
Upper level of water in outer cylinder	$d' = 8.0$ "
Barometric pressure	$p' = 746.3$ "
Temperature of the absorptiometer	$t' = 19.0^{\circ}\text{C}$.
Temperature of the barometer	$\tau' = 18.9^{\circ}$ "

From the first series of observations, the pressure on the dry nitrogen is obtained by subtracting the height of the column of mercury in the tube, ($a - b = 299.5$ mm.), and the tension of the vapour of water at 19.2° ($= 16.6$ mm.), from the barometric pressure, the height of both the columns of mercury being corrected for the expansion which they undergo in being heated from 0° to 19.2° . This pressure, P , is found to be equal to $744.4 - 298.5 - 16.6 = 429.3$ mm.

The volume of nitrogen employed, when reduced to 0° , is, according to the table of capacity of the instrument, found to be $32.608 = V$, expressed in arbitrary units. The barometric pressure, corrected for expansion, after the experiment, is 743.8 mm.; the height of the corrected column of mercury inside the tube, is 1.5 mm.; the height of the column of water in the tube is 285.2 mm.; that in the outer cylinder 344.2 mm.; so that the column of water which has to be added to the barometric pressure is $344.2 - 285.2 = 59.0$ mm., equal to 4.4 mm. of mercury; the tension of the vapour of water at 19.2° is 16.3 mm.; and hence the pressure on the unabsorbed nitrogen is $P_1 = 743.8 + 4.4 - 1.5 - 16.3 = 730.5$ mm.

The volume of unabsorbed gas, reduced to 0° , is found from the table of capacity to be $16.522 = V_1$ of the same arbitrary units, whilst the volume of water employed is $182.37 = A$ units.

From these data, the coefficient of absorption can be easily obtained. The volume of nitrogen reduced to the pressure 760 mm. was, before the absorption, $\frac{VP}{760}$; the reduced volume after the absorption is $\frac{V_1P_1}{760}$; and hence the volume absorbed under the

pressure P_1 is $\frac{VP}{760} - \frac{V_1P_1}{760}$. If now the law of Henry be correct in the case of nitrogen and water, the volume of gas absorbed under the pressure of 760 mm. will be greater than that absorbed under the pressure P_1 in the proportion $\frac{760}{P_1}$; or it will be

$\frac{VP}{P_1} - V_1$. Hence the volume of gas absorbed by the unit-volume of liquid in the co-efficient of absorption is:

$$C = \frac{1}{h} \cdot \left(\frac{VP}{P_1} - V_1 \right),$$

or, for the special case we are considering:

$$C = \frac{1}{182.37} \cdot \left(\frac{32.608 \times 429.3}{730.5} - 16.522 \right) = 0.01448.$$

It is absolutely essential that the liquids employed in these absorptiometric determinations be freed completely from air or other gases held in solution; this is best accomplished by continuous boiling in a flask whose neck has been drawn out to a fine point before the blowpipe, so that the flask can be instantly hermetically sealed. The vessel containing the liquid, which ought to strike against the glass like a water-hammer, is opened under mercury, and thus all possible entrance of air is prevented.

By the help of this instrument, and by the application of a method of calculation similar to the example just cited, the following coefficients of absorption in water and absolute alcohol were experimentally determined. In cases in which the solubility of the gas varied with the temperature, a simple interpolation formula, $c = A + Bt + Ct^2$, serves to express the relation with sufficient exactness.

1. *Nitrogen*.—The nitrogen was prepared by passing atmospheric air, freed from carbonic acid and ammonia, over red-hot copper turnings.

In water (from 0° to 20° C.); $c = 0.020346 - 0.00053887t + 0.000011166t^2$.

In alcohol* (from 0° to 25° C.); $c = 0.126338 - 0.000418t + 0.000006t^2$.

From these formulae the following coefficients are calculated:

For Water.				For Alcohol.			
0° C.	0.02035	12° C.	0.01549	0° C.	0.12634	14° C.	0.12166
2°	0.01932	14°	0.01500	2°	0.12553	16°	0.12119
4°	0.01838	16°	0.01458	4°	0.12476	18°	0.12076
6°	0.01752	18°	0.01426	6°	0.12404	20°	0.12038
8°	0.01657	20°	0.01403	8°	0.12338	22°	0.12005
10°	0.01607			10°	0.12276	24°	0.11976
				12°	0.12219		

2. *Hydrogen*.—The hydrogen was prepared from pure zinc and sulphuric acid.

In water (from 0° to 20° C.); $c = 0.0193$.

In alcohol (from 0° to 25° C.); $c = 0.06925 - 0.0001487t + 0.000001t^2$.

Hence:

In Water.		In Alcohol.			
$c = 0.0193$		0° C.	0.02569	10° C.	0.06786
constant.		2°	0.06896	12°	0.06761
		4°	0.06867	14°	0.06731
		6°	0.06839	16°	0.06713
		8°	0.06813	18°	0.06690
				20° C.	0.06668
				22°	0.06646
				24°	0.06626

3. *Carbonic Oxide*.—Prepared by heating pure formate of magnesia with strong sulphuric acid; treatment with a potash-ball showed that the gas was pure.

In water (from 0° to 20° C.); $c = 0.032874 - 0.00081632t + 0.000016421t^2$.

In alcohol (from 0° to 25° C.); $c = 0.20443$.

Hence:

For Water.				For Alcohol.	
0° C.	0.03287	8° C.	0.02739	$c = 0.20443$	
2°	0.03131	10°	0.02635	constant.	
4°	0.02987	12°	0.02544		
6°	0.02857	14°	0.02466		
		16° C.	0.02402		
		18°	0.02350		
		20°	0.02312		

4. *Carbonic Acid*.—Prepared by the action of strong sulphuric acid on chalk, due precautions as to its purification being taken.

In water (from 0° to 20° C.); $c = 1.7967 - 0.07761t + 0.0016424t^2$.

In alcohol (from 0° to 25° C.); $c = 4.32955 - 0.09395t + 0.00124t^2$.

* The coefficients of absorption for all the following gases in alcohol were determined by Carius. See Ann. Ch. Pharm. xcix. 126.

Hence:

For Water.				For Alcohol.			
0° C.	1.7967	12° C.	1.1018	0° C.	4.3295	14° C.	3.2573
2°	1.8481	14°	1.0321	2°	4.1466	16°	3.1438
4°	1.5126	16°	0.9753	4°	3.9736	18°	3.0402
6°	1.3901	18°	0.9318	6°	3.8105	20°	2.9465
8°	1.2809	20°	0.9014	8°	3.6573	22°	0.28628

				12°	3.3807		

5. *Marsie Gas*.—The gas employed for the experiments with water was collected from the mud-volcanoes at Bulganak in the Crimea, and being preserved in sealed tubes was shown by analysis to contain neither oxygen, nitrogen, carbonic acid, nor any other gas. The gas used for the alcohol-absorption was prepared by the usual process from acetate and hydrate of potassium, and eudiometric analysis showed that it was pure.

In water (from 0° to 20° C.); $c = 0.05449 - 0.0011807 t + 0.000010278 t^2$.
In alcohol (from 0° to 24° C.); $c = 0.522586 - 0.0028655 t + 0.0000142 t^2$.

Hence:

For Water.				For Alcohol.			
0° C.	0.05449	12° C.	0.04180	0° C.	0.52259	14° C.	0.48525

10°	0.04372			10°	0.49535	24°	0.46199
				12°	0.49024		

6. *Ethylene*.—Prepared in the usual manner from alcohol and sulphuric acid; all traces of alcohol and ether-vapour and of higher hydrocarbons, were removed by absorbing a large portion of the collected gas by strong sulphuric acid before the experiment. Eudiometric analysis proved the purity of the gas.

In water (from 0° to 20° C.); $c = 0.25629 - 0.00913631 t + 0.000188108 t^2$.

In alcohol (from 0° to 24° C.); $c = 3.59498 - 0.057716 t + 0.0006812 t^2$.

Hence:

For Water.				For Alcohol.			
0° C.	0.2563	12° C.	0.1737	0° C.	3.5950	14° C.	2.9205

4°	0.02770	10°	0.02355	16°	0.02121		

10. *Methyl-gas in Water.*—Prepared by the action of zinc-methyl upon iodide of methyl.

In water (from 0° to 20° C.); $c = 0.0871 - 0.0033242t + 0.0000603t^2$.

Hence:

For Water.

0° C.	0.0871	6° C.	0.0693	12° C.	0.0559	18° C.	0.0468
2°	0.0807	8°	0.0644	14°	0.0524	20°	0.0447
4°	0.0748	10°	0.0599	16°	0.0493		

11. *Oxygen in Water.*—The coefficients of absorption of oxygen in water were not determined directly by the process described, because it was found that although the mercury contained in the absorption tube was purified as completely as possible, it still contained traces of foreign metals, which on agitation were oxidised at the expense of the dissolved gas, thus rendering the determination of the coefficients of absorption incorrect.

In order to determine the solubility of oxygen in water, the following indirect method was adopted, which, however, presupposes the applicability of Dalton's law of partial pressures. If both oxygen and nitrogen obey this law, it is not difficult from the known coefficients of absorption of nitrogen, from the known composition of the air, and from the relative amounts of the two gases dissolved when water is saturated with air, to calculate the coefficients of absorption of oxygen in water. The relative quantities of oxygen and nitrogen dissolved in water through which air was passed to saturation were found by experiment to remain constant; that is, at all the observed temperatures, the quantity of oxygen contained in 100 parts of absorbed gas is 35.91 = V^o , and that of nitrogen 65.09 = V^n . Hence we see that, as the total amount of air absorbed at different temperatures varies, the curve representing the relation between the amount of absorbed oxygen and the temperature, must be parallel with the curve representing the same relation for nitrogen.

The composition of one volume of the atmosphere we may take to be 0.2096 = O volume of oxygen, and 0.7904 = N volume of nitrogen; if now, C^o represent the coefficient of absorption of oxygen, and C^n that of nitrogen at any given temperature, the volumes of absorbed oxygen and nitrogen contained in the volume V of air absorbed under the pressure P , are, according to Dalton's law,—

$$V^o = \frac{C^o V O P}{0.76 (N + O)}; \text{ and } V^n = \frac{C^n V N P}{0.76 (N + O)};$$

hence by division we have

$$C^o = C^n \frac{V^o N}{V^n O}; \text{ or } C^o = C^n \frac{35.91 \times 0.7904}{65.09 \times 0.2096} = C^n \times 2.0225$$

or expressed in terms of the temperature alone:

$$(\text{from } 0^\circ \text{ to } 20^\circ); c = 0.4115 - 0.00108986t + 0.000022563t^2.$$

And hence:

0°	0.04114.	2°	0.03907.	4°	0.03717.	6°	0.03544.	8°	0.03389.	10°	0.03250.
12°	0.03133.	14°	0.03034.	16°	0.02949.	18°	0.02884.	20°	0.02838.		

12. *Oxygen in Alcohol.*—The determinations of the solubility of oxygen in alcohol were made in the usual way with the absorptiometer, the error arising from oxidation of the metals contained in the mercury proving in this case inappreciable. The quantity of oxygen dissolved in alcohol between 0° and 24° C. remained constant:

$$(\text{from } 0^\circ \text{ to } 24^\circ); c = 0.28397 \text{ constant.}$$

13. *Atmospheric Air in Water.*—When the volume of a mixture of two or more gases is infinitely large as compared with that of the absorbing liquid, the total quantity of gas absorbed, or the coefficient of absorption of the mixture, is easily found from the several coefficients of absorption of the component gases and their relative proportion in the mixture. When the volume of the gas bears a finite relation to that of the absorbing liquid, and the gases are unequally soluble, the alteration effected in the

composition of the gas by the absorption must be brought into consideration. In the following calculations of the solubility of atmospheric air in water, the volume of the gas is considered as infinite compared with that of the water. Hence, as 1 volume of air contains 0.2096 vol. of oxygen, and 0.7904 vol. of nitrogen, the coefficient of absorption of air in water, according to Dalton's law, is $C^a = C^o \times 0.2096 + C^n \times 0.7904$ where C^o and C^n represent the coefficient of absorption of oxygen and nitrogen at the given temperature. The coefficient expressed in terms of the temperature alone is:

$$(\text{from } 0^\circ \text{ to } 20^\circ); C^a = 0.247064 - 0.000654358t + 0.0000135469t^2.$$

and hence:

0° C. 0.02471	6° 0.02128	12° 0.01882	18° 0.01732
2° 0.02345	8° 0.02034	14° 0.01822	20° 0.01704
4° 0.03227	10° 0.01953	16° 0.01771	

The coefficients of absorption of the following gases, which are much more soluble than the preceding, were determined by the chemical method referred to above. The determinations of the solubility of sulphurous acid, sulphuretted hydrogen, and chlorine in water, were made by Schönfeld (Ann. Ch. Pharm. xcv. 1); those in alcohol by Carius (*loc. cit.*)

14. *Sulphurous Acid in Water*.—The amount of absorbed gas was estimated chemically, by the iodometric method of analysis, reduction being made in the calculation for the alteration of the bulk of the liquid by the absorption of gas.

The following expressions give coefficients which approximate very closely to the observed amounts:

$$(\text{from } 0^\circ \text{ to } 20^\circ) \text{ for pure water; } c = 79.787 - 2.6077t + 0.029349t^2.$$

$$(\text{from } 20^\circ \text{ to } 40^\circ) \text{ " " " } c = 75.182 - 2.1716t + 0.01903t^2.$$

Hence the following values:

$$0^\circ 79.789; 10^\circ 56.647; 20^\circ 39.374; 30^\circ 27.161; 40^\circ 18.766.$$

15. *Sulphurous Acid in Alcohol*.—In pure alcohol the coefficient is found from the formula—

$$(\text{from } 0^\circ \text{ to } 24^\circ), c = 328.62 - 16.95t + 0.3119t^2,$$

hence the coefficients are:

$$0^\circ 328.62; 5^\circ 251.67; 10^\circ 190.31; 15^\circ 144.55; 20^\circ 114.48; 24^\circ 101.47$$

16. *Sulphydic Acid in Water*.—The sulphur of the dissolved gas was weighed as sulphate of barium. The interpolation formula obtained from the experiments is—

$$(\text{from } 0^\circ \text{ to } 40^\circ); c = 4.3706 - 0.083687t + 0.0005213t^2,$$

hence the coefficients are

$$0^\circ 4.3706; 10^\circ 3.5858; 20^\circ 2.9053; 30^\circ 2.3290; 40^\circ 1.8569.$$

17. *Sulphydic Acid in Alcohol*.—Experiment gave—

$$c = 17.891 - 0.65598t + 0.00661t^2.$$

Hence:

$$(\text{from } 0^\circ \text{ to } 25^\circ) 0^\circ 17.891; 4^\circ 15.373; 8^\circ 13.066; 12^\circ 10.971; 16^\circ 9.086; 20^\circ 7.415; 24^\circ 5.955.$$

18. *Chlorine in Water*.—The coefficients of chlorine in water cannot be determined below 10° , as at that temperature a crystalline hydrate of chlorine is formed. The quantity of absorbed gas was determined by the iodometric method. Experiment gave the following interpolation formula:

$$(\text{from } 10^\circ \text{ to } 40^\circ) c = 3.0361 - 0.046196t + 0.0001107t^2.$$

Hence:

$$10^\circ 2.5852; 20^\circ 2.2405; 30^\circ 1.7499; 40^\circ 1.3655.$$

18. *Ammonia in Water*.—The solubility of ammonia in water has been determined by Dr. Carius (Ann. Ch. Pharm. xcix. p. 129). The following formula gives the result of his experiments:

$$(\text{from } 0^\circ \text{ to } 25^\circ), c = 1040.63 - 29.496t + 0.067687t^2 - 0.0095621t^3.$$

More recently the solubility of ammonia in water at different temperatures and under direct variation of pressure, has been exactly estimated by Messrs. Roscoe and Dittmar (Chem. Soc. Qu. J. xii. 147). These chemists have shown that the numbers given by Carius are all 10 per cent. too low, owing to the existence of unobserved experimental errors running through his determinations. They have also proved that the quantity of ammonia absorbed by water at a constant temperature is not (as supposed by Carius) proportional to the pressure under which the absorption occurs. This is

clearly seen from the following table, in which (G) gives the weight in grammes of ammonia absorbed by 1 gramme of water at 0° C. under variation of direct pressure (P) from 0.01 m. to 2.0 m. of mercury.

P.	G.	P.	G.	P.	G.	P.	G.	P.	G.
0.01	0.044	0.30	0.515	0.80	0.906	1.30	1.310	1.80	1.906
0.04	0.149	0.40	0.607	0.90	0.968	1.40	1.415	1.90	2.046
0.10	0.275	0.50	0.690	1.00	1.037	1.50	1.526	2.00	2.195
0.15	0.351	0.60	0.768	1.10	1.117	1.60	1.645		
0.20	0.411	0.70	0.840	1.20	1.208	1.70	1.770		

The following numbers give the weight of ammonia absorbed by one gramme of water at the temperatures annexed under the barometric pressure 0.76 m., as found by Roscoe and Dittmar.

° C.	grm.	° C.	grm.	° C.	grm.	° C.	grm.
0°	0.875	16°	0.582	32°	0.382	48°	0.244
4°	0.792	20°	0.526	36°	0.343	52°	0.214
8°	0.713	24°	0.474	40°	0.307	56°	0.186
12°	0.645	28°	0.426	44°	0.275		

The experiments which have been made to verify the law of pressures, have been applied not so much to the determination of the exactitude of the law under high pressures, as to the exemplification of the truth of the law of partial pressures. Thus the solubility of carbonic acid, under varying pressures, has only been examined by Bunsen between the limits of 523 and 725 millimetres of mercury, whilst Henry employed a pressure as high as 1.4 metres of mercury. In the case of gaseous mixtures, for which the instrument was more suited, the precision of the law has been demonstrated by a large number of experiments with different gases. Thus, in mixtures of carbonic acid and hydrogen in water, of carbonic acid and carbonic oxide, of carbonic oxide and marsh gas, of carbonic acid and hydrogen, and of carbonic oxide, marsh gas, and hydrogen in alcohol, it has been shown that the component gases are absorbed in quantities exactly regulated by Dalton's law.

In order to understand the mode in which these verifications of the law are obtained, it will be necessary in the first place to develop the general expression for the alterations which a mixture of *two* gases undergoes on absorption, and then to apply this general formula to special examples. If Dalton's law be correct, that in a gaseous mixture undergoing absorption, when the volume of the liquid is not inappreciable compared with that of the gas, the component gases are dissolved in quantities dependent upon the pressures of the respective components of the residual gas, it will not be difficult to calculate from absorptometric data the relative proportion of the gases in the unabsorbed residue. If this calculated result agrees with a direct eudiometric analysis, the law is proved to be true. What we have first to calculate is, then, the composition of the residual gas from the other absorptometric data. For this purpose let all the volumes of gas be reduced to 0° C.; then let the total volume of V gas employed in the experiment, be under the pressure P . In the unit-volume of this mixed gas let there be v volumes of the one, and v_1 volumes of the other gas. Let the coefficient of absorption of the first gas be α , that of the second β , and the volume of the absorbing liquid h . Further, let the total volume of the gas remaining after the absorption be V_1 ; and, lastly, let the unit-volume of this gas contain u volumes of the one, and u_1 volumes of the other constituent gas. These values of u and u_1 are the unknown quantities which have to be found from the given data.

The volume V contains vV volumes of the first gas at the pressure P , or $\frac{vVP}{0.76}$ volumes at 0.76. This volume is divided by absorption into two parts; the first part x remains behind after the absorption as free gas; the second, x_1 , is that absorbed by the liquid. The quantity of this latter is determined by the law of absorption; the unit of liquid absorbs α volume under the pressure 0.76: hence, under the pressure P , h volumes of liquid will absorb $\frac{\alpha h P}{0.76}$. As, however, the first gas is expanded by mixing with the second, from x to $\frac{V_1 P}{0.76}$, the quantity of gas absorbed by h is, by virtue of the partial pressure $\frac{\alpha h x}{V_1} = x_1$. Hence, $x + \frac{\alpha h x}{V_1} = \frac{vVP}{0.76}$, and $x = \frac{vVP}{0.76(1 + \frac{\alpha h}{V_1})}$; and, by similar reasoning, the volume of the second residual gas, $y = \frac{v_1 V P}{0.76(1 + \frac{\beta h}{V_1})}$.

Hence if $vVP = A$; $v_1VP = A_1$; $\left(1 + \frac{\alpha h}{V_1}\right) = B$, and $\left(1 + \frac{\beta h}{V_1}\right) = B_1$, we obtain

$$\frac{AB_1}{AB_1 + A_1B} = \frac{x}{x+y} = u \quad (1)$$

$$\frac{A_1B}{AB_1 + A_1B} = \frac{y}{x+y} = u_1$$

The reverse of this calculation is to obtain the composition of the original gaseous mixture from the observed quantities V , P , V_1 , P_1 , α , β , and h . In this way an analysis is in fact made of the mixture of gases, without resort to any chemical decomposition; and this absorptiometric analysis is often of the greatest importance, as it solves questions which cannot be attacked by the usual eudiometric methods.

Let x represent the original volume, and x_1 the unabsorbed residue of the first gas in both cases reduced to the pressure 1; and, as before, let V_1 be the volume of the unabsorbed gas under the pressure P_1 .

The pressure of the unabsorbed portion of the first gas is then $\frac{x_1}{V_1}$ and the volume of absorbed gas reduced to this pressure is αh , or reduced to the pressure 1, it is $\frac{x_1}{V_1} \cdot \alpha h$.

Hence $x = x_1 + \frac{x_1}{V_1} \cdot \alpha h$; and the pressure of the unabsorbed portion of the first is $\frac{x_1}{V_1} = \frac{x}{V_1 + \alpha h}$. In like manner, the pressure of the second gas is obtained, and we have the following expressions for the pressure before and after the absorption:

$$P = \frac{x}{V} + \frac{y}{V}; \quad P_1 = \frac{x}{V_1 + \alpha h} + \frac{y}{V_1 + \beta h}.$$

If we then set $VP = W$; $(V_1 + \alpha h)P_1 = A$; $(V_1 + \beta h)P_1 = B$, we have the volumes of the first and second gases in the unit-volume of the mixture, namely:

$$\frac{x}{x+y} = \frac{W-B}{A-B} \cdot \frac{A}{W}; \quad \text{and} \quad \frac{y}{x+y} = \frac{A-W}{A-B} \cdot \frac{B}{W}. \quad (2)$$

By help of these formulæ we can test the truth of Dalton's law; for if the result thus calculated agrees with those determined by experiment, the basis upon which the calculations are founded must be correct.

In order then to test the applicability of these formulæ, a mixture of carbonic acid and hydrogen was made, and the volume of each gas determined by eudiometric analysis; the gas was found to consist of:

Hydrogen	26.81
Carbonic acid	73.19
	<hr/> 100.00

An absorptiometric analysis of the same gas was then made, and by means of formula (2), the composition of the original gaseous mixture found to be:

Hydrogen	26.67
Carbonic acid	73.33
	<hr/> 100.00

The composition of the residual gas was found by direct analysis to be:

Hydrogen	93.01
Carbonic acid	6.99
	<hr/> 100.00

Or the partial pressure of the hydrogen was 0.6688 m., and that of the carbonic acid 0.04275 m.

The mean of three absorptiometric experiments gave as the composition of the residual gas, calculated according to formula (1):

Hydrogen	91.64
Carbonic acid	8.36
	<hr/> 100.00

or the partial pressure of the hydrogen was 0.6685 m., and that of the carbonic acid 0.0693 m.

From the close agreement between the results of the eudiometric and absorptiometric analyses, it is seen that Dalton's law holds good, at least for the two gases here considered. Many other gaseous mixtures have already been examined with a like

result; for the details of these experiments, we must, however, refer to the memoirs already cited.

There are, nevertheless, cases in which the constituents of a mixture of gases are not dissolved in liquids in the proportion required by the law of partial pressures, although no definite chemical combination occurs. Thus, for instance, Roscoe (Chem. Soc. Qu. J. viii. 14) has shown that mixtures of equal volumes of chlorine and hydrogen, and mixtures of varying proportions of chlorine and carbonic acid, do not dissolve in water in quantities proportional to the partial pressures of each gas. As, however, both hydrogen and carbonic acid have been shown to obey the law, the discrepancy can only arise from the chlorine. The mixture of equal volumes of chlorine and hydrogen was obtained perfectly pure and of constant composition, by the electrolysis of concentrated hydrochloric acid; and it was found that when water was saturated with this gas, the amount of chlorine dissolved was always much larger than that required by the law of partial pressures, as calculated from the coefficients of absorption and the relative volumes of the two gases; thus, at 14.4° , 9.834 grms. of water dissolved 14.70 volumes of chlorine, whereas the calculated quantity is only 11.65 volumes; and similarly for other temperatures. From a number of experiments, Roscoe concluded that no definite decomposition of the water by the chlorine takes place, which might possibly account for the increased solubility of that gas; and hence it appeared that, at temperatures not very far removed from the point at which a hydrate is formed (the experiments extended from 13° to 38°), chlorine is retained by water with a force which, although not great enough to effect a definite combination, is sufficient to disturb the regular action of the law of absorption. The amount of this disturbance, that is, the quantity of chlorine contained in the liquid over and above that required by the law, can be easily calculated, and it has been shown that this amount, in the case of chlorine and hydrogen, diminishes with increase of temperature. In order to see whether this molecular disturbance is dependent upon the nature of the gas in contact with the chlorine, the solubility of mixtures of chlorine and carbonic acid was determined, and it appeared that an excess of chlorine above the quantity required by the law is dissolved, but that the amount of this chemically attached chlorine is, as far as the experiments reached, independent of changes of temperature, proving, therefore, that the amount of this molecular disturbing action depends on the nature of the gases or other substances present.

The limits of pressure beyond which gases do not obey the law of pressure, have not as yet been experimentally ascertained in many cases. It appears, however, that the law is not strictly applicable, at least, in the case of the more soluble gases, within ranges of pressure varying from 0 to 2 atmospheres. Thus, as has been stated, the quantity of ammonia absorbed by water under varying pressure differs very considerably from that required by theory; and this result was fully proved by experiments made by Mr. Sims in the writer's laboratory (Chem. Soc. J. xiv. 1). These experiments showed that under direct variation of pressure from 0.050 to 2.5 metres of mercury the quantity of ammonia dissolved in water at all temperatures below 100° C. is not directly proportional to the pressure; but that the deviation becomes less as the temperature increases, until at 100° C. the law of Dalton holds good. Similar results were obtained for *sulphurous acid*; this gas was shown to obey the law only at temperatures above 50° C. Further experiments on this subject, made at the writer's suggestion, by Mr. W. M. Watts, prove that admixture of ammonia with air produces the same effect on the solubility of that gas in water as a direct diminution of pressure.

When gases obeying Dalton's law are absorbed in a liquid, and this liquid is placed in conditions under which the pressure on the absorbed gases is reduced to 0, these gases escape in time completely from the liquid. This reduction of the pressure can be effected in many ways, either by actually removing all pressure, except that of the tension of the liquid, by evacuation under the receiver of an air-pump; or by placing the saturated liquid in an atmosphere of a gas different from any of those absorbed, whose volume may be regarded as infinite as compared with that of the absorbed gases; or lastly by bringing the liquid to its boiling point and continuing the ebullition, or what is the same thing, by passing a foreign gas or vapour through the liquid. In all these cases, the absorptiometric equilibrium is, after a certain time, established, and is dependent upon the partial pressures. From these considerations we see how impossible it is to keep a gas pure for any length of time when standing over a liquid in which it is ever so slightly soluble; thus, for instance, when hydrogen, one of the least soluble of the gases, is placed over water, a continuous interchange between the air outside, and the hydrogen inside, goes on through the medium of the water, the hydrogen dissolving and then escaping into the air where the partial pressure on it is 0, and the air in turn entering into the hydrogen, until an equilibrium in accordance with the pressures is established, which in this case only occurs when all the hydrogen has escaped and the vessel is filled with air.

This complete removal of absorbed gases by ebullition, or by contact with a foreign gas, does not occur in the case of most of those which are retained by the liquid with a greater degree of force than those obeying the law of pressures; thus, for instance, hydrochloric acid gas cannot be completely expelled from its aqueous solution by boiling or by passing air through the liquid. Water saturated at ordinary temperature with hydrochloric acid gas, loses on heating more gas than water, until a certain point is reached, at which the gas and water distil over in constant proportions. For the ordinary atmospheric pressure, this constant ratio occurs at a temperature of 110° , when the distilled liquid contains 20·2 per cent. of anhydrous acid; this ratio is, however, dependent upon the temperature; when the temperature is diminished, the concentration of the residual acid is increased. Hence, under ordinary pressures, a solution containing less than 20 per cent. of acid must become more concentrated when boiled and such is found to be the case, hydrochloric acid being in fact non-volatile when mixed with a certain quantity of water.*

The solubility of hydrochloric acid gas in water at different temperatures, and under variation of pressure, has been determined by Messrs. Roscoe and Dittmar (Chem. Soc. Qu. J. xii. 128). As might be expected, the amount of hydrochloric acid dissolved increases but slightly with increase of pressure. The following table gives the weight of this gas (G), which is absorbed by one gramme of water at 0° C. under the pressure (P) of mercury.

P.	G.	P.	G.	P.	G.	P.	G.
0·06 m.	0·613	0·30 m.	0·738	0·70 m.	0·817	1·10 m.	0·869
0·10	0·657	0·40	0·763	0·80	0·831	1·20	0·882
0·15	0·686	0·50	0·782	0·90	0·844	1·30	0·895
0·20	0·707	0·60	0·800	1·00	0·856		

The relation between the amount of dissolved hydrochloric acid gas and the temperature is seen from the appended numbers, giving the weight of gas absorbed under the normal pressure of 0·76 m.

0° C.	grm.	16°	grm.	32°	grm.	48°	grm.
4°	0·804	20°	0·721	36°	0·649	52°	0·589
8°	0·783	24°	0·700	40°	0·633	56°	0·575
12°	0·762	28°	0·682	44°	0·618	60°	0·561

Although not obeying the simple laws of absorption, hydrochloric acid gas does not, as Roscoe and Dittmar have shown, form any compounds with water which can be regarded as definite hydrates, the amount of absorbed gas varying with every change of physical circumstance. Roscoe has also shown (Chem. Soc. J. xiii. 146, and xv. 270) that the same law applies to the formation of all the hydrated acids of constant boiling point, none of which can be regarded as definite chemical compounds. For further information upon this subject we must, however, refer the reader to the original memoirs.

Although gases, as a rule, increase in solubility with diminution of temperature, yet it is found in most cases that the whole of the absorbed gas is liberated on the solidification of the liquid. Thus when water freezes, the whole of the dissolved air escapes in bubbles; and silver, which, according to Gay-Lussac, absorbs when melted about twenty times its volume of oxygen, expels it on solidifying, giving rise to the remarkable phenomenon of the "spitting" of silver. In the case of the liquefiable gases, however, such as carbonic acid, hydrochloric acid, and ammonia, no such expulsion of the gas on solidification of the liquid has been observed.

Many of the applications of these laws of absorption are both interesting and important; thus, instances occur in which eudiometric analysis by itself is unable completely to decide the composition of a gaseous mixture, as, for example, in the case of a mixture of equal volumes of methyl and hydrogen gases, which we cannot distinguish by combustion-analysis from marsh-gas; so that we are in uncertainty as to whether the gas evolved by the action of a hydrated alkali upon an acetate is really marsh-gas or a mixture of hydrogen and methyl. In this case, then, absorptiometric determinations are of the highest value; for in this way, by means of a single physical experiment, we are able to solve this doubtful question. The considerations and the formulae already given, generally developed in Bunsen's memoir, render it possible to calculate from the absorptiometric data, the composition of an unknown gaseous mixture; that is to say, to determine at the observed temperature the coefficients of the absorbed

* The vapour of water acts precisely as a foreign gas would do in reducing the partial pressure hence in all the calculations of the absorption-coefficients of gases in liquids determined above the vapour of water present in the atmosphere of otherwise pure gas existing above the liquid, it is regarded as a foreign gas, which therefore alters the pressure on the absorbed gas. It has been attended to in but few of the chemical determinations yet made of the mixture.

and the partial pressures of the unabsorbed gases. If, then, with the data afforded by the absorption of the gas of the acetates, the coefficients are calculated, on the assumption that the gas consists of a mixture of equal volumes of hydrogen and methyl, it is found that the sum of the coefficients has a negative value, instead of being equal to the sum of the two numbers given in the tables for methyl and hydrogen. If, on the other hand, the calculation is based on the supposition that the gas from the acetates is not a mixture but a single gas, the value found for the coefficient by calculation is identical with that determined for true marsh-gas at the observed temperature. Hence we may conclude that the gas prepared from the acetates is neither a mixture of methyl and hydrogen, nor a substance isomeric with marsh-gas, but that it is actually the same body that issues from the mud-volcanoes in the Crimea.

The same degree of uncertainty prevails respecting the identity of chloride of methyl when prepared in different ways. Baeyer (Ann. Ch. Pharm. c. iii. p. 181) has, however, lately shown that the substance prepared by heating cacodylic and hydrochloric acids has exactly the same coefficient of absorption in water as the chloride of methyl prepared in the ordinary way from wood-spirit by chloride of sodium and sulphuric acid, whilst the solubility of the compound prepared by the union of marsh-gas and chlorine in diffused light is totally different. Hence Baeyer concludes that the two first are identical, and that these two are distinct substances from the third. [Berthelot, however (Compt. rend. xlv. 916), has made other experiments from which he concludes this third substance is also a true chloride of methyl.]

Many other interesting deductions from, and applications of, the laws of absorption have already been made, for the details of which we must again refer to the original memoirs. Thus, by means of the formulæ previously developed, the composition of the gases absorbed in the water of a mineral spring can be calculated from the composition of the free gas which escapes from the water, or *vice versa*. In all cases, in fact, in which a statical equilibrium between the absorbed and free gases can occur, these calculations are applicable; and in none more so than in the composition of the gases contained in rain and dew. The composition of the atmosphere we may take to be:

Oxygen	20.9512
Nitrogen	79.0073
Carbonic acid	0.0415
							100.0000

From these numbers, and from the coefficients of the three gases, Bunsen obtained by calculation the following composition of the gases contained in rain-water.

	0°	5°	10°	15°	20°
Nitrogen	63.20	63.35	63.49	63.62	63.69
Oxygen	33.88	33.97	34.05	34.12	34.17
Carbonic acid	2.92	2.68	2.46	2.26	2.14
	100.00	100.00	100.00	100.00	100.00

A very important extension of these laws of absorption has lately been made in an investigation upon the gases of the blood carried out by Lothar Meyer.* This chemist collected the gases dissolved in the blood by boiling the diluted blood in a vacuum space, according to the method described by Bunsen in his gasometry, and liberated the portion of the carbonic acid which is combined with the alkalis of the blood by adding tartaric acid to the blood before boiling. In 100 vols. of blood, Meyer found the following volumes of gas reduced to 0° and 0.76:

Description of Blood.	Free Gas.	O.	N.	Free CO ₂ .	Combined CO ₂ .	Total CO ₂ .	Total volume of gas.

* Abstract of paper in Phil. Mag. (4) xiv. 263. The original memoir is found in Henlé and Pfister's Zeitschrift für rationelle Medizin. Neue Folge, viii. 256.

In order to obtain the coefficients of absorption of defibrinated blood for various gases, Meyer employed an apparatus somewhat different from the one used by Bunsen. It appears from his experiments that the amounts of carbonic acid, oxygen, and nitrogen absorbed in the blood, vary with the pressure, but that whereas the whole of the nitrogen obeys the law of natural pressures, only a portion of the carbonic acid and the oxygen does so; that is, in the case of both these gases, one portion of the dissolved quantity is more forcibly retained by the blood than the other, and is independent of changes of pressure, exactly as has been shown to be the case with chlorine and water. The amount of this attached oxygen is far larger than the truly absorbed portion; and from these facts we may draw the interesting conclusion that the richness or poverty of a given volume of air in oxygen, at various heights above the sea level for instance, can exert but a very slight influence on the total volume of oxygen contained in the blood, and therefore upon animal life.

II. Absorption of Gases by Solids.—Porous carbon in the form of charcoal is the only solid substance whose coefficients of absorption for various gases have been determined with any approach to accuracy. From the experiments of Saussure, made with the charcoal of box-wood, it appears that 1 volume of charcoal absorbs, at 12° C. and under a pressure of 724 millimetres of mercury, the following volumes of gas :

	Volumes.		Volumes.
Ammoniacal gas	90	Olefant gas	35.0
Hydrochloric acid gas	85	Carbonic oxide	9.4
Sulphurous acid	65	Oxygen	9.4
Sulphuretted hydrogen	55	Nitrogen	7.5
Nitrous oxide	40	Hydrogen	1.75
Carbonic acid	35		

The absorption which several other solid bodies, such as gypsum, meerschaum, woods of various kinds, wool, silk, &c., effect upon gases has also been determined by Saussure, but from the indefinite nature of the substances operated upon, the numbers obtained have but slight interest. Later experiments of Favre (Compt. rend. xxxix. 729) confirm Saussure's results, in so far, at least, as concerns the order of solubility in which the gases are arranged.

The coefficients above given represent the quantity of gas taken up by one volume of charcoal previously freed from any foreign gas absorbed in the pores. This purification of the charcoal can only be effected by a high temperature, for it has been shown that the simple removal of the atmospheric pressure by no means expels all the gas previously absorbed. Whether the whole of the absorbed gas is expelled at a red heat is as yet an unascertained matter; but it is known that much more gas is thus driven off than can be removed by the mere withdrawal of the atmospheric pressure, and hence we see that, at a high temperature, the attraction of the particles of solid and gas effecting the absorption is, if not altogether destroyed, at any rate much diminished. When a solid body is brought into an atmosphere consisting of a mixture of different gases, each one of the several gases will be absorbed in quantities dependent upon the relative amount of that gas present and its particular coefficient of absorption. Thus, for example, a piece of charcoal, or any other solid, exposed to the air, absorbs a definite quantity of nitrogen, oxygen, carbonic acid, and aqueous vapour, which thus lose their gaseous elasticity or tension, become in fact solid, and can be removed only with great difficulty. Dr. R. Angus Smith has quite recently communicated the results of some experiments upon the solubility of certain gases in charcoal (Proc. Roy. Soc. xii. 424), the most important points of which he summarises in the following sentences :

1. Charcoal absorbs oxygen so as to separate it from common air, or from its mixtures with hydrogen and nitrogen at common temperatures.

2. Charcoal continues the absorption of oxygen for at least a month, although the chief amount is absorbed in a few hours, sometimes in a few seconds, according to the quality of the charcoal.

3. It does not absorb hydrogen, nitrogen, or carbonic acid for the same period.

4. Although the amount absorbed is somewhat in the relation of the condensability of the gases by pressure, this is not the only quality regulating the absorption of oxygen at least.

5. When it is sought to remove the oxygen from charcoal by warmth, carbonic acid is formed, even at the temperature of boiling water, and slowly even at lower temperatures.

Although, from the complicated nature of the modifying conditions, we are as yet acquainted with but few exact quantitative relations concerning the absorption of gases by solid bodies, still there are many interesting proofs of the existence of this absorption, even in the case of solids whose surface is small in comparison with their bulk.

GASES—COLLECTION AND PRESERVATION OF. 805

Thus, for example, in the manufacture of exact barometers, great difficulty is experienced in separating from the interior of the tube the adhering or absorbed air, which, if not completely expelled, gradually resumes the gaseous condition, and entering into the Torricellian vacuum, renders the instrument incorrect. Thus, too, in the chemical photometer used by Bunsen and Roscoe, in which a perfectly pure mixture of equal volumes of chlorine and hydrogen is employed as the sensitive substance, the only conceivable reason why the chlorine and hydrogen must be passed for several days through the apparatus before the maximum and permanent degree of sensibility is reached, is that the oxygen and nitrogen absorbed by the glass is expelled with the greatest difficulty, and that (as proved by direct experiment) the most minute trace of foreign gas disturbs the action of the light to an immense extent. Similar effects produced by the layer of air which covers all solid bodies are well known to photographers, who carefully guard against the presence of this condensed atmosphere, removing it by mechanical means immediately before the plate receives the sensitive coating. Almost the whole of the singular phenomena, first investigated by Moser, and ascribed by him to the action of "latent light," may be more rationally explained by the application of the authenticated facts of the absorption of gases by solid bodies. The well-known experiment, for instance, of allowing a coin to remain for a short time on a freshly cleaned and brightly polished metallic plate, when, on removing the coin and breathing on the plate, the image is plainly seen, depends upon the absorptive action which the newly cleaned surface of the plate exerts upon the condensed gases of the coin; if the surface both of the plate and of the coin be equally saturated with gas no such image will be perceived, and if both be equally free from any condensed atmosphere, the same negative result will be obtained.

Many of the so-called "catalytic" actions which various metals produce upon gases may also be explained in a similar manner. The effect which finely divided platinum, or even a clean plate of that metal, exerts in producing the combination of oxygen and hydrogen, doubtless depends on the absorption of these gases on the surface of the platinum, the consequent approximation of the gaseous particles being sufficient to induce their chemical union, thus evolving heat enough to cause the combustion of the surrounding gas. The most definite, and therefore the most interesting, experiments on this subject have been made by Magnus (Pogg. Ann. lxxxix. 604). He has not only shown that, owing to the absorption of gases by solids, the coefficients of expansion of gases by heat differ when the extent of surface of the vessel in which they are confined is altered, but he has actually determined the quantity of gas absorbed by a square millimetre of glass. Thus in two vessels, the relation of whose surfaces (the capacity being the same) was as 1 to 36, the coefficients of expansion of sulphurous acid from 0° C. to 100° C. were 0.3822 and 0.3896 respectively, or the amount of sulphurous acid absorbed on each square millimetre of surface was 0.0008 cubic millimetre. The same result was obtained when spongy platinum was placed in the gas: without spongy platinum the coefficient of expansion of sulphurous acid was found to be 0.3832, and in presence of the finely divided metal, 0.3922. It is more than probable that in Regnault's classical researches upon the action of pressure on gases, a portion of the deviation which in every case was observed from the law of Mariotte, was due to this condensation of the gas upon the surfaces of the enclosing vessels. In the exact determination of gaseous specific gravities, these absorptive phenomena also exert a disturbing influence.

H. E. R.

GASES, COLLECTION AND PRESERVATION OF. There are three general methods of collecting gases, the choice between which must depend upon the manner in which the gas is generated, and the degree of purity required by the use to which it is to be applied.

1. *By reception in an exhausted vessel.*—A vessel of glass or metal, provided with a stopcock, is exhausted as completely as possible by the air-pump, and then connected with the reservoir containing the gas.

This method is not of very frequent application, partly because it requires somewhat complicated apparatus, and partly from the impossibility of obtaining a complete vacuum with the air-pump. When, however, the supply of gas is unlimited, as when samples of air are to be collected from different localities for analysis, it answers very well; because the vessel, after having been once exhausted and filled with the gas, may be exhausted again and re-filled, and this operation repeated till every trace of the air originally contained in the vessel is removed.

A method similar in principle, and often very convenient, especially for lecture experiments, is to collect the gas in a bladder or caoutchouc bag, provided with a stopcock, and previously emptied of air by pressure. Larger quantities of gas, such as are required for the oxy-hydrogen blowpipe, may be collected in large linen bags coated on both sides with caoutchouc. The bags when full are connected by flexible

tubes with the nozzle of the blow-pipe, and the gases are pressed out by laying weight upon the bags, placed for the purpose between boards.

2. *By displacement of the air.*—To fill a vessel in this manner with a gas heavier than the air, such as chlorine, hydrochloric acid, or carbonic anhydride, the delivery-tube proceeding from the generating vessel is made to pass down to the bottom of the receiver placed with its mouth upwards. The gas then gradually fills the vessel, driving out the atmospheric air at the top. The operator judges when the vessel is full of gas, in the case of chlorine, by the colour; in the case of acid gases, by the reddening of litmus held over the mouth of the vessel; and in the case of carbonic anhydride, by the rapid extinction of a lighted taper held there. For gases lighter than air, such as hydrogen and ammonia, the generating vessel is fitted with an upright delivery-tube, and the vessel in which the gas is to be collected is inverted and held over it, with the end of the delivery-tube reaching quite to the top of the vessel. This method is especially convenient for collecting large quantities of gases which are quickly absorbed by water or when a considerable quantity of gas is required in the dry state.

3. *Collection over liquids.*—The mode of collection which is applicable in the greatest number of cases, is to receive the gas over a liquid which will not absorb it; the liquids most frequently used for the purpose being water or mercury. A jar or bottle is filled with the liquid and inverted in a trough of the same, and the end of the delivery-tube proceeding from the gas-generating apparatus is inserted beneath the mouth of the jar, so that the gas may rise in bubbles through the liquid, displace it and fill the vessel. The method is too well known to need more particular description. If a gas not absorbed by water is to be kept, it is collected in a bottle in the manner just indicated, and the bottle, when nearly full, is closed, while still standing in the trough, with a cork or ground stopper, then placed with its mouth downwards in a small basin containing sufficient water to cover the mouth. Or the bottle may be quite filled with the gas and closed with a greased stopper, afterwards tied down; or with a closely-fitting cork, which is afterwards covered and fastened down with sealing-wax, or tied round with bladder or sheet caoutchouc.

The methods of collecting and transferring gases over the mercurial trough for audiometric analysis are described in the article ANALYSIS OF GASES (i. 268).

An excellent substitute for a mercurial, and even for a water trough, in many

Fig. 510.

experiments, is the instrument known as *Cooper's mercurial receiver*. It consists of a glass tube, *a, b* (fig. 510), closed at one end and bent upwards. It is filled with mercury by inverting it and pouring in the mercury at *b*. On again inverting it, as in the figure, the mercury is retained in the tube by the pressure of the atmosphere. On inserting the delivery-tube at *b*, gas enters and displaces the mercury, which is received in the basin *c*. The operation must be stopped when the tube is filled with gas to the bend.

The apparatus affords great facilities for making a number of experiments on a small quantity of gas; for by placing the thumb on the end *b*, and inclining the tube so as to allow a little of the gas to flow round the bend into the short arm, it may be examined as to its chemical or physical characters, such as smell, inflammability, reaction with test-papers, &c. (*Greville Williams's Chemical Manipulation*, p. 320.)

For collecting and preserving large quantities of gases not absorbed by water, vessels called gas-holders or gasometers are frequently employed. The most convenient form of gas-holder is that invented by Pepys, and represented in fig. 511. It consists of a drum or reservoir, *a*, of sheet copper, surmounted by a shallow trough or cistern, *b*, the communication between the two being made by a couple of tubes furnished with cocks, *g, h*, one of the tubes passing nearly to the bottom of the drum. A short wide open tube, *i*, is inserted obliquely near the bottom of the vessel, into which a plug may be tightly screwed. A glass water-gauge, *e, f*, affixed to the side of the drum, and communicating with both top and bottom, indicates the level of the liquid within. Sometimes a divided scale is attached to this tube to measure the in- and out-flow of the gas.

To use the gas-holder, the plug is first to be screwed into the lower opening, and

the drum completely filled with water. All three stopcocks are then to be closed, and the plug removed. The pressure of the atmosphere retains the water in the gas-holder, and if no air-leakage occurs, the escape of water is inconsiderable. The extremity of the delivery-tube is now to be well pushed through the open aperture into the drum, so that the bubbles of gas rise without hindrance to the upper part, displacing the water, which flows out in the same proportion into a vessel placed for its reception. When the drum is filled, or enough gas has been collected, the tube is withdrawn, and the plug screwed into its place.

When a portion of the gas is to be transferred to a jar, the latter is to be filled with water at the pneumatic trough, carried by the help of a basin or plate to the cistern of the gas-holder, and placed over the shorter tube. On opening the cocks of both tubes, water will flow down the longer tube into the drum, and force the gas through the shorter tube into the jar. The vessel when filled may again have the plate slipped under it and removed.

This gas-holder is very convenient for passing a stream of gas over any substance contained in a tube or other vessel, as in experiments of oxidation and reduction. For this purpose, the vessel containing the substance to be operated upon is connected air-tight with the cock *c* of the gas-holder, and the cocks *c, g* are opened. The pressure of the water then forces the gas through the tube. In the same manner a bladder may be filled with gas by attaching it to the stopcock *c*. If great pressure is required, a long tin tube, terminating in a funnel, may be screwed into the upper end of the long tube of the gas-holder, and water poured in at the funnel.

The gas-holder may also be used as an aspirator, by filling it with water, closing the cocks *g, h*, connecting the vessel through which the air is to be drawn with the cock *c*, and opening the plug. The water then runs out, and its place is supplied by air.

Another form of gas-holder or gasometer, more used in manufacturing operations than in the laboratory, consists of two metal cylinders, (*fig. 512*) one inverted within the other, which contains water. The inner cylinder *A* is counterpoised by weights, *w*, passing over pulleys, so that it will easily move upwards when pressed from below. A metal tube, *cde*, provided with a stopcock, *s*, passes through the side of the outer cylinder close to the bottom, then vertically upwards to within a short distance of the top of the inner cylinder when in its lowest position.

To use this apparatus, the stopcock *s* is opened, the inner cylinder depressed to its lowest position, and water poured into the outer vessel till it fills the inner one, driving the air before it through the open tube. The outer extremity *c* of this tube being then connected with the delivery-tube proceeding from the generating vessel, the gas enters, passes upwards, and pushes up the inner cylinder, which is thus gradually raised to its highest position, and filled with gas. The stop-cock is then closed. To transfer the gas, a delivery-tube is attached to the end *c* of the tube *cde*, the stopcock is opened, and a portion of the weight which counterpoises the inner cylinder is removed. This cylinder then descends by its own weight, driving the gas before it through the tube *cde*. The flow may be made slow or rapid by removing less or more of the counterpoise.

This form of gas-holder is equally convenient with that of Pepys for passing a continuous stream of gas through a tube or vessel; but it does not afford the same facility of filling jars or bottles with gas.

For figures of the large gasometers used in gas-works, see *Ure's Dictionary of Arts, art. COAL-GAS* (i. 749-763).

Gases required to be preserved in a state of purity must not, however, be left standing over water; for water absorbs the gases of the external atmosphere, and these dissolved gases afterwards diffuse themselves into the gas standing over the water (p. 801); moreover, as all gases are more or less soluble in water, each to an extent peculiar to itself, the composition of a gaseous mixture standing over water, necessarily undergoes alteration in course of time.

Fig. 511.

Fig. 512.

808 GASES—COLLECTION AND PRESERVATION OF.

To avoid this source of error, and at the same time to obtain an apparatus which gives facility for withdrawing successive samples of a gaseous mixture for examination, Bunsen has contrived the mercurial gasometer represented in *fig. 513*. Its construction is exactly similar to that of the common gasometer last described. The outer cylinder, *aa*, is filled with mercury, and the bell-jar, *bb*, can be moved up and down in it by means of the holder *c*. The delivery and exit tubes, *e, e'*, are bent in the V shape, and pass under the bell-jar; to the outer end of each of them is attached a caoutchouc tube, *d, d'*, within which is placed a small piece of glass-rod, fitting it loosely, so as to afford easy passage for a gas, but forming a perfectly air-tight joint when the caoutchouc tube is tied round it with a silk cord. When the bell-jar is to be filled, it must be sunk as far as possible in the cylinder *aa*, care being taken that the tubes *e, e'*, do not dip under the mercury. As soon as the air has been completely displaced by the current of gas, the valve *d* is closed, the bell-jar drawn out of the mercury as it fills, and when this is accomplished the valve *d'* is also closed. To take a sample of the gas thus collected, a capillary gas-delivery-tube, *f*, filled with mercury, is fixed air-tight into the closed caoutchouc valve *d*, and the end of the delivery-tube being placed under the vessel to which the gas is to be transferred—a endiometer, for example—in the mercurial trough, the valve *d* is slowly opened; the bell-jar then descends by its own weight, and forces the gas through the tube.

Fig. 513.

If the nature of the investigation requires the transference of a given volume of gas without loss, the vessel represented in *figs. 37, 38, 39*, (pp. 243, 244, vol. i.), or one of similar construction, but with a cylindrical body and having a divided scale marked on it, may be used. (See *Bunsen's Gasometry*, p. 20.)

Preservation of gases in sealed tubes.—In researches on the nature of the gases evolved in manufacturing operations or from natural sources, such as volcanic fissures, clefts in mines, spring-waters, or samples of air from particular localities, it is frequently necessary to keep the gases for some time, and transport them to a distance before they can be analysed; and the only way of securing them absolutely from alteration, or from admixture with air, is to receive them in vessels which can be hermetically sealed. Bunsen has contrived for this purpose a number of highly ingenious methods, which are fully described in his "*Gasometry*."

If the gas issues under pressure, a number of tubes 5 or 6 inches long, about $\frac{1}{2}$ of an inch wide, and drawn out at each end, so as to be quickly and easily sealed by the blowpipe, are connected together by caoutchouc tubes, and the gas is made to flow through the whole arrangement long enough to drive out all the atmospheric air. The outer extremities of the first and last tubes are then sealed by the blowpipe; afterwards the necks of the intermediate tubes in succession, so as to separate them, and enclose a quantity of the gas in each. It was by an arrangement of this kind that Bunsen collected the gases from blast-furnaces for analysis. A wide wrought iron tube, consisting of several pieces screwed together, was sunk in the furnace, and the gases, forced through it by the blast, were conveyed by a flexible leaden pipe into a series of glass tubes connected as above.

If the pressure under which the gas issues from its source is not sufficient to drive it through the series of glass tubes, it must be drawn through them by an exhausting syringe or an aspirator. This is sometimes the case with the gas which issues from clefts in coal strata or from volcanic fissures. To collect such gases, the series of narrow tubes is connected at one end with a long wide tube of lead or glass, which can be inserted into the fissure, and at the other end with the syringe, which is worked long enough to ensure the complete expulsion of atmospheric air from the apparatus. The tubes are then sealed and separated as before.

For collecting gases in situations easy of access, as for instance in researches on the

composition of the atmosphere, or of the air of mines and caves, a common flask of a capacity of from 2 to 16 ounces, and having its neck drawn out to a narrow tube at the distance of $\frac{1}{2}$ of an inch from the mouth, may be used. To fill this bottle with the gaseous mixture of the locality, the air is sucked out of it through a long tube, reaching to the bottom, five or six deep inspirations being sufficient for the purpose; after which, the flask is closed with a cork, and the neck sealed by the blowpipe flame.

Gases evolved under water, like marsh-gas from stagnant pools, or the gases from springs, may be collected by means of the apparatus represented in *fig. 514*. It consists of a small test-tube having a capacity of 40 to 60 cubic centimetres, drawn out before the blowpipe at *a* to the thickness of a straw, and fixed by a cork or a vulcanised caoutchouc tube to the funnel *b*. Instead of the test-tube, a small long-necked flask may be used, having its neck similarly drawn out before the blowpipe. The apparatus is first filled with the water by immersing it with the mouth of the funnel upwards; but as the water is thus brought in contact with the air, which will alter the composition of the gases absorbed by the water, the water must be sucked out of the apparatus through a small tube reaching to the lowest part, till the whole has been displaced by other water from the spring. The apparatus may then be inverted, and the gas suffered to rise into the tube. If the bubbles stop in the neck of the funnel, or in the narrow part of the tube, they may be made to ascend by tapping the edge of the funnel against any hard substance.

When the tube is full of gas, the apparatus may be removed from the spring by means of a small basin, and the tube melted off at *a* by the blowpipe, the moisture at that part having been previously expelled by the flame. The column of water which rises in the funnel above the level of the water in the basin, renders the pressure on the gas less than that of the atmosphere; hence no bulging of the tube can take place. (Bunsen.)

Fig. 514.

Fig. 515.

Another way of mounting an apparatus for collecting gases from springs is that adopted by Hofmann in the examination of the Harrogate waters (*Chem. Soc. Qu. J. vii. 169*). In this apparatus (*fig. 515*), the tube, narrowed in one part, *a*, as above, is supported on an iron tripod *t*, and fixed by means of a strong caoutchouc connector *b*, into a large perforated wooden float, the lower surface of which is hollowed out so as to collect the gas-bubbles, and cause them to ascend into the receiver, which is filled with water at the commencement of the operation. As soon as the receiver is filled, the caoutchouc connector is closed by means of a screw-clamp, and the receiver is disconnected and sealed before the blowpipe. For the method of collecting the gases dissolved in waters, see **WATERS, MINERAL**.

GASES, COMBINATION OF, BY VOLUME. The specific gravities of elementary bodies in the gaseous state are to one another, for the most part, in the same ratio as their atomic weights; thus the volume which corresponds to any given quantity, say 1 gramme of hydrogen, corresponds also to 14 grammes of nitrogen, 16 grammes of oxygen, 32 grammes of sulphur-vapour, 35.5 grammes of chlorine, 80 grammes of bromine, and 127 grammes of iodine, so that the specific gravities, or weights of equal volumes, of these elements in the gaseous state, referred to hydrogen as unity,

810 GASES—COMBINATION OF, BY VOLUME.

are expressed by the same numbers as their atomic weights; and the symbols H, N, O, Cl, Br, &c., which represent the atomic weights, likewise represent equal volumes of the several gases.

The exceptions to this law are the following:—1. The specific gravities of phosphorus and arsenic in the state of gas or vapour are twice as great as their atomic weights ($P = 31$, $As = 75$), so that their atoms in the gaseous state occupy only half the volume of an atom of hydrogen. To bring these elements under the general law, it would be necessary to double their atomic weights, to which, however, there are grave objections.

2. The vapour-densities of mercury and cadmium accord with the atomic weights given in the table at page 465, vol. i.; but if the atomic weights of these elements are doubled, for which there appear to be conclusive reasons (see CLASSIFICATION, i. 1008, footnote), their atoms in the gaseous state will occupy twice the volume of an atom of hydrogen. The duplication of their atomic weights would, in fact, bring these metals into accordance with the majority of diatomic radicles, the atoms or smallest combining weights of which occupy, in the gaseous state, twice the volume of those of monatomic radicles*; e. g.

Monatomic radicles.
1 at. = $\frac{1}{2}$ molecule = 1 vol.

H
CH³
C²H⁴
C³H⁸
&c.

Diatomic radicles.
1 at. = 1 molecule = 2 vol.

Cd²
Hg²
C²H²
C²H⁴
&c.

From the preceding relations, it follows that the volumes of any two elementary gases which make up a compound molecule, are to one another in the same ratio as the numbers of atoms of the same elements which enter into the compound, excepting in the case of phosphorus and arsenic, for which the number of volumes thus determined has to be halved, and of mercury and cadmium, for which it should probably be doubled: thus:—

The molecule		contains	1 vol. H	and 1 vol. Cl.
HCl			1 " H	1 " Cl.
H ² O	"	2 " H	2 " H	1 " O.
H ² N	"	3 " H	3 " H	1 " N.
H ² P	"	3 " H	3 " H	1 " P.
	"	or 6 " H	6 " H	1 " P.
Cl ² As	"	3 " Cl	3 " Cl	1 " As.
	"	or 6 " Cl	6 " Cl	1 " As.
Hg ² Cl ²	"	2 " Hg	2 " Hg	2 " Cl.

If the smallest volume of a gaseous element that can enter into combination be called the combining volume of that element, the law of combination may be expressed as follows:—*The combining volumes of all elementary gases are equal, excepting those of phosphorus and arsenic, which are only half those of the other elements in the gaseous state, and probably also those of mercury and cadmium, which are double those of the other elements.*

It will of course be understood that the law, as thus stated, is true only for the atomic weights adopted in this work; according to the older system (that of Gmelin's *Handbook*), in which the atomic weights of oxygen and sulphur have only half the values here adopted, the combining volumes of those elements are likewise equal to those of phosphorus and arsenic.

But whichever system of atomic weights be adopted, the volumes in which gaseous elements combine together may be expressed by very simple numbers. This is the "Law of Volumes," first observed by Humboldt and Gay-Lussac in 1805, with regard to the combination of oxygen and hydrogen, and afterwards established in other cases by Gay-Lussac, whose observations published in his *Theory of Volumes*†, shortly after the announcement of the Atomic Theory by Dalton, afforded new and independent evidence of the combination of bodies in definite and multiple proportions, in corroboration of that derived from the observed proportions of combination by weight.

Gay-Lussac likewise observed that the product of the union of two gases, when itself a gas, sometimes retains the original volume of its constituents, no contraction or change of volume resulting from the combination, but that when contraction takes place, which is the most common case, the volume of the compound gas always bears a simple ratio to the volumes of its elements.

* If this be really the general law of the vapour-volumes of diatomic radicles, the elements O, S, Se, and Te, whose vapour-volumes accord with that of hydrogen, must be regarded as exceptional.

† "Sur la combinaison des substances gazeuses les unes avec les autres."—*Mémoires d'Arcueil*, ii. 207 (1808).

Subsequent observation extended over a very large number of compounds, organic as well as inorganic, has shown that, with a few exceptions, probably only apparent, the molecules of compound bodies in the gaseous state occupy twice the volume of an atom of hydrogen gas. No matter what may be the number of atoms or volumes that enter into the compound, they all become condensed into two volumes : thus

1 vol.	H	and	1 vol.	Cl	form	2 vol.	HCl.
1 "	N	"	1 "	O	"	2 "	NO.
2 "	H	"	1 "	O	"	2 "	H ² O.
3 "	H	"	1 "	N	"	2 "	H ³ N.
3 "	H	"	$\frac{1}{2}$ "	P	"	2 "	H ³ P.

Similarly in the union of compound gases, *e.g.*

1 vol.	ethyl,	C ² H ³	and	1 vol.	Cl	form	2 vol.	C ² H ³ Cl.
2 "	ethyl,	C ² H ³	"	1 "	O	"	2 "	(C ² H ³) ² O.
2 "	ethylene,	C ² H ⁴	"	2 "	Cl	"	2 "	C ² H ⁴ Cl ² .
2 "	ethylene,	C ² H ⁴	"	1 "	O	"	2 "	C ² H ⁴ O.

Hence it follows that the *specific gravity of any compound gas or vapour, referred to hydrogen as unity, is equal to half its molecular weight.*

The exceptions to this law have already been considered in the article **ATOMIC WEIGHTS** (i. 467-470). Those in which the observed vapour-density is less than that determined by calculation, according to the rule just given, may be explained by supposing that, at the high temperature at which the specific gravity of the vapour is determined, the compound molecule splits up into two others, *e.g.* NH³Cl into NH³ + HCl (which subsequently recombine, as the temperature falls), so that we are really operating, not on one compound molecule, but on two of less complexity, whence the observed density corresponds to four volumes of vapour instead of two. The validity of this explanation has been experimentally demonstrated in the case of hydrate of di-ethyl-ethylene-diamine, C⁶H¹⁶N².H²O, by Hofmann (p. 588); and the experiments of Pelal on sal-ammoniac, and of Wanklyn and Robinson on monohydrated sulphuric acid and pentachloride of phosphorus, which will be described hereafter (p. 817), point to the same conclusion. On the other hand, the recent experiments of Deville and Troost (Ann. Ch. Pharm. cxxvii. 274) throw considerable doubt upon the reality of these supposed decompositions and recompositions, at least in the case of ammoniac-salts. These chemists find indeed : 1. That sal-ammoniac bears without decomposition a temperature at which free ammonia is in great part resolved into its elements, and that when the heat is raised high enough to decompose the salt, the result is a mixture of hydrochloric acid, hydrogen, and nitrogen; moreover, a mixture of these three gases passed through a tube heated to dull redness, does not form sal-ammoniac. Bromide and iodide of ammonium yield similar results.—2. Cyanide of ammonium, which is produced at 1000° C. by the action of ammonia on charcoal, cannot be resolved into prussic acid and ammonia at 100° C., though at that temperature its vapour-density corresponds to a four-volume condensation.—3. Hydrochlorate of ethylamine is not resolved by heat into ammonia and chloride of ethyl; neither can it be produced by the direct union of those two gases.

With regard to those cases in which the observed density of the compound gas or vapour is greater than it should be according to calculation, it has been found that some of the exceptions arise from the vapour actually exhibiting a greater density at temperatures not far above the boiling point of the liquid, than at temperatures high enough to bring it into that state in which its physical properties agree in all respects with those of permanent gases. This has long been known to be the case with acetic acid and a few of its homologues, viz. formic, butyric and valeric acids, and the same anomaly has recently been demonstrated by Playfair and Wanklyn (Chem. Soc. J. xv. 156), in the case of pernitr oxide, NO², which at 97.5° C. has a density of 1.783 (air = 1) whereas at 24.5° it is 2.52, and at 11.3°, it is 2.69. The first of these densities corresponds nearly with the formula NO², the latter approximates to that required by NO⁴: for NO² gives $\frac{46}{2} \times 0.0693 = 1.593$; and NO⁴ gives $\frac{92}{2} \times 0.0693 = 3.188$. Hence it would appear that, at all the temperatures observed, the gas is a mixture of two polymeric compounds, and at 100° C., or above, it consists for the most part of NO².

The vapour-densities of mercuric chloride, ethylide of mercury, ethylide of zinc, and methylide of zinc, which correspond to 1 vol. of vapour of their molecules, as represented by the formulæ HgCl, C²H³Hg, C²H³Zn, CH³Zn, respectively, become normal and correspond to 2 vols. if the atomic weights of mercury and zinc are doubled, as is now generally done, and these molecules are accordingly represented by the formulæ Hg²Cl², C⁴H⁶Hg², C⁴H⁶Zn², and C²H⁴Zn².

GASES, DIFFUSION OF. All gases, even when under existing circumstances they do not enter into chemical combination, yet diffuse themselves through one another and form a uniform mixture, though their specific gravities may be very different and they may be kept externally at perfect rest. If, for example, two bottles be connected by an upright glass tube, 10 inches long and $\frac{1}{10}$ inch wide, the upper bottle being filled with hydrogen, nitrogen, nitric oxide, or common air, and the lower with the heavier gas carbonic anhydride, or the upper with hydrogen and the lower with common air, nitrogen, oxygen, or nitric oxide, a portion of the heavier gas will after a few hours be found in the upper bottle, and after two or three days both bottles will contain the two gases in the same proportion (Dalton, Phil. Mag. xxiv. 8). The same result was obtained by Berthollet (Mém. d'Arcueil, ii. 463) with a tube 10 inches long and $\frac{1}{8}$ of an inch wide, placed in a cellar where no change of temperature could take place to the gases in motion. When hydrogen was the gas contained in the upper vessel, the two gases were found to be uniformly mixed in 12 days; but when air, oxygen, or nitrogen was contained in the upper vessel and carbonic anhydride in the lower, several weeks elapsed before the mixture became perfectly uniform.

If a cylinder filled with any gas and placed in a horizontal position be made to communicate with the external air by means of a tube bent at right angles, the end of the tube being directed downwards when the gas is lighter, and upwards when it is heavier than the air, the gas will gradually escape from the cylinder, its place being supplied by the air. According to Graham,

Of 100 volumes of gas there disappeared:

Sp. gr.		In 4 hours.	In 10 hours.
1	Hydrogen	81.6 . . .	94.5 . . .
8	Light carburetted hydrogen	43.4 . . .	62.7 . . .
8.5	Ammonia	41.4 . . .	59.6 . . .
14	Olefiant gas	34.9 . . .	48.3 . . .
22	Carbonic anhydride	31.6 . . .	47.0 . . .
32	Sulphurous anhydride	27.6 . . .	46.0 . . .
35.4	Chlorine	23.7 . . .	39.5 . . .

From this it appears that gases escape the more quickly the lighter they are; and their expansive power, or *diffusibility*, varies nearly in the inverse ratio of the square roots of their specific gravities. Thus 47 measures of hydrogen escaped in two hours and the same volume of carbonic anhydride in 10. Now this proportion of 1:5 is nearly that of the square root of 1 (spec. grav. of hydrogen) to the square root of 25 (spec. grav. of carbonic anhydride).

If the cylinder contains a mixture of two gases, the more diffusible of the two will escape in greater proportion into the air, and the less diffusible in smaller proportion than if each gas were contained in the cylinder alone. Thus, of 50 measures of hydrogen and 50 of olefiant gas, there escape in 10 hours 47.7 measures of the former and 12.5 of the latter: similarly 47 measures of hydrogen and 20 of carbonic anhydride though in these cases the opening of the bent tube is directed downwards: further in 4 hours there escape 26.8 vols. of marsh-gas and 12.5 of carbonic anhydride; and 22.8 of marsh-gas and 18.6 of olefiant gas. If two bottles be connected together by a tube placed in a vertical position, the lower bottle being seven times as large as the upper and filled with carbonic anhydride, while the upper one is filled with a mixture of hydrogen and olefiant gas in equal volumes, the upper vessel will, after 1 hour be found to contain, besides carbonic anhydride, a quantity of olefiant gas whose volume is 4 times as great as that of the hydrogen still remaining; the latter has therefore, in spite of its greater levity, diffused itself through the lower vessel with greater rapidity. (Graham, Qu. Jour. of Sc. vi. 74.)

In the same manner also vapours diffuse themselves through one another and air through the more permanently elastic fluids.

When different elastic fluids have once diffused themselves uniformly through one another, they never separate again according to their different specific gravities, however long a time the mixture may be left at rest.

So great indeed is the tendency of gases to diffuse through one another, that the mixture or interdiffusion likewise takes place when the gases communicate with each other through minute pores or apertures of insensible magnitude. Priestley (*Exp. and Obs. on different kinds of air*, iii. 29), in transmitting gases through stone ware tubes surrounded by burning fuel, observed that the tubes were porous and that the gas escaped outwards into the fire, while at the same time the gases from the fire penetrated into the tube, even though the gas within the tube was in a compressed state. Döbereiner in 1825 made the remarkable observation that hydrogen kept in a cracked glass receiver standing over water escaped by degrees through the crack into the surrounding air, the water under the receiver rising to the height of about $2\frac{1}{2}$ inches above the outer level. The remaining hydrogen contained

7 per cent. of nitrogen, but no oxygen. If the receiver be filled with oxygen and nitrogen instead of hydrogen, nothing will escape from it. In the same manner hydrogen escapes out of bottles closed even with well-ground stoppers, if the stoppers are not greased. (Döbereiner.)

Graham (*Elements of Chemistry*, 2nd ed. i. 87), in repeating Döbereiner's experiment and varying the circumstances, observed that hydrogen never escapes outwards by the fissure, without a certain portion of air penetrating inwards; in fact, that when hydrogen gas communicates with air through such a chink, the air and hydrogen exhibit a powerful disposition to change places, a particle of air however exchanging with a particle of hydrogen, not of the same, but of 3.83 times its own magnitude. And by extending the observation to different gases, with an instrument admitting of exact measurement of the rate at which the interchange took place, it was found that the diffusion of gases through porous septa is regulated by the same law as when they communicate freely with one another, namely, that *the relative diffusibilities are inversely as the square roots of the densities*.

The instrument with which these observations are made is called a diffusion-tube or diffusiometer. It consists of a glass tube, nearly an inch in diameter, from six to fourteen inches long, open at one end, and having the other end closed by a thin diaphragm of some porous substance. The material originally used was gypsum, which was applied by thrusting into the tube a cylinder of wood of somewhat smaller diameter, so as to occupy the whole of it with the exception of about a fifth of an inch, which space was then filled with gypsum-paste, of the consistence commonly used for taking casts. The plaster sets in a few minutes, and, on withdrawing the wooden cylinder, forms a receiver closed by an immovable plate of stucco, which, though air-tight in the wet state, is permeable to gases when dried by exposure to the air for a day.

When such a diffusion-tube, ten inches long, is filled with hydrogen over mercury, the interchange of air for hydrogen takes place through the minute pores of the stucco with such rapidity, that in three minutes the mercury inside the tube attains a height of three inches above that in the trough, and in twenty minutes the whole of the hydrogen has escaped. In making such an experiment over water, it is necessary to avoid wetting the stucco. With this view, the shorter leg of an inverted siphon is introduced into the diffusion-tube to within an inch of the stucco, and the tube is then sunk in the water-trough, so that the air escapes by the siphon, with the exception of a small quantity, which is noted. The diffusion-tube is then filled up, either entirely or to a certain extent, with the gas to be diffused. (Graham, *Phil. Mag.* 1834, vol. ii.)

In experiments made for the purpose of determining the exact proportion between the gas diffused and the air which replaces it, it is necessary to guard against any inequality of pressure, by placing the diffusion-tube in a jar of water or mercury, and filling the jar with the liquid in proportion as it rises in the tube. Bunsen (*Gasometry*, p. 200) has adapted a lever arrangement to the diffusion-tube, by which the adjustment of the level is greatly facilitated.

A superior material for the porous plate is now found by Graham in the artificially compressed graphite of Mr. Broekedon, of the quality used for making writing pencils. This material is sold in London in small cubic masses about two inches square. A cube may easily be cut into slices of a millimetre or two in thickness by means of a saw of steel spring. By rubbing the surface of the slice, without wetting it, upon a flat sand-stone, the thickness may be further reduced to about one-half of a millimetre. A circular disk of this graphite, which is like a wafer in thickness but possesses considerable tenacity, is attached by resinous cement to one end of the glass tube, above described, so as to close it and form a diffusiometer. The tube is filled with hydrogen gas over a mercurial trough, the porosity of the graphite plate being counteracted for the time by covering it tightly with a thin sheet of gutta percha. On afterwards removing the latter, gaseous diffusion immediately takes place through the pores of the graphite. The whole hydrogen leaves the tube in forty minutes or an hour, and is replaced by a much smaller proportion of atmospheric air (about one-fourth), the mercury rising in the tube, if allowed, so as to form a column of several inches in height—a fact which illustrates strikingly the intensity of the force with which the interpenetration of different gases is effected. Native or mineral graphite is of a lamellar structure, and appears to have little or no porosity: it cannot be substituted for the artificial graphite as a diffusion septum. Unglazed earthenware comes next in value to graphite for this purpose.

Dry and sound cork also forms a very good material, but permits the diffusion to go on but very slowly, not being sufficiently porous: so do thin slips of many granular foliated minerals, such as flexible dolomite; charcoal, woods, and dry bladder may also be used for the same purpose.

The following table exhibits the densities of several gases; the square root of the density, or the calculated ratio of the times required for the diffusion of equal volumes, that of air being assumed = 1; the reciprocal of the square root, or the calculated

diffusiveness of the gas; and, lastly, the rates of diffusion, as determined by experiment, the barometric pressure and the temperature being supposed to be the same for all the gases.

Diffusion of Gases.

Gas.	Density.	Square root of density.	$\frac{1}{\sqrt{\text{Density}}}$.	Velocity of diffusion, air = 1.
Hydrogen . . .	0.06926	0.2632	3.7794	3.83
Marsh gas . . .	0.559	0.559	1.3375	1.344
Steam . . .	0.6235	0.7896	1.2664	
Carbonic oxide . . .	0.9678	0.9837	1.0165	1.0149
Nitrogen . . .	0.9713	0.9856	1.0147	1.0143
Ethylene . . .	0.978	0.9889	1.0112	1.0191
Nitric oxide . . .	1.039	1.0196	0.9808	
Oxygen . . .	1.1056	1.0515	0.9510	0.9487
Sulphydic acid . . .	1.1912	1.0914	0.9162	0.95
Nitrous oxide . . .	1.527	1.2357	0.8092	0.82
Carbonic anhydride . . .	1.52901	1.2365	0.8087	0.812
Sulphurous " . . .	2.247	1.4991	0.6671	0.68

The agreement between the observed and calculated rates of diffusion exhibited in this table is very close. It is only, however, when the diaphragm through which the diffusion takes place is very thin, not exceeding $\frac{1}{8}$ of an inch for stucco, that this closeness of agreement is observed. When thicker diaphragms are used, the gases have to pass through a number of long capillary tubes, the sides of which offer to the passage of a gas a resistance analogous to that of friction, and therefore retard its motion considerably. In fact, the passage of gases through capillary tubes, called "Transpiration," is regulated by laws totally distinct from those of diffusion; the former is a movement of masses, the latter of molecules. (See GASES, TRANSPARATION OF, p. 820.)

The resistance of a capillary tube to a gas passing through it is proportional to the surface, and consequently increases as the tube or tubes are multiplied in number and diminished in diameter, with the area of discharge preserved constant. The resistance to the passage of a liquid through a capillary was observed by Poiseuille to be nearly as the fourth power of the diameter of the tube. In gases the resistance also rapidly increases, but in what ratio has not been observed. The consequence, however, is certain that, as the diameter of the capillaries may be diminished beyond any assignable limit, so the flow may be retarded indefinitely, and caused at last to become too small to be sensible. We may therefore have a mass of capillaries of which the passages form a large aggregate, but which are individually too small to permit a sensible flow of gas under pressure. A porous solid mass may possess the same reduced penetrability as the congeries of capillary tubes. Indeed the state of porosity described appears to be more or less closely approached by all loosely aggregated mineral masses, such as lime-plaster, stucco, chalk, baked clay, non-crystalline earthy powders, like hydrate of lime or magnesia, compacted by pressure, and in the highest degree perhaps by artificial graphite.

A plate of artificial graphite, although it appears to be practically impenetrable to gas in the mass, is readily penetrated by the agency of the molecular or diffusive movement of gases. This appears on comparing the times required for the passage of equal volumes of different gases under a constant pressure. Of the following three gases, oxygen, hydrogen, and carbonic anhydride, the times required for the passage of an equal volume of each through a capillary glass tube, in similar circumstances as to pressure and temperature, are as follows:

	Time of capillary transpiration.
Oxygen	1
Carbonic anhydride	0.72
Hydrogen	0.44

But through a plate of graphite, of half a millimetre in thickness, the same gases were observed to pass, under a constant pressure of a column of mercury of 100 millimetres in height, in times which are as follows:—

	Time of molecular passage.	Square root of density (oxygen 1).
Oxygen	1	1
Hydrogen	0.2472	0.2502
Carbonic anhydride	1.1886	1.1760

It appears then that the times of passage through the graphite plate have no relation to the capillary transpiration times of the same gases. The times in question, however, show a close relation to the square roots of the densities of the respective gases, as is seen in the last Table; and so far they agree with the theoretical times of diffusion usually ascribed to the same gases.

The experiments were varied by causing the gases to pass into a Torricellian vacuum, and consequently under the full pressure of the atmosphere. The times of penetration of equal volumes of gases were now—

	Times.	$\sqrt{\text{Density.}}$
Oxygen	1	1
Air	0.9501	0.9507
Carbonic anhydride	1.1860	1.1760
Hydrogen	0.2505	0.2502

This penetration of the graphite plate by gases appears to be entirely due to their own proper molecular motion, quite unaided by transpiration. It seems to offer the simplest possible exhibition of the molecular or diffusive movement. This pure result is to be ascribed to the wonderfully fine porosity of the graphite. The interstitial spaces, or channels, appear to be sufficiently small to extinguish transpiration, or the passage of masses, entirely. The graphite becomes a molecular sieve, allowing molecules only to pass through.

With a plate of stucco, the penetration of gases under pressure is very rapid, and the volumes of air and hydrogen passing in equal times are as 1 to 2.891, which is a number for hydrogen intermediate between its transpiration volume 2.04 and diffusion volume 3.8; showing that the passage through stucco is a mixed result.*

With a plate of biscuit-ware, 2.2 mm. in thickness, the volume of hydrogen rose to 3.754 (air = 1), approaching closely to 3.8, the molecular ratio.

The rate of passage of a gas through graphite appeared also to be closely proportional to the pressure.

Further, hydrogen was found to penetrate through a graphite plate into a vacuum with sensibly the same absolute velocity as it diffused into air, establishing the important fact that the impelling force is the same in both movements. (Graham, Phil. Trans. 1863.)

The passage of a gas through a graphite plate into a vacuum is due entirely to its intestine molecular or diffusive movement, and is to be distinguished from the passage of gas through a minute opening, such as a puncture made by a fine needle in platinum foil (See GASES, EFFUSION OF.)

Separation of Gases by Diffusion. Atmolysis.—A partial separation of mixed gases and vapours of unequal diffusibility can be effected by allowing the mixture to permeate through a graphite plate into a vacuum, as was to be expected from the preceding views. The amount of the separation is in proportion to the pressure, and attains its maximum when the gases pass into a nearly perfect vacuum. When a portion of air confined in a jar is allowed to penetrate into a vacuum through graphite or unglazed earthenware, the nitrogen should pass more rapidly than the oxygen in the proportion of 1.0668 to 1; and the proportion of oxygen be proportionally increased in the air left behind in the jar. The increase in the oxygen actually observed when the air in the jar was reduced from 1 volume

to 0.5	volume, was 0.48 per cent.
0.25	" 0.98 "
0.125	" 1.54 "
0.0625	" 2.02 "

Or, the oxygen increased from 21 to 23.02 per cent. in the last sixteenth part of air left behind in the jar.

The most remarkable effects of separation are produced by means of the *tubato-atmolyser*. This is simply a narrow tube of unglazed earthenware, such as a tobacco-pipe stem, two feet in length, which is placed within a shorter tube of glass and secured in its position by corks, so as to appear like a Liebig's condenser. The glass tube is placed in communication with an air-pump, and the annular space between the two tubes is maintained as nearly vacuum as possible. Air or any other mixed gas is then allowed to flow in a stream along the clay tube, and collected as it issues. The gas so atmolyzed is of course reduced in volume, much gas penetrating through the pores of the clay tube into the air-pump vacuum; and the more slowly the gas is collected,

* This may perhaps explain the results obtained by Bunsen who used, in his experiments on diffusion, a stucco diaphragm of considerable thickness, and was led to conclude that the pores of gypsum act upon gases, not as a series of fine openings, but as a series of capillary tubes, and thence to call in question the truth of the law of gaseous diffusion through porous diaphragms deduced from Graham's experiments. (See *Bunsen's Gasometry*, p. 203; also *Graham's Elements*, 2nd ed. ii. 624.)

the greater is the proportional loss. In the gas collected, the denser constituent of the mixture is thus concentrated in an arithmetical ratio, while the volume of the gas is reduced in a geometrical ratio. In one experiment, the proportion of oxygen in the air, after traversing the atmolyser, was increased to 24.50 per cent. or 16.7 upon 100 oxygen originally present in the air. With gases differing so much in density and diffusibility as oxygen and hydrogen, the separation is of course much more considerable. The explosive mixture of two volumes of hydrogen and one volume of oxygen, gave oxygen containing only 9.3 per cent. of hydrogen, in which a taper burned without explosion; and with equal volumes of oxygen and hydrogen, the proportion of the latter was easily reduced from 50 to 5 per cent. (Phil. Trans. 1863.)

The atmolytic method may sometimes be advantageously applied to determine whether a certain gas is a mixture or a simple gas; to distinguish, for example, marsh-gas, CII^4 , from a mixture of equal measures of hydrogen and hydride of ethyl, $\text{H}^2 + \text{C}^2\text{H}^6$, each of which would give, when detonated with oxygen, the same proportion of carbonic anhydride and water. But suppose that, after the proportions of carbon and hydrogen have been thus determined, a portion of the mixture is submitted to diffusion, and the residue again analysed; the proportions of carbon and hydrogen will then remain unaltered, if the gas consists of marsh-gas, whereas if it is a mixture, the proportion of hydrogen will be found less than before the diffusion.

The method of diffusion has also been applied to determine whether certain compounds, which, like hydrochlorate of ammonia, yield anomalous vapour-densities (p. 811), are resolved at high temperatures into their components, thus yielding vapours which are no longer chemical compounds, but mixtures. This mode of attacking the question was first proposed by Playfair and Wanklyn (Edinb. Phil. Trans. vol. xxii. Part 3; Chem. Soc. J. xv. 142), and has been carried out as follows by Pebal (Ann. Ch. Pharm. cxxiv. 199). A plug of asbestos, *c*, supporting a few fragments of sal-ammoniac, *d*, is placed within a vertical tube, *c* (fig. 516), drawn out to capillary end, and supported within a wider tube *n*, closed at the top, the whole being surrounded by a charcoal furnace. Both tubes project below the furnace, and are closed at the bottom with corks, through each of which pass two bent tubes, the one for admitting a stream of hydrogen, the other for carrying it off. The heat of the burning charcoal volatilises the hydrochlorate of ammonia in the inner tube above the asbestos plug; so that, if the salt is actually resolved into hydrochloric acid and ammonia, the latter, being the more diffusible of the two, will diffuse downwards through the plug into the hydrogen in the inner tube *c*, and may be demonstrated

Fig. 516.

Fig. 517.

by causing the issuing gas to come in contact with a piece of reddened litmus paper, *a*, while the less diffusible hydrochloric acid will remain mixed with the hydrogen in the space *n* between the two tubes; and its presence may be demonstrated by placing a piece of blue litmus paper, *b*, in contact with the gas which issues from that space. Such indeed, is found to be the case; hence Pebal concludes that the sal-ammoniac has been actually resolved by the heat into hydrochloric acid and ammonia.

Messrs. Wanklyn and Robinson (Proc. Roy. Soc. xii. 307) object to this conclusion, that the decomposition of the sal-ammoniac in Pebal's apparatus is probably effected

by the action of the finely-divided silicate forming the porous diaphragm, inasmuch as the acid of that salt, having an indefinite capacity of saturation, may take up the ammonia and set the hydrochloric acid free.* They therefore discard the use of a porous diaphragm altogether, and allow the vapours to diffuse through a simple aperture, as in Graham's original experiments (p. 811). The apparatus used consists of two glass flasks (*fig. 517*), the necks of which do not fit air-tight: the narrow tube proceeding from the upper one is fused into it. The lower flask is for the reception of the vapour to be operated on; the upper flask is for the atmosphere into which the vapour is to be diffused. The atmosphere of dry air, or other suitable gas, is kept constantly renewed by the transmission of a slow stream of gas, which enters the upper flask by the narrow tube, and passes out by the space between the two necks. The whole apparatus is kept at a temperature above the condensing point of the vapour by means of an air-bath. After the diffusion has gone on for a sufficient length of time, the apparatus is left to cool, and the contents of the lower flask are analysed, by which means it is seen whether diffusion has effected any alteration in the composition of the vapour.

Sulphuric acid thus treated is resolved into water and sulphuric anhydride, the vapour of water diffusing more readily than that of the anhydride, and consequently leaving in the lower flask a residue richer in sulphuric anhydride than the acid before diffusion. In one experiment, an acid composed of 95 pts. monohydrated sulphuric acid and 5 water, diffused for an hour at 520°C ., left a residue composed of 60 pts. SO_3H^2 and 40 SO^3 . In another experiment, a mixture of 99 pts. SO_3H^2 and water, left, after diffusion for a shorter time at 445°C ., a residue containing 75 SO_3H^2 and 25 SO^3 . In both cases the residues fumed strongly on exposure to the air, and consisted partly of crystals and partly of liquid.—*Pentachloride of Phosphorus* diffused into carbonic anhydride for three quarters of an hour at 300°C . was resolved into free chlorine, which was found in the diffused gases by the reaction with iodide of potassium and starch, and trichloride of phosphorus, which remained in the flask, and when treated with water yielded phosphorous acid, which reduced corrosive sublimate to calomel.

These experiments, as well as that of Pebal, cannot be looked upon as quite decisive of the question which they were intended to solve: for it is possible that the decompositions observed may have been determined, at least in part, by the tendency of the more diffusive vapour to expand into the atmosphere of hydrogen or carbonic anhydride. At all events, the experiments of Deville and Troost already cited (p. 811) show conclusively that, at least in the case of ammonia-salts, the supposed decomposition is not brought about by the action of heat alone.

Theory of Diffusion.—The diffusion of gases through one another was regarded by Dalton as a necessary consequence of the self-repulsive property of the particles of gaseous bodies. He considered that each gas expands into the space occupied by the other just as it would into a vacuum; and, in fact, experiment shows that the velocities with which gases diffuse into each other are to one another in the same ratio as the velocities with which they rush into a vacuum through an aperture in a thin plate (p. 818). The ultimate result is certainly in accordance with Dalton's view; still we cannot suppose, as he did, that gases act as absolute vacua to each other; for the actual rate of diffusion of any gas is many thousand times slower than the effusion of the same gas into a vacuum.

But though Dalton's hypothesis cannot be admitted, we must still regard the diffusion of gases as a consequence of that intestine movement of molecules which is now generally recognised as an essential property of the gaseous condition of matter. According to this view, a gas is represented as consisting of solid and perfectly elastic spheroidal particles or atoms, which move in all directions, and are animated with different degrees of velocity in different gases. Confined in a vessel, the moving particles are constantly impinging against its sides and occasionally against each other, and such collisions take place without any loss of motion, owing to the perfect elasticity of the particles. Now if the containing vessel be porous, like a diffusimeter, then gas is projected through the open channels, by the atomic motion described, and escapes. Simultaneously the external air or gas, whatever it may be, is carried inwards in the same manner, and takes the place of the gas which leaves the vessel. To the same atomic or molecular movement is due the elastic force, with the power to resist compression, possessed by gases. The molecular movement is accelerated by heat and retarded by cold, the tension of the gas being increased in the first instance and diminished in the second. Even when the same gas is present both within and without the vessel, and is therefore in contact with both sides of the porous plate, the

* In that case, however, the hydrochloric acid gas might be expected to diffuse into the hydrogen more readily than the ammonia, which, though not absolutely retained by the silicic acid at the high temperature of the apparatus, would probably be retarded by it.

movement is sustained without abatement, molecules continuing to enter and leave in equal number, although nothing of the kind is indicated by change of volume or otherwise. If the gases in communication be different, but possess sensibly the same specific gravity and molecular velocity, as nitrogen and carbonic oxide do, an interchange of molecules also takes place without any change in volume. With gases opposed of unequal density and molecular velocity, the amount of penetration ceases of course to be equal in both directions. (See *Graham's Elements*, 2nd. ed. ii. 449; also the article **HEAT** in this dictionary.)

GASES, EFFUSION OF. This term is used to denote the passage of a gas into a vacuum through a minute aperture in a thin plate of metal or other substance. Now it can be shown, on mechanical principles, that the velocity with which a gas rushes into a vacuum through such an aperture, is the same as that which a heavy body would acquire in falling from the height of an atmosphere composed of the gas in question, and of uniform density throughout. The height of such an atmosphere will be inversely as the specific gravity of the gas, the atmosphere of hydrogen, for example, being sixteen times higher than that of oxygen. But as the velocity acquired by a falling body varies, not directly as the height, but as the square root of the height, it follows that the rate of flow of different gases into a vacuum must be inversely as the square root of their respective densities. This law has been experimentally verified by Graham (*Phil. Trans.* 1846, p. 573). A jar on the plate of an air-pump was kept vacuum by continued exhaustion, and a measured quantity of air, or any gas, allowed to find its way into the jar through a minute aperture in a thin metallic plate, such as platinum foil, made by a fine steel point, and not more than $\frac{1}{500}$ of an inch in diameter. With an imperfect exhaustion, the velocity with which the gas flows into the jar increases rapidly till the degree of exhaustion amounts to one third of an atmosphere. Higher degrees of exhaustion do not produce a corresponding increase of velocity, and the difference of an inch in the column of the barometer-gauge scarcely affects the rate at which the gas enters when the vacuum is nearly complete, and the pressure to which the gas is subject approaches that of a whole atmosphere. Through a perforated plate such as that described, 60 cubic inches of dry air entered the vacuum or nearly vacuum receiver in about 1,000 seconds; and in successive experiments, the time of passage did not vary more than one or two seconds.

The velocities of effusion of different gases are given in the following table:—

Gas.	Velocity of Effusion.
Air	1
Hydrogen	3.613
Marsh-gas	1.322
Carbonic oxide	1.0123
Nitrogen	1.0164
Ethylene	1.0128
Oxygen	0.950
Nitrous oxide	0.834
Carbonic anhydride	0.821

For gases which do not differ greatly from the air in specific gravity, these rates correspond very closely with the inverse ratios of the square roots of the densities, and therefore with the rates of diffusion (see Table, p. 814). Nevertheless, the phenomena of diffusion and effusion are essentially different in their nature, the effusive movement affecting masses of a gas, while the diffusive movement affects only molecules; and a gas is usually carried by the former kind of impulse with a velocity many thousand times greater than by the latter.

Mixed gases are effused at the same rate as one gas of the actual density of the mixture; and no separation of the gases occurs, as in diffusion into a vacuum.

GASES, LIQUEFACTION AND SOLIDIFICATION OF. See **HEAT**.

GASES, OSMOSE OF. This term is applied to the passage of gases through membranous diaphragms such as caoutchouc, bladder, gold-beater's skin, &c. The rate of interchange depends in this case, partly on the relative diffusibilities of the gases, partly on the porosity of the membrane, as well as on the different degrees of adhesion which it exerts upon the different gases, by virtue of which the gas which adheres most powerfully penetrates the diaphragm most easily, and attaining the opposite surfaces, mixes with the other. If the membrane is moist, the result is likewise affected by the different degrees of solubility of the gases in the water or other liquid contained in it.

Caoutchouc.—A sheet of caoutchouc tied over the opening of a wide-mouthed bottle full of hydrogen gas, is soon pressed inwards even to bursting. If the bottle be filled with air and placed in an atmosphere of hydrogen, the swelling and bursting take place outwards. A well closed bottle of caoutchouc perfectly empty does not distend

when placed in hydrogen gas: but if it contains a small quantity of air, distension takes place. Almost all gases excepting nitrogen exhibit the same relations towards common air as hydrogen does, but in different degrees; they all penetrate caoutchouc with various velocities in order to mix with air. In order to measure these various velocities, a sheet of caoutchouc is tied over the shorter funnel-shaped arm of a siphon-tube; mercury is poured into the other arm, which is made very long, so that a portion of air may remain between the mercury and the caoutchouc; and the shorter arm is introduced under a receiver standing over the mercurial trough and filled with the gas to be examined. The gas penetrates the caoutchouc, mixes with the air, and increases its volume; consequently the mercury in the longer arm is driven upwards, sometimes to the height of 63 inches, and might be driven higher if the caoutchouc could sustain a greater pressure without bursting. By experimenting in this manner on different gases, it is found that the same volume of ammoniacal gas obtains access to the air in 1 minute, as of sulphydric acid in $2\frac{1}{2}$, of cyanogen in $3\frac{1}{2}$, of carbonic anhydride in $5\frac{1}{2}$, of protoxide of nitrogen in $6\frac{1}{2}$, of arsenetted hydrogen in $27\frac{1}{2}$, of olefiant gas in 28', of hydrogen in $37\frac{1}{2}$, of oxygen in 1 hr. 53', and of carbonic oxide in 2 hrs. 40'. Caoutchouc appears from this to absorb gases with different degrees of facility; of carbonic anhydride it absorbs its own volume and swells up in consequence. (Mitchell, J. Roy. Inst. 2, 101.)

Animal Membranes.—A moist bladder or moistened gold-beater's skin acts like a sheet of caoutchouc (Mitchell). A moist bladder, two-thirds filled with coal-gas or air, swells when suspended in carbonic anhydride, and finally bursts. In this experiment as much as 40 per cent. of carbonic anhydride sometimes mixes with the coal-gas, while only a very small quantity of the latter escapes into the atmosphere of carbonic anhydride. Hence the water of the moistened bladder absorbs carbonic anhydride and gives it up again on the inner side (Graham, Qu. J. of Sc. vi. 88). A perfectly dry bladder containing air does not distend in carbonic anhydride: a bladder moderately wetted expands to a greater extent than one which is thoroughly soaked; for the thinner the film of water which absorbs the gas, the sooner will the gas reach the opposite surface. If the bladder containing air be moistened with alcohol (which absorbs carbonic anhydride more readily than water does) it will expand in an atmosphere of carbonic anhydride as quickly as if it were moistened by water—but not more so: the alcohol likewise causes it to shrivel and soon destroys its power of transmitting gases. Rubbing the bladder with oil of anise or olive oil (neither of which absorbs carbonic anhydride) prevents the expansion. A wet bladder containing air expands more quickly in sulphydric acid than in carbonic anhydride: after being distended as far as possible in the last-mentioned gas, it will expand still further if placed in an atmosphere of sulphydric acid; whereas if exposed to the air it will regain its original size. A bladder containing air also expands when immersed in water holding carbonic anhydride in solution, but not so quickly as in an atmosphere of the gas. A fish's ir-bladder expands under the above-mentioned circumstances more quickly than a urinary bladder: on the contrary, this property is not exhibited by the lining membrane of a fowl's egg or by curried sheepskin: the latter allows air and carbonic anhydride to pass through it with equal facility (Baumgartner, Zeitschrift Ph. Math. i. 9). These experiments show that gases cannot be preserved in bladders without alteration. If a piece of bladder be tied over the upper and widened end of a glass tube, the tube then filled with water, and its lower end plunged under mercury, the mercury will rise within it to the height of 3 inches, in consequence of the water penetrating the bladder and escaping into the air; but as soon as this height is attained, the pores of the bladder allow air to pass through them and the further rise of the mercury is prevented (Magnus, Pogg. Ann. x. 157). According to Fischer (Pogg. Ann. xi. 130) who perhaps made use of a stronger bladder, the mercury may attain the height of 12 inches or even more; it ultimately reaches to the bladder itself, the whole of the water evaporating and leaving nothing but a slimy residue. If a tube, sealed at top and tied over with a piece of bladder at the bottom, be filled with water and exposed to the air, the bladder will be pressed inwards in consequence of the evaporation of the water, and air will enter, not however in bubbles, but dissolved by the water: the air thus introduced collects at the upper end of the tube in the gaseous form, and finally all the water evaporates and the tube becomes filled with air (Fischer.)

GASES, RELATIONS OF, TO PRESSURE AND TEMPERATURE.

The volume of a given quantity of any gas is affected by the pressure and temperature to which it is exposed, according to two general laws, which must be attended to in any comparison of the volumes of different gases. The law of Boyle and Mariotte affirms that the volume of a gas is inversely as the pressure to which it is subjected; this pressure being usually measured in inches or millimetres of mercury (see ELASTICITY, p. 370). The law of Dalton and Gay-Lussac affirms that the volume of a gas

is increased or decreased by $\frac{1}{273}$ of its bulk at zero, for every centigrade degree of temperature above or below zero (or $\frac{1}{459}$ of its bulk at Fahrenheit's zero for every Fahrenheit degree). These two laws apply equally to vapours, when at temperatures considerably above their condensing points. Hence two volumes of gas or vapour, at very different pressures and temperatures, may be compared with one another, provided the proper corrections are applied according to the following formulæ:—1°. As h inches or millimetres are to h' inches or millimetres, so is bulk at h' to bulk at h . 2°. As $273 \pm t$ is to $273 \pm t'$ so is bulk at t degrees above or below zero C., to bulk at t' degrees.

Or, if V and V' be the volumes of the gas at the respective pressures and temperatures, then

$$V = V' \frac{h}{h'} \cdot \frac{273 + t'}{273 + t} = V' \frac{h}{h'} \cdot \frac{1 + 0.003663 t'}{1 + 0.003663 t}.$$

To find the volume V_0 , which a given volume, V , of a gas, at pressure h (in inches), and temperature t° C., will occupy, when subjected to a pressure of 30 inches and a temperature of 0° C., we have, in the preceding formula, $h' = 30$ and $t' = 0$, therefore,

$$V_0 = V \frac{h}{30} \cdot \frac{1}{1 + 0.003663 t}.$$

Regnault has shown that neither of the above laws is absolutely accurate, especially with reference to the condensable gases; but the variations are, for the most part, exceedingly minute, and, except in special experiments, may be altogether disregarded. (See HEAT.)

GASES, SPECIFIC GRAVITY OF. See SPECIFIC GRAVITY.

GASES, SPECIFIC HEAT OF. See HEAT.

GASES, TRANSPIRATION OF. (Graham, Phil. Trans. 1846, p. 591, and 1849, p. 349; *Elements of Chemistry*, 2nd ed. i. 82.)—The law of effusion stated on p. 818, is true only under the conditions there specified, viz. that the gas shall pass through a minute aperture in a very thin plate. If the plate be thicker, so that the aperture becomes a tube, very different rates of efflux are observed; and when the capillary tube is considerably elongated, so that its length exceeds its diameter at least 4,000 times, the rates of flow of different gases again assume a constant ratio to each other; following, however, a law totally distinct from that of effusion. To examine this kind of motion, called "Capillary Transpiration," the gas was placed over water in a graduated jar, so suspended that the liquid in the jar and in the bath could be easily kept at the same level. The gas was dried by passing it through a tube filled with chloride of calcium, and was then made to pass through a long fine capillary tube, into a receiver standing on the plate of an air-pump; this receiver was sometimes kept vacuum by continued pumping; at other times the state of exhaustion was ascertained at intervals by the pressure-gauge. By this method of observation the following general results were obtained:—

1. The rate of transpiration for the same gas increases, *ceteris paribus*, directly as the pressure; in other words, equal volumes of air, at different densities, require times inversely proportional to the densities. For example, a pint of air of double the density of the atmosphere will pass through the capillary tube in half the time which would be required for a pint of air of the natural density, under an equal propulsive force. This result stamps the process of transpiration with a character quite distinct from that of diffusion or effusion.

2. With tubes of equal diameter, the volume transpired in equal times is inversely as the length of the tube.

3. As the temperature rises, the transpiration of equal volumes becomes slower.

4. The same uniformity in the results was obtained, whether the tubes were of copper or of glass, or whether a porous mass of stucco was employed, provided always that the length of the tubes exceeded their diameter in the ratio above-mentioned.

The rates of transpiration of different gases bear a constant relation to each other, totally independent of their densities, or indeed of any known property of the gases.

A comparison of the numbers in the following table exhibits some very simple relations between the rates of transpiration of certain gases.

1. Equal weights of oxygen, nitrogen, air, and carbonic oxide are transpired in equal times.

2. The velocities of transpiration of nitrogen, nitric oxide, and carbonic oxide are equal.

3. The velocities of hydrochloric acid, carbonic anhydride, and nitrous oxide are equal.

Transpirability of Gases.

Gases.	Times for transpiration of equal volumes.	Velocities of transpiration.
Oxygen	1 0000	1·0000
Air	0·9030	1·1074
Nitrogen	0·8768	1·141
Nitric oxide	0·8764	1·141
Carbonic oxide	0·8737	1·145
Nitrous oxide	0·7493	1·335
Hydrochloric acid	0·7363	1·358
Carbonic anhydride	0·7300	1·370
Chlorine	0·6664	1·500
Sulphurous anhydride	0·6500	1·538
Sulphydric acid	0·6195	1·614
Marsh-gas	0·5510	1·816
Ammonia	0·5115	1·955
Cyanogen	0·5060	1·976
Ethylene	0·5051	1·980
Hydrogen	0·4370	2·288
Vapours.		
Bromine (about)	1·0000	1·0000
Sulphuric anhydride	1·0000	1·0000
Sulphide of carbon	0·6195	1·614
Chloride of methyl	0·5475	1·826
Chloride of ethyl	0·4988	2·005
Oxide of methyl	0·4826	2·072
Hydrocyanic acid	0·4600	2·174
Ether	0·4400	2·273

4. The velocities of hydrogen and vapour of ether are equal: so likewise are those of sulphydric acid and vapour of sulphide of carbon; and those of marsh-gas and chloride of ethyl.

5. The velocity of hydrogen is double that of nitrogen, of nitric oxide, and of carbonic oxide.

6. The velocities of chlorine and oxygen are as 3 : 2. The velocities of bromine and of sulphuric anhydride appear to be nearly the same as that of oxygen. No gas appears to be slower than oxygen.

7. The velocities of hydrogen and marsh-gas are as 5 : 4.

8. Ethylene, cyanogen, and ammonia have each nearly double the velocity of oxygen.

The transpiration time of mixtures of the following gases was found to be exactly the mean of the times of the individual gases, viz. oxygen, nitrogen, carbonic oxide, carbonic anhydride, and nitrous oxide; but the transpiration time of hydrogen and carburetted hydrogen, particularly the former, is greatly increased when these gases are mixed either with one another or with gases of the former class. Thus, the transpiration time of a mixture of equal volumes of oxygen and hydrogen was 0·9008 and not 0·72, the mean time of the two gases. The transpiration time of hydrogen in such a mixture is as high as 0·8016, or its transpiration is then less rapid than that of carbonic anhydride.

The rates of transpiration of the vapours have not been determined with so much accuracy as those of the permanent gases, in consequence of the necessity of experimenting upon them in a state of mixture with some permanent gas.

GASTERASE. Syn. with **PEPSIN**; see the next article.

GASTRIC JUICE. (Bidder and Schmidt, *Die Verdauungssäfte und der Stoffwechsel*, Mitau und Leipzig, 1852, pp. 29–97.—Cl. Bernard, *Leçons de physiologie expérimentale*, Paris, 1856, ii. 382.—Huebenet, *Disq. de succo gastrico*, Dorpat, 1850.—E. v. Schröder, *Succi gastrici humani indoles physica et chemica*; O. v. Grunewaldt, *Succi gastrici humani vis digestiva*, &c., Diss. inaug., Dorpat, 1853.—Lehmann, *Lehrb. der physiolog. Chemie*, Leipzig, 1853, ii. 35–50; *Physiological Chemistry*, Cav. Soc. Ed. London, 1851–4, ii. 40; iii. 503; *Gmelin's Handbuch*, viii. [2] 25.—Pavy, *On the Immunity enjoyed by the Stomach from being digested by its own Secretion during Life*, Proc. Roy. Soc. xii. 386.—C. Schmidt, *Ann. Ch. Pharm.* xcii. 44.)—This fluid, which accumulates in the stomach after the

ingestion of food, is, after being freed by filtration from mucus and fragments of epithelium, perfectly transparent and nearly colourless, having only a slight yellow tint. It has a faint peculiar odour, generally resembling that of the animal from which it is taken, and a scarcely perceptible saline-acid taste. It is slightly heavier than water, neutral or slightly alkaline when taken from the empty stomach, but acid after the ingestion of food; it is not rendered turbid by boiling. At temperatures below 0°C ., it solidifies without becoming turbid. It is precipitated by tannin, alcohol, and most metallic salts. If carefully freed from mucus, &c., it may be exposed to the air for months, or even years, without undergoing alteration; and even when a fungous growth has appeared, it still retains its most essential character, viz. its digestive power.

The constituents of the gastric juice are *water, inorganic salts, organic substances, and a free acid*. Its constitution appears to be nearly the same in all vertebrate animals.

The solid constituents do not exceed from 1 to 1.75 per cent. the remaining 98.25 to 99 pts. being water. The solid residue, when incinerated, is found to consist chiefly of *chloride of sodium*, with smaller quantities of *alkaline sulphate, carbonate and phosphate of calcium*, and sometimes *sulphate and chloride of calcium*.

The organic constituents of the gastric juice have been but little examined, in consequence of the extremely small quantities in which they occur. They consist of a substance soluble in water and in absolute alcohol (formerly known as *osmazome*), and a substance soluble in water only. This latter, called *pepsin, chymosin, or gastrase*, is the true digestive principle of the gastric juice. It may be precipitated by treating the juice with alcohol, the greater portion of the other matters then remaining in solution. The precipitate, which contains sulphur and nitrogen, dissolves pretty freely in water, and is thrown down from the aqueous solution by corrosive sublimate, protochloride of tin, basic acetate of lead, and tannic acid, and imperfectly by neutral acetate of lead. The solution is not rendered turbid by boiling, and exhibits strong digestive powers when mixed with hydrochloric or lactic acid; but, like the gastric juice itself, it loses these properties by boiling, by treatment with absolute alcohol, or by neutralisation with alkalis. In an alkaline solution, pepsin soon becomes putrid, and in a neutral solution, it seems to give rise to the formation of fungi; but when rendered acid, it remains unaltered for a long time, exactly like natural gastric juice.

Respecting the nature of the free acid in gastric juice, the opinions of different observers are greatly at variance. Prout (Ann. Phil. new ser. xii. 407), and Bracconot (Ann. Chim. lix. 438), concluded from their own experiments, that the gastric juice contains free hydrochloric acid. Lehmann, on the other hand, found free lactic acid in this secretion, and attributed the free hydrochloric acid given off on evaporating gastric juice in vacuo, to the decomposition of chloride of calcium by the lactic acid. Bernard and Barreswil (J. Pharm. 1845, p. 49) altogether deny the existence of free hydrochloric acid in the gastric juice, on the ground that this liquid in the pure state is rendered turbid by a drop of dilute oxalic acid, whereas an equal quantity of that acid added to a lime-solution containing only $\frac{1}{1000}$ of free hydrochloric acid produces no precipitate; moreover that starch, after boiling with lactic acid or gastric juice, still gives a blue colour with iodine, whereas it loses this property by boiling with hydrochloric acid. Bernard and Barreswil also find that gastric juice when distilled yields at first a neutral distillate; when concentrated to $\frac{2}{3}$ of its bulk it yields an acid distillate, in which, however, nitrate of silver produces no precipitate; and it is not till the liquid has been distilled down to a few drops, that the distillate affords any indications of the presence of hydrochloric acid. Von Grönwaldt likewise maintains that human gastric juice contains no free hydrochloric acid, but that the acid reaction which it exhibits when mixed with food, is due to organic acids, chiefly lactic and butyric, either contained in it, or developed from the food.

On the other hand, Bidder and Schmidt have shown, by experiments which scarcely leave room for doubt, that the quantity of chlorine precipitated by nitrate of silver from gastric juice acidulated with nitric acid, is equivalent to a quantity of hydrochloric acid more than sufficient to neutralise all the bases contained in the juice; a portion of this acid must therefore be present in the free state, and the excess, determined as above, was found very nearly equal to the quantity of free acid in the gastric juice, estimated by neutralisation with standard solutions. With regard to the non-appearance of hydrochloric acid in the distillate from gastric juice, excepting in small quantity at the end of the distillation, as observed by Bernard and Barreswil, Schmidt, and likewise Mulder, observe that hydrochloric acid can unite with albuminous substances, forming compounds from which it is not expelled by distillation. (For further details, see *Gmelin's Handbuch*, viii. [1] 29.)

According to Marcet (Chem. Soc. J. xv. 407), the gastric juice of dogs contains

another free acid besides hydrochloric acid. A portion of the gastric juice of a dog, which gave an abundant precipitate with nitrate of silver, being placed upon a dialyser (p. 316), the hydrochloric acid in the liquid gradually passed through the diaphragm into the water below, and after a while the remaining liquid, when freed from albumin by boiling and filtering, gave no precipitate with nitrate of silver, but nevertheless, still exhibited a distinct acid reaction, showing that another acid was present, besides the hydrochloric acid. Acetic acid is said by some authorities to be occasionally present in normal gastric juice.

Of the *abnormal constituents* of the gastric juice, says Lehmann, very little is known. In the normal state, the stomach when empty, is invested with a layer of mucus, which is neutral to vegetable colours. In gastric catarrh, this *mucus*, which differs but little from the secretions of other mucous membranes, accumulates in larger quantities, and when it comes in contact with amylaceous or saccharine food, it enters into abnormal processes of fermentation, viz., acetous, butyrous, and lactous fermentation. The contents of the stomach then contain much more free acid than in normal digestion. The butyrous and lactous fermentations are especially promoted by the presence of fat, giving rise to heart-burn, a sensation of constriction in the throat, and vomiting; and at the same time there is often a revulsory (antiperistaltic) motion of the intestinal tube, which causes a regurgitation of bile into the stomach. *Biliary matters* are almost always present in the stomach, even of recently killed animals; nevertheless, they cannot, strictly speaking, be regarded as normal constituents of the gastric juice, inasmuch as they are never produced from the same sources. In uræmia, or after extirpation of the kidneys, urea is secreted by the gastric glands. *Foreign matters* introduced in solution into the body appear to circulate through the gastric glands; thus Bernard found that when sulphocyanate of potassium and sesquichloride of iron were injected into different veins of the same dog, the red colour of ferric sulphocyanide first appeared in the gastric juice.

The quantity of gastric juice secreted varies greatly at different times of the day; it is least when the stomach is empty, and is promoted by the ingestion of food; even mechanical excitation, such as that produced by swallowing stones or peas, increases the secretion. The effect of different kinds of food in this respect varies considerably. Sugar, aromatic substances, alcohol, and alkalis, immediately excite profuse gastric secretion: animal substances act more slowly, but ultimately give rise to a still larger production of the gastric juice. Psychological causes also increase the secretion, e.g. the sight of food by a fasting animal.

From the experiments of Bidder and Schmidt, made with animals in which gastric fistulæ had been established, it appears that dogs secrete, on the average, in 24 hours for each kilogramme of their weight, 100 grms. of gastric juice, containing 2.883 grammes of solid matter (including lactic acid) and 0.270 grms. hydrochloric acid, the quantity of gastric juice secreted in an hour varying from 24 to 204 grms. per kilogramme of the animal's weight. A sheep secretes per kilogramme in 24 hours 120 grms. of pure gastric juice, containing 1.663 grms. solid constituents, and 0.187 grms. hydrochloric acid.

Schmidt (Ann. Ch. Pharm. xcii. 44) found, by observations on a woman having a gastric fistula, that the quantity of gastric juice secreted, per kilogramme of bodily weight, in 24 hours was 264 grms., containing 1.447 grms. solid matter, and 0.053 grms. hydrochloric acid.

The following table exhibits a comparative view of the composition of the gastric juice obtained from these several sources.

Composition of Gastric Juice.

	Man.	Sheep.	Dog.	Ratio.
Water	994.404	986.148	971.171	1 : 0.45 : 0.37
Ferment and ammonia .	3.195	4.205	17.507	1 : 0.6 : 2.1
Hydrochloric acid . . .	0.200	1.557	2.703	1 : 3.5 : 5.1
Chloride of calcium . .	0.061	0.114	1.661	1 : 0.9 : 1.04
Chloride of sodium . .	1.465	4.368	3.147	1 : 1.3 : 0.9
Chloride and potassium	0.550	1.518	1.073	1 : 1.3 : 0.7
Phosphates of calcium, magnesium and ferri- cum	0.125	2.090	2.738	1 : 7.6 : 8.3
	1000.000	1000.000	1000.000	

The acidity of gastric juice ranges, according to Marcet, from 0.085 to 0.303 per

cent. of hydrochloric acid, and varies according to the time, after ingestion of food, at which the secretion is collected. The first quantity removed from the stomach is the most abundant, but the least acid, the secretion gradually becoming smaller in quantity but more acid, and the last quantity exhibiting the highest degree of acidity. This gradual increase of acidity arises partly from the fact that the first quantities of gastric juice secreted are diluted and neutralised by the slightly alkaline mucus contained in the fasting stomach, but more especially, perhaps, from actual increase of the proportion of acid secreted in the latter portions.

The free hydrochloric acid of the gastric juice appears to result from the decomposition of chloride of sodium; this explanation of its origin was first suggested by Prout, who further supposed that the soda separated from it was directed to the liver, and passed off in the bile. But from the experiments of Dr. Bence Jones (Phil. Trans. 1849), it appears that, during the secretion of the gastric juice, the acidity of the urine is greatly diminished, and is at its minimum at the time when digestion is at its height; hence it appears probable that, when the chloride of sodium in the blood yields hydrochloric acid to the gastric juice, the soda separated from it at the same time is taken up by an acid which, during fasting, would have been excreted by the urine, but which remains in the circulation while digestion is going on. (Marcet.)

Physiological action of the Gastric Juice.—All alimentary substances are permeated and softened by the gastric juice; but its principal action is exerted upon the azotised portions of the food, and on the neutral fats. Most of the non-azotised constituents, gum, sugar, starch, &c., placed in pure gastric juice, at the temperature of the animal body, do not undergo any perceptible alteration; but the neutral fats are resolved by it into glycerin and fatty acids, and are then ready to be transformed into emulsions by the bile, which exerts that action upon fatty acids but not on neutral fats. (Marcet, see DIGESTION, p. 325.)

The albuminous and gelatinous matters are dissolved and converted into new substances, which, although they coincide with the bodies from which they are derived, in composition and in many of their physical properties, nevertheless differ essentially from them in being easily soluble in water, and even in dilute alcohol, and in not forming insoluble compounds with metallic salts. The formation of these compounds, called peptones, depends solely on the action of the gastric juice, and is not attended by the evolution or absorption of any gas, or the production of any secondary substance. Soluble casein is coagulated in the stomach before it undergoes the actual process of digestion.

According to Lehmann, cartilage and gelatinous bodies are converted in the stomach into substances which correspond perfectly in their physical and in most of their chemical characters, with the peptones of the protein-bodies. Marcet has, however, shown that the peptones obtained from gelatinous bodies—or at least one such peptone—possess the power of rotating the plane of polarisation of a ray of light, a character not exhibited by the peptones of the protein substances. Hoppe, in 1859 (*Hentle and Meissner's Bericht über die Vortschritte der Anatomie und Physiologie*), observed that gastric juice acts on polarised light, and attributed this action to the gastric secretion itself. Marcet in 1860 made the same observation, but showed further that pure gastric juice, obtained by keeping a dog fasting for thirty hours or longer, then washing out the stomach thoroughly with water, and making the animal swallow siliceous pebbles, has no power of rotating the polarised ray. After exciting the secretion with fragments of bone, however, a gastric fluid was obtained which exerted a slight influence on polarised light, showing a rotation of 7° to the left of Soleil's saccharometer; whereas, when the secretion was excited by cartilage, the rotation amounted to 30° or 40° , also to the left. Gastric juice mixed with cartilage, or with the internal tissue of boiled tripe, and heated in a water-bath to the temperature of the animal body, acquires, after a short time, an optical rotatory power, which may be twice as great as that which it possessed before the commencement of the artificial digestion.

To determine the rotatory power of the polarising peptone, it was separated from the gastric juice, dried, and dissolved in 25 c.c. of water. The solution yielded, for 1° of deviation, an average quantity of 0.024 gm. of dry substance. Therefore when gastric juice is examined in the saccharometer, the fluid contains, for every degree of rotation to the left, 0.024 gm. of polarising peptones, or a quantity approximating thereto, in 25 c.c. (Marcet.)

The only two animal tissues which have been observed to yield polarising peptones, are cartilage and the mucous tissue of boiled intestine. No appreciable quantity of polarising substance was obtained from pure coagulated albumin, or coagulated casein, when digested out of the body. (Marcet.)

The constituents of the gastric juice which are mainly essential to the process of digestion are the pepsin and the free acid; but it can scarcely be doubted that every

one of its constituents has a certain share in its action on food. The necessity of a free acid in the digestive process is shown by the fact that the gastric juice, when neutralised by an alkali, completely loses its action on the azotised portions of the food. The acidity of the juice is, however, only one element of its activity: for the digestive power is likewise destroyed by heating the liquid to a temperature near the boiling point, the pepsin, which appears to act like a ferment, being, like other ferments, unable to withstand that temperature.

The neutralisation of the free acid of the gastric juice by an alkali is the cause which prevents the stomach of a living animal from being acted upon and dissolved by its own secretion. During life, the walls of the stomach are very freely permeated by a current of blood, which, in its normal state, is always alkaline, and therefore neutralises the acid in the gastric juice, and protects the stomach from its action. After death, however, the blood becomes stagnant and incapable of supplying the alkali with the same rapidity as a circulating current; consequently, in many cases, especially when death is sudden or violent, and the gastric juice healthy and vigorous, the stomach is found to be dissolved, even to the extent of perforation. This was first noticed by John Hunter (Phil. Trans. 1772), who attributed the immunity of the stomach during life to the vital principle. But Bernard showed that parts of living animals, frogs' legs for example, are digested when introduced through a fistulous opening into a living stomach; and Dr. Pavy has obtained the same result with the extremity of the ear of a living rabbit, clearly showing that it is not vitality which protects the stomach from the action of its own secretion.

The protecting action has also been attributed to the epithelial lining or mucous membrane of the stomach, which, though acted on and dissolved, is constantly renewed, and therefore defends the stomach from injury; but Pavy has shown that a patch of mucous membrane of the size of a crown-piece may be removed from the stomach of a dog, and food afterwards digested, without the stomach showing the least signs of attack.

The only satisfactory explanation of the immunity of the stomach during life is that of Dr. Pavy above mentioned, namely, that the acidity of the gastric secretion is neutralised by the alkalinity of the circulating blood. Even when the circulation through the stomach is arrested during life by ligatures, the mucous membrane is not always attacked, because there is then still a circulation all round the stomach, and from the facility with which the permeation of fluids takes place, a certain amount of counteractive influence is still exerted; but if a dilute non-corrosive acid (phosphoric or citric) is introduced at the same time into the stomach, so as completely to neutralise the alkali of the blood, the gastric juice then exerts its action, and solution and perforation quickly take place.

The digestion of certain living tissues, viz. the frog's legs and the extremity of the rabbit's ear in the experiments above mentioned, probably arose from the supply of blood to those organs not being sufficient to yield the quantity of alkali required to neutralise the acid of the gastric juice.

Artificial Gastric Juice is a fluid obtained by treating the glandular tissue of the stomach in a peculiar manner with hydrochloric acid: it possesses, in common with natural gastric juice, the power of converting nitrogenous articles of food into soluble non-coagulable substances. (See PEPSIN.)

GAULTHERIA-OIL, or *Oil of Wintergreen*, is a volatile oil or essence obtained from the *Gaultheria procumbens* (wintergreen, or Canada tea), a trailing plant of the Ericaceous order, which grows abundantly in New Jersey. The oil exists in all parts of the plant, but chiefly in the leaves, whence it is extracted by maceration with alcohol or ether, or by distillation with water. It is colourless when fresh, but on exposure to the air it acquires a red-brown colour, which, indeed, the commercial oil usually exhibits. It has an agreeable aromatic odour, and is used for scenting soaps,

&c. It consists of *methyl-salicylic* or *gaultheric acid*, $\begin{matrix} (\text{C}_7\text{H}_5\text{O}) \\ \text{H.C}_6\text{H}_4 \end{matrix} \text{O}_2$ (see *SALICYLIC* ETHERS), mixed with a small quantity of *gaultherilene*, a hydrocarbon isomeric with oil of turpentine. When distilled, it begins to boil at 200°C ., at which temperature the gaultherilene chiefly passes over, and the boiling point then gradually rises to 222° , at which temperature the pure methyl-salicylic acid distils over. On distilling the oil with strong potash- or soda-ley, methylic alcohol, water, and gaultherilene pass over, and salicylate of potassium remains in the retort. (Cahours, *Ann. Ch. Phys.* [3] x. 327.—Procter, *J. Pharm.* [3] iii. 275.)

An oil nearly identical in properties with wintergreen oil, and consisting of methylsalicylic acid, unmixed with gaultherilene, is obtained by distilling with water the bark of the *Betula lenta* (sweet birch, blair birch, cherry birch), a tree growing in North America. This oil does not exist in the bark ready formed, but appears to be produced by the action of a substance resembling emulsin on *gaultherin*, a compound

analogous to the amygdalin of bitter almonds: for, when the dry pulverised bark is exhausted with cold alcohol of 90 per cent., the residue does not yield methyl-salicylic acid by distillation with water; but on evaporating the alcoholic tincture, and treating the residue with water, the odour of wintergreen oil is evolved, and by distillation a liquid is obtained which reddens ferric salts, an indication of the presence of salicylic acid. (Procter, *loc. cit.*)

GAULTHERIC ACID. Syn. with METHYL-SALICYLIC ACID.

GAULTHERILENE. The hydrocarbon isomeric with oil of turpentine which exists in wintergreen oil. The best mode of isolating it is to distil wintergreen oil with caustic alkali, as above described, wash the heavy oil which settles at the bottom of the watery distillate, first with alkaline, then with pure water, and rectify it over potassium. It is a colourless mobile oil, having an odour like that of pepper. Boils at 160°C . Vapour-density 4.92. It forms a resinous mass with nitric acid, and viscid products with chlorine and bromine. (Cahours.)

GAY-LUSSITE. A native carbonate of sodium and calcium, $2\text{NaCaCO}_3 + 5\text{H}_2\text{O}$, found at Lagunilla, near Merida, in Columbia, disseminated at the bottom of a small lake in a bed of clay, covering *urao*. The natives call it *clavos* or *nails*. It is also found near Sangerhausen in Thuringia. The crystals are prisms belonging to the monoclinic system, transparent or translucent, with yellowish-white colour, and exhibiting double refraction. Specific gravity 1.92 to 1.99. Hardness 2 to 3. Extremely brittle. Fracture conchoidal, with vitreous lustre on the fractured surface. Streak greyish-white. Decrepitates slightly when heated, and becomes opaque from loss of water. Melts rapidly before the blowpipe to an opaque bead, which has a strong alkaline taste, and when once formed is no longer fusible. The pulverised mineral, before ignition, dissolves sparingly in water without decomposition, forming a solution which reddens turmeric. The anhydrous salt is resolved by water into soluble carbonate of sodium and insoluble carbonate of calcium. (Dana, i. 455; Gm. ii. 216.)

GEDRITE. A variety of hornblende, resembling anthophyllite, from Gedré in the Pyrenees. It contains, according to Dufrenoy, 38.81 per cent. SiO_2 , 9.31 AlO_3 , 45.83 FeO , 4.13 MgO , 0.67 CaO , and 2.70 H_2O .

GELENITE. A silicate found mostly at Mount Manzoni, in the Fassa Valley (Tyrol), in isolated or aggregated crystals invested by calc spar. The crystals are short square prisms, sometimes tabular. Cleavage imperfect parallel to the base. Specific gravity 2.9 to 3.067. Hardness 5.5 to 6. Lustre resinous, inclining to vitreous. Colour various shades of green to grey and brown. Fracture uneven—splintery. The powder is easily decomposed by hydrochloric acid, with separation of gelatinous silica. According to Rammeisberg's analysis (*Mineralchemie*, p. 732), the mineral contains—

SiO_2	Al_2O_3	Fe_2O_3	FeO and MnO	CaO	MgO	H_2O
29.78	22.02	3.22	1.92	37.90	3.88	1.28 = 100.00

whence may be deduced the formula $3\text{M}''\text{O}.\text{R}^2\text{O}.2\text{SiO}_2$ or $(\text{M}'')^3(\text{R}^2)^2\text{Si}_2\text{O}^{10}$ (M' denoting a monatomic, and R^2 a triatomic radicle, such as aluminium); and if we write $m = \frac{2}{3}\text{R}$, this formula becomes $(\text{M}''m)^2\text{Si}_2\text{O}^{10}$, which is of the general form $(\text{M}'')^2\text{Si}_2\text{O}^{10}$, or $(\text{M}'')^2\text{SiO}_5 = 3\text{M}''\text{O}.\text{SiO}_2$. (Dana, ii. 256.) The term *massive Gelenite* is applied to a variety of Mellitite (*q.v.*)

OSIC ACID and OSIN. See ULMIC ACID and ULMIN.

GELATIN. *Bone-gelatin. Animal glutin.* (Lehmann's *Physiological Chemistry*, i. 39. Gerhardt's *Tratât*, iv. 507.)—When bones are digested for some length of time with hydrochloric or nitric acid diluted with 9 pts. water, and the liquid is decanted and replaced by water less and less acid, the whole of the mineral constituents of the bones are dissolved out, leaving the chief organic constituent, bone-cartilage, as a yellowish, transparent, elastic substance, retaining the primitive form of the bone, and becoming exceedingly hard and slightly brittle on drying. This substance, which is also the chief constituent of the serous membranes, the connective tissue, the epidermis, tendons, horn, &c., has been termed ossein, or ostein, by Verdeil and Robin. Ossein, when completely exhausted by dilute acid, contains but a trace of mineral matter; it is washed with distilled water until the wash-waters no longer acquire an acid reaction, then dried, and treated with alcohol and ether. According to Frémy, it always has an acid reaction, which it loses by washing with feebly alkaline water. Boiled with water, ossein is converted into gelatin, without either evolving or absorbing gas; indeed, the composition of the two bodies does not sensibly differ. The presence of an acid greatly facilitates this transformation. Ossein contains 49.2 C, 7.8 H, and 17.9 N (Frémy), with between 0.6 and 0.7 per cent. sulphur. (Verdeil, Schlieper.)

Several kinds of gelatin occur in commerce. The purest, called *ichthyocoll*, or *isinglass*, is extracted from the internal membrane of the swimming-bladder of the sturgeon, a fish very common in Russia. An inferior kind of isinglass is manufactured from fish-bones. Glue is a crude product, prepared by boiling down pieces of hide, bones, horn, hoof, cartilage, &c., with water, either at the common atmospheric pressure or under a higher pressure (at 106° or 107° C.). After the concentrated solution has been clarified, it is converted by cooling into a trembling jelly, which is cut into thin slices by means of a wire, and then dried. In this form it is met with in commerce.* Common glue is far from being pure gelatin: it contains substances soluble in cold water and in alcohol. To purify it, the solution of glue is allowed to gelatinise in cold water, and the jelly is mechanically divided, tied in a cloth, and placed in contact with warm water, which is renewed from time to time. When the whole of the colouring matter has thus been extracted, the jelly is melted in water at a gentle heat, and the insoluble portion is filtered off. The clear solution, mixed with its own volume of alcohol, yields a precipitate of pure gelatin. Gelatin is often prepared by treating bones with dilute hydrochloric acid. The ossein thus obtained is washed and melted in a little water.

Chemical and physical properties.—Dry gelatin is a colourless or yellowish substance, transparent in thin plates, elastic, vitreous, hard, and brittle. It has neither taste nor smell, is not affected by the atmosphere, and is neutral to vegetable colours. It is heavier than water, and is insoluble in alcohol and ether. In contact with cold water, gelatin swells and increases about 40 per cent. in weight, becoming translucent, but does not dissolve appreciably. The jelly dissolves in hot water, and the concentrated solution is precipitated by alcohol in the form of a white clotted mass.

When a concentrated solution of gelatin is boiled for some time, it gradually loses the property of gelatinising on cooling, and the liquid on evaporation leaves a deliquescent residue, resembling terebinthin. The solution, however, yields with alcohol a precipitate of the same composition as gelatin.

Schlieper found in bone- and ivory-gelatin between 0.12 and 0.14 per cent. of sulphur; and v. Bibra always found very appreciable quantities of sulphur in bone-gelatin. Gelatin precipitated by alcohol gives but a trace of ash. Common glue, however, always contains a large quantity of phosphate of calcium, and, according to Mulder, this substance is an essential constituent of gelatin.

Moist gelatin exposed to the air rapidly putrefies; the liquid at first becomes highly acid, but afterwards gives off a large quantity of ammonia. This property of first becoming acid is characteristic of gelatin.

Submitted to dry distillation, gelatin yields an aqueous distillate charged with carbonate of ammonium, and a thick brown oil containing sulphide, carbonate, and cyanide of ammonium, various volatile alkaloids (aniline, picoline, methylamine, tritylamine, tetrylamine, pyridine, lutidine, pyrrol), together with certain neutral oils not yet investigated.

Pure solution of gelatin is not precipitated by *dilute alkalis*. Boiled with concentrated solution of potash, it yields leucine, glycocine, and other products. The same reaction takes place when gelatin is carefully fused with hydrate of potassium.

It is not precipitated or rendered turbid by any acid, except the *tannic acids*. Gelatin is dissolved by concentrated *sulphuric acid* in the cold. The solution, diluted with water and boiled, yields leucine, glycocine (sugar of gelatin), and other products. Gerhardt, by boiling isinglass for several days with dilute sulphuric acid, obtained sulphate of ammonium, and a considerable quantity of a saccharine matter, convertible into alcohol and carbonic acid by fermentation. This reaction supports to a certain extent Hunt's view of the constitution of gelatin. He finds that by adding the elements of ammonia to the formula of starch, and subtracting the elements of water, a formula is obtained agreeing pretty nearly with the composition of gelatin:—

This formula would require 50.70 C; 7.04 H; 19.71 N; and 22.55 O; the nitrogen is much too high.

* On the manufacture of gelatin for culinary purposes, see *Ure's Dictionary of Arts, &c.* II. 324; Manufacture of glue, *ibid.* 376.

Gelatin is attacked by hot *nitric acid*, oxalic and saccharic (?) acids being produced, together with a fat and an astringent substance. (Berzelius.)

Lime and phosphate of calcium are much more soluble in a solution of gelatin than in cold water. Chemical compounds of gelatin and phosphate of calcium may be prepared. It is not unlikely that ossein and phosphate of calcium may be in chemical combination in the bones. (Lehmann, *Gmelin's Handbuch*, viii. [2] 557.)

Solution of gelatin is not precipitated by *alum* or *ferrio sulphate*; on the addition of alkali in sufficient quantity, a precipitate is formed containing gelatin and a basic sulphate. It is not precipitated by *ferrocyanide of potassium* (this distinguishes gelatin from the protein-compounds), nor by *neutral or basic acetate of lead*. It is rendered turbid by the addition of a small quantity of *mercuric chloride*; the precipitate redissolves on shaking, but becomes permanent on the addition of excess of the salt. It is not precipitated by *nitrate of silver* or *chloride of gold*, but reduces them partly to the metallic state. It is precipitated by *platinic chloride*.

Sulphate of copper does not precipitate gelatin; the green liquid turns violet on addition of potash, and is not precipitated by ammonia or phosphate of sodium.

By distillation with dilute *sulphuric acid* and *pyroxide of manganese* or *acid chromate of potassium*, the same products are obtained with gelatin as with albumin, viz. carbonic acid, formic acid and its homologues up to caproic acid; also prussic acid, valeronitrile, acetic and butyric aldehydes, benzoic acid, hydride of benzoyl, and a heavy oil having the odour of essence of cinnamon.

Gallotannic acid, and other kinds of tannic acid, form compounds with gelatin. The precipitate, from concentrated solutions, is obtained in clotted flakes, or as a soft, elastic, imputrescible mass. The precipitate is insoluble in water, alcohol, and ether, but soluble in a warm solution of potash. It becomes hard and brittle on drying. 100 pts. gelatin dried at 130° C. yield, with gallotannic acid, between 134 and 135.6 pts. product. The composition of the precipitate does not appear to be constant. This reaction is so delicate that a solution containing 0.0002 pts. gelatin is rendered turbid by an infusion of gall-nuts (p. 763).

When a current of gaseous *chlorine* is passed through a solution of gelatin, a white pellicle forms round each bubble of gas, and the whole of the gelatin is finally precipitated in flexible, elastic, macerous, gelatinous, transparent flakes or filaments (Thénard, Bouillon-Lagrange). The precipitate is tasteless, slightly acid, imputrescible, insoluble in water and in alcohol, and soluble in alkalis. On exposure to the air it exhales an odour of chlorine. A similar product is obtained with gelatin which has been boiled for some time with water. No similar products are obtained by substituting bromine or iodine for chlorine.

Sources and physiological relations. Bone-gelatin is obtained from the following tissues by boiling them for a longer or shorter time with water: from the cartilages of bone (after ossification), from tendons, the skin, calves' feet, harts' horns, isinglass, the scales of fish, and from the permanent cartilages, when they become ossified by disease (see CHONDRIIN, i. 930). The conversion of these animal parts into gelatin proceeds without any evolution or absorption of gas. Indeed, a comparison of the analyses of pure gelatin with those of the tissues yielding it shows that there is no chemical difference between the two, or that at most they differ only by a few molecules of water. Hence it appears that, in the formation of gelatin, the material of the tissues merely undergoes a re-arrangement of its atoms, or that at most it only assimilates water, just as starch does when converted into glucose by prolonged boiling. The formation of gelatin from the gelatinous tissues is greatly facilitated by the presence of acids. Schlieper found that the ossein of fossil bones, the organic substance of which had been preserved, had been converted into a gelatinous substance or into true gelatin. That of diseased bones does not appear to differ from normal ossein. In the bones of certain waterfowl, and in the ribs of certain fishes, Frémy found, instead of ossein, an organic body isomeric with that substance, but incapable of being converted into gelatin by boiling. The fibrous tissue of embryos does not yield gelatin by boiling with water. It contains an intercellular substance yielding a gelatinous substance and albumin. (Scherer.)

According to J. Müller (Pogg. Ann. xxxviii. 313), the cornea contains, not gelatin but a substance resembling chondrin. In cases of leucocythemia, Scherer found gelatin in the blood. The filtered serum of the pus from a femoral abscess was found to contain gelatin (*Gmelin's Handbuch*, viii. [2] 527). Beef contains 1.9 per cent. tendinous tissue capable of being converted into gelatin by boiling with water. (Berzelius.)

Liebig has remarked that gelatin has the property of inducing saccharification. Gelatin, and tissues yielding gelatin, are converted in the stomach into substances which correspond perfectly in most of their physical and chemical properties with the peptones of albuminoids, but are distinguished by the power of turning the plane of

polarisation of a luminous ray to the left (p. 824). Ready-formed gelatin is more easily metamorphosed than connective tissue, and the latter far more readily than tendons or cartilage.

Gelatin and gelatinous tissue belong to the most digestible substances. According to Blondlot, when a dog was fed with 100 grms. gelatin from calves' feet, very little remained undissolved in the stomach after three quarters of an hour; and in one hour the stomach was empty. The same observation was made with ichthyocoll. Gelatinous tissue, previously boiled, readily undergoes the same change. Pieces of leather were not in the slightest degree acted upon by five days' digestion in a dog's stomach. (*Gmelin's Handbuch*, viii. [2] 616.)

According to Frerichs, digested gelatin loses on cooling the properties of gelatinising and of being precipitated by chlorine, but still gives the characteristic precipitate with tannic acid. The same effect is not produced by artificially digesting gelatin with a dilute acid.

The nutritive qualities of gelatin have been much disputed. Liebig ascribes little if any nutritive qualities to it, but his experiments do not appear to be quite conclusive. In jellies, &c., it does not perhaps add much to the highly nutritive properties of the substances for which it usually serves as a vehicle. C. E. L.

GELATIN, VEGETABLE. See GLUTEN.

GELIDIUM CORNEUM. See the next article.

GLOSE. (Payen, *Compt. rend.* xlix. 521; *Précis de Chimie Industrielle*, 4^{me} éd. ii. 727.)—A gelatinous principle which forms the essential constituent of a vegetable substance called Chinese moss (*mousse de Chine*), first imported into France from China in 1856. This substance, which is found in commerce in small bundles of long and very fine threads, is said to be obtained from several lichens growing on trees in the south of China, and the southern islands of the Philippine Archipelago. It is quite destitute of organised structure, and contains only 0.0607 per cent. of matter soluble in cold water, and a still smaller quantity, viz. 0.007 per cent. soluble in alcohol. It swells up in cold water, and dissolves almost wholly in boiling water, leaving only a small quantity (2 or 3 per cent.) of azotised corpuscles. The solution on cooling coagulates into a colourless translucent jelly, containing a quantity of water equal to about 500 times the weight of the original substance.

This jelly, when dried, yields *glose*, a substance insoluble in cold water, alcohol, ether, weak solutions of potash, soda, or ammonia, dilute acids, and ammoniacal solution of copper. Acetic acid of 8° Bm. dissolves it. It is soluble also in a very small quantity of strong sulphuric or hydrochloric acid, acquiring a brown colour, and gradually forming a brown coagulum, which may be washed without alteration in hot or cold water, or in caustic alkaline solutions.

Glose contains 42.770 per cent. carbon, 5.775 hydrogen, and 51.455 oxygen. No definite compound has yet been formed of it, so that its atomic weight and rational formula must for the present remain undetermined; but it belongs to that class of proximate principles which contain a larger proportion of oxygen than is required to form water with the hydrogen.

The species of lichen which yield the commercial article are not exactly known. Payen has examined several lichens with the view of obtaining it, but has only found slight traces. On the contrary, he has obtained it in abundance from certain algae, viz. the Java sea-weed (*Gelidium corneum*), and the *Placaria lichenoides*, a sea-weed from the Mauritius; in small quantity also from several European algae. From Java sea-weed it is extracted by treating the plant in the cold successively with dilute hydrochloric acid of 0.02, or dilute acetic acid, water, and weak ammonia; washing it thoroughly to remove earthy and alkaline salts (including 53 per cent. of carbonate of calcium), and extraneous organic matter; exhausting the residue, which contains 58 per cent. of glucose, with boiling water as above; and drying the jelly which forms on cooling.

Glose yields ten times as much jelly as an equal weight of isinglass, and may, therefore, perhaps be economically used in place of that substance. It is true that it contains no nitrogen; but as gelatin is said to serve rather as a vehicle for nutritious matter, than as a directly nutritious substance, it is possible that glose may be found applicable to the same purpose.

GEMS, ARTIFICIAL. See *Ure's Dictionary of Arts*, &c. ii. 328.

GENTIAN. *Gentiana lutea*.—The root of this plant, which is abundant in Switzerland, the Tyrol, and the Auvergne, is cylindrical, knotted, of yellowish-brown colour, disagreeable odour, and strong bitter taste. The aqueous infusion is much used as a tonic. The root contains gentianic acid, a peculiar bitter called gentian-bitter, uncrystallisable sugar, gum, a volatile oil, a green oily matter, pectic acid, yellow colouring matter and cellulose.

Gentian-bitter may be separated from the aqueous infusion of the root by animal charcoal, and extracted therefrom by hot alcohol. It is yellow, uncrystallisable, and reduces an alkaline cupric solution.

The liquid from which the bitter has been extracted by animal charcoal retains in solution a large quantity of uncrystallisable sugar, and a substance which imparts to it a strong green iridescence or fluorescence. (H. Ludwig, Arch. Pharm. [2] cviii. 132; Jahresh. 1861, p. 753.)

GENTIANIC ACID. $C^{14}H^{10}O^5$. *Gentianin, Gentisic acid, Gentisin.*—An organic acid existing in the root of gentian (*Gentiana lutea*), discovered by Henry and Caventou (J. Pharm. vii. 173), more fully examined by Baumert (Ann. Ch. Pharm. lxi. 106). It is extracted by treating the powdered root with cold water, to remove the bitter principle; then pressing, drying, and exhausting it with strong alcohol; distilling off the greater part of the alcohol; and treating the brown, resinous, very bitter residue with water, which separates light-brown flakes containing gentianic acid, a resin similar to caoutchouc, a fatty substance, and a bitter principle. They are treated with ether to remove the fat, and then dissolved in alcohol, which leaves on evaporation a crystalline mass, still bitter, and mixed with resin. By repeated crystallisation from alcohol, the gentianic acid is obtained in needles, quite tasteless, and having a light-yellow colour; 10 kilogrammes of the dried root yield only 3 or 4 grms. of pure gentianic acid. (Baumert.)

Gentianic acid crystallises in slender needles, which require 36·30 pts. of water at 16° C. to dissolve them. It is more soluble in ether, and still more in boiling alcohol. The solutions are neutral to vegetable colours. It is also very soluble in alkalis, a small quantity sufficing to impart a golden tint to an alkaline liquid. It contains, according to Baumert's analysis, 65·06 per cent. C, 4·12 H, and 30·82 O, agreeing nearly with the formula $C^{14}H^{10}O^5$.

Gentianic acid is unalterable in the air, and may be heated to 200° C. without decomposing. Between 300° and 340° it sublimes partially in yellow needles, the greater part, however, becoming carbonised and emitting a peculiar odour. It is not attacked by hydrochloric, acetic, sulphurous or dilute sulphuric acid; strong sulphuric acid dissolves it with yellow colour. Nitric acid of specific gravity 1·43, free from nitrous acid, dissolves it, forming a green solution from which water throws down a green powder, consisting of dinitrogentianic acid, $C^{14}H^8(NO^2)^2O^5 + H^2O$. This acid, in contact with alkalis, assumes a fine cherry colour, even the ammonia in the air sufficing to produce it in a certain degree. When gentianic acid is added by small portions to fuming nitric acid, the violent action being each time allowed to subside before a fresh portion is added, a solution is obtained from which water precipitates a yellow crystalline substance, probably consisting of trinitrogentianic acid, $C^{14}H^7(NO^2)^3O^5$.

Chlorine passed into an alcoholic solution of gentianic acid throws down light-yellow flocks containing chlorine.

Gentianic acid decomposes alkaline carbonates. The gentianates of the alkali-metals are soluble and crystallise in needles, but do not appear to be of constant composition. The barium-salt forms an orange-coloured flocculent precipitate, containing $C^{14}H^8Ba^2O^5 + H^2O$. The lead-salt is also an orange-coloured precipitate, obtained by adding gentianic acid mixed with ammonia to neutral acetate of lead: it contains $C^{14}H^8Pb^2O^5$, $PbHO$.

Gentianic acid forms green precipitates with cupric salts, brown with ferric salts, and reduces salts of silver.

GENTIANIN. Syn. with GENTIANIC ACID.

GEOCERAIN. A waxy body isomeric with geoceric acid.

GEOCERIC ACID.— $C^{28}H^{42}O^8$? (L. Brückner, J. pr. Chem. lvii. 1; Jahresh. 1852, p. 647).—A waxy acid similar to and perhaps identical with cerotic acid, obtained, together with other waxy and resinous substances, from some peculiar kinds of earthy lignite found at Gerstewitz, near Weissenfels.

A yellowish-brown variety of the lignite exhausted with ether yielded by evaporation a yellowish-brown residue, consisting: 1. Of a resinous substance, leucopettrin, $C^{28}H^{42}O^8$, insoluble in alcohol of 80 per cent., but slightly soluble in boiling absolute alcohol, whence it crystallises in tufted groups of needles, melting above 100° C.—2. Of waxy and resinous substances, soluble in boiling alcohol of 80 per cent. One of these latter, precipitated from the concentrated and cooled alcoholic solution by alcoholic acetate of lead, separated from the lead precipitate by strong acetic acid, and recrystallised from alcohol, formed small needles. Its solution yielded a dirty green precipitate with cupric acetate; its ammoniacal solution gave off all the ammonia on evaporation. Brückner assigns to the substance which unites with the

bases in these salts the formula $C^{24}H^{21}O^7$, and calls it geoceric acid.—3. The filtrate from the lead precipitate contained two resins, one of which separated by slow evaporation in the pulverulent form, and exhibited the composition $C^{23}H^{20}O^6$, and the other separated after further evaporation as a soft, tough, brown, transparent mass.

The same variety of the lignite subjected to dry distillation gave off a large quantity of illuminating gas and white vapours, which at first condensed to an oily liquid, afterwards to a buttery mass, the solution of which in boiling alcohol of 80 per cent. yielded on cooling a combustible crystalline substance, geocerinone, $C^{110}H^{110}O^2$, or $C^{55}H^{55}O$, the acetone of geoceric acid, which, when purified by recrystallisation, exhibited microscopic six-sided plates, melted at $50^\circ C.$, was not altered by aqueous potash, but was converted by chromic acid in the nascent state into a waxy acid. The alcoholic liquid from which the geocerinone had separated retained an oil in solution.

A dark brown variety of the lignite, freed from geoceric acid and other resins by exhaustion with cold alcohol of 80 per cent. yielded, on subsequent boiling with the same alcohol, the following substances: 1. The hot-filtered alcoholic liquid deposited on slight cooling, a pulverulent substance, geomyricin, $C^{68}H^{68}O^1$, or $C^{34}H^{34}O^2$, which, however, was obtained in greater quantity when the resin, after exhaustion with cold alcohol of 80 per cent., was boiled with absolute alcohol. After several recrystallisations, it formed white pulverulent masses of microscopic capillary crystals, melting between 80° and $83^\circ C.$ —2. The still hot alcoholic liquid, filtered from the geomyricin, heated to the boiling point, and mixed with a hot alcoholic solution of acetate of lead, deposited the lead-salt of geoceric acid, which was extracted therefrom by strong acetic acid, and purified by recrystallisation from alcohol. This acid may also be obtained by saponifying the waxy bodies contained in the alcoholic decoction of the lignite with potash, decomposing the soap with chloride of barium, and the purified barium-salt with acetic acid. It dissolves readily in hot alcohol, and separates almost completely on cooling in the form of a gelatinous mass. It melts at $82^\circ C.$ Brückner expresses its composition by the formula $C^{36}H^{36}O^2$, or $C^{18}H^{18}O$, and observes that it closely resembles corotic acid, $C^{22}H^{22}O^2$.—3. The liquid filtered from the precipitate of geocerate of lead contained in solution a neutral wax, geoceraïn, isomeric with geoceric acid, which separated from the hot-filtered liquid, on cooling, in the gelatinous form, and, when purified, melted at $80^\circ C.$

GEOCERINONE. $C^{33}H^{33}O$.—The acetone of geoceric acid, obtained by dry distillation of either the yellow-brown or the dark brown variety of the lignite of Weissenfels.

GEOCRONITE. (Dana, ii. 85; Gm. iv. 176.) A native sulphantimonite of lead, $5Pb''S.Sb^2S^3$, or $\left\{ \begin{smallmatrix} Pb'' \\ Sb''' \end{smallmatrix} \right\}^5 S^8$, from the silver mines of Sala in Sweden; also found in Galicia, at Meredo in Spain, where it forms nodules in galena, and in the Valley di Castello, near Pietro Santo, in Tuscany. Usually massive, but sometimes in crystals belonging to the dimetric system; also granular or earthy. Specific gravity 6.4 to 6.6. Hardness = 2 to 3. Lustre metallic. Colour and streak from light lead-grey to greyish blue. Fracture uneven. Crumbles easily and soils the fingers. Fuses readily before the blowpipe, giving off fumes of antimony and sulphur, and colouring the charcoal yellow. A variety called *Kilbrickenite*, from Kilbricken, County Clare, Ireland, contains 6 at. lead to 1 at. antimony; $6Pb''S.Sb^2S^3$ or $\left\{ \begin{smallmatrix} Pb'' \\ Sb''' \end{smallmatrix} \right\}^6 S^8$.

GEOIDE. A rounded nodule of stone containing a cavity usually lined with crystals: geodes frequently consist of lignite, chalcedony, &c.

GEOLOGY, CHEMISTRY OF. Since the severance of geological science, properly so-called, from the speculative systems of cosmogony, with which it was associated up to the commencement of the present century, its development has been materially aided by the application of the knowledge acquired in other departments of research, to the critical examination of geological phenomena, and to the elucidation of

the various problems suggested by them, as to the mode in which rocks and strata have been formed or altered from their original conditions. It being no longer regarded as the object of geology to discover how the earth originated, but merely to ascertain the history of its existence and changes, it is evident that the records of that history must be read in accordance with those laws of nature which are known to obtain in the phenomena and changes taking place at the present time. An eminent geologist, in referring to the relation between geology and other physical sciences, has remarked that, as an historian should be at once profoundly acquainted with all branches of knowledge by which any insight into human affairs, or into the moral and intellectual nature of man, can be obtained, so "it would be no less desirable that a geologist should be well versed in chemistry, natural philosophy, mineralogy, zoology, comparative anatomy, botany; in short, in every science relating to organic and inorganic nature." (*Lyell's Principles*, p. 2.)

This necessity, now fully acknowledged by all geologists, has been complied with to a less extent in the case of chemistry than in any other. And yet it is from chemistry alone that data can be obtained which will admit of correct conclusions being formed as to many geological phenomena, such, for instance, as the formation and alteration of rocks and strata, or of the individual minerals of which they are constituted. Prior to the latter part of last century, chemistry was not in a position to furnish the necessary data for the interpretation of geological facts, and the opinions of geologists with regard to the formation and alteration of rocks and strata conformed to one or other of two extreme views, according to which, on the one hand, everything was supposed to have been produced by fire, while on the other hand, everything was supposed to have been produced by water. These two opposite doctrines were equally adopted, without any inquiry being made as to how far the nature of particular rocks or minerals might be consistent with the opinion that they had been produced by the agency of fire or of water. Thus granite and all similar crystalline rocks were very generally regarded as having acquired their present condition by the crystallisation of melted masses; but in granite it is always found that quartz, the least fusible of its three constituent minerals, appears to have been the last to crystallise, while felspar, the most fusible of them, appears to have crystallised first, the crystals of felspar being imbedded in those of mica and quartz. In syenite and other crystalline quartzose rocks, as well as in granite, the quartz is found to be, as it were, the matrix in which the crystals of the other more fusible minerals are imbedded: hence it would appear that the constituent minerals of these rocks were not crystallised in such an order of succession as would be indicated by their relative degrees of fusibility, and as might be expected if they were of igneous origin.

Granite dykes and veins, not more than an inch or two thick, and sometimes as thin as paper, are frequently met with traversing and extending into other rocks, which must have been very intensely heated if these veins were injected in a melted state; but generally speaking the strata in which such veins are found do not present any indications of having been, at any period, intensely or at all heated, nor is there at the lines of contact between the granite veins and the surrounding rock any indication of the action of heat.

These facts, and many others of a similar nature, are quite irreconcilable with the opinion that granite has in all cases been formed by igneous action; and if they do not prove that it has not been so formed, they at least open a wide field of inquiry as to the conditions under which granite has been produced.

The various kinds of porphyritic lava furnish another instance in which the characters of the minerals they contain are inconsistent with the opinion that these rocks were formed, as they now exist, from melted masses. These rocks are undoubtedly of volcanic origin, but the important fact with regard to them is, that they are all of very remote origin, far anterior to the historic period. Generally speaking, the lava of more recent periods is either amorphous, or if it be of crystalline texture, it rarely presents imbedded crystalline minerals of any size or symmetry, so as to have a porphyritic character. It is only in the most ancient products of volcanoes that such crystals of wernerite, garnet, leucite, and vesuvian are met with. A variety of circumstances connected with the relation these minerals bear to others with which they are associated in these rocks, all tend to the conclusion that they have been formed subsequently to the solidification of the lava, and not at all under the influence of heat.

The existence of hydrated minerals, such as zeolites, in some rocks may also be regarded as evidence that those rocks have not been formed by igneous action, or that they have undergone some considerable alterations by other means subsequent to their formation. Thus, for instance, no zeolites are found in lava, but in many kinds of basalt they are very abundant.

Iron-pyrites is a very frequent constituent of most crystalline rocks, but this mineral is decomposed by a red heat. Its occurrence likewise in almost every variety of sedimentary rock is clearly indicative of its formation without the agency of heat,

and lends probability to the same mode of formation in crystalline rocks. It is therefore necessary to abstain from regarding crystalline minerals, occurring even in volcanic rocks, as being products of fusion, or from regarding their occurrence in such rocks as evidence of their formation in that way; and it is still more necessary to abstain from concluding that rocks whose geognostic relations indicate an eruptive origin were originally in the same condition that they exhibit at the present time.

The class of rocks comprised under the general term of metamorphic rocks, have always furnished wide scope for speculation as to the mode in which they have acquired their present condition. These rocks, presenting evident signs of stratification, fossil remains, and sometimes all the features of sedimentary strata, also possess a structure more or less crystalline, and sometimes a general character so closely resembling that of massive crystalline rocks, as to be distinguishable from them only by retaining faint signs of stratification which reveal their sedimentary origin. Hence it has been impossible to overlook the fact that the present condition of these rocks has been brought about by the alteration of sedimentary strata. Very remarkable theories of metamorphism have at various times been propounded, in which fire and water, pressure, electricity, and magnetism have been made to perform strangely incoherent and anomalous functions; but it is only quite lately that any attempts have been made to trace, as it were, the various stages of metamorphism in rocks, and by ascertaining what mineralogical and chemical differences accompany these various degrees of alteration, to obtain a basis on which to found some general view with regard to the metamorphism of rocks, that shall be consistent with observed facts, and with recognised principles of chemistry and physics.

Among the facts which have contributed to afford evidence of the extent to which chemical action is concerned in the formation and alteration of rocks, the phenomena of pseudomorphism and petrification have been the most important. Pseudomorphs are minerals presenting definite crystal-forms which do not belong to the substances of which those minerals now consist, but to other substances which have either wholly disappeared, or of which some fragments still remain. Pseudomorphs, though presenting an outward crystal-form, are not really crystals, but merely aggregates of the substances which have been produced simultaneously with the destruction of those whose outward crystal-form they present. In like manner petrified or fossil organic remains are abundantly met with, consisting of a variety of substances, such as carbonate of calcium, the sulphates of barium, calcium, and strontium, fluoride of calcium, quartz, opal, talc, sesquioxide of iron, the carbonates of zinc, lead, and iron, black oxide of manganese, phosphate of iron, iron and copper pyrites, the sulphides of lead, zinc, copper, and mercury, metallic copper, chlorite, &c. Here the organic substance, or the material of the bony or shelly structures, has been removed, while in their place, and with their form, some one or other of the above-named substances have been substituted.

The alterations recognisable, to a greater or less extent, in many minerals are perfectly analogous to those presented by pseudomorphs and petrifications, and this is equally true whether it be an isolated crystal of a mineral that is altered, or whether the alteration has taken place throughout an extensive mass of rock consisting of minute crystals of that mineral or merely amorphous masses of it. In the latter case, the indications of the change which has taken place cannot be traced as in a large well-defined crystal, but the clue to the real nature of that change may be obtained from the study of the more apparent instance.

Strictly speaking, it may be impossible to say whether any particular mineral is really in a normal condition of integrity, or whether it has not undergone some degree of alteration. The analysis of minerals almost invariably indicates the presence of minute quantities of substances not belonging to their chemical constitution. These substances, regarded as foreign or accidental, are often deducted in calculating the chemical formulæ. Thus for instance, andalusite is reasonably considered to be anhydrous silicate of alumina, but all analyses of this mineral indicate the presence of potash, lime, magnesia, the oxides of iron and manganese, and water. If these substances are merely accidental admixtures, that variety of andalusite which contains the smallest amount of them will be nearest to its normal condition.

The alteration of minerals is an extremely slow process. The material changes progress so gradually as to be chemically recognisable only after the lapse of long periods. Andalusite, for example, is known to undergo conversion into mica, in which change part of the alumina is removed, while potash, magnesia, and ferric oxide are introduced in its place; hence it may be inferred that this mineral, as usually met with, is already in a state of incipient alteration. Andalusite also undergoes conversion into staurolite, in which change the whole of the alumina is abstracted, and magnesia substituted in its place.

This example will suffice to show the importance, in a geological point of view, of the

minute quantities of substances present in minerals. These acquire significance when compared with the constituents of the pseudomorphs resulting from the alteration of minerals in which such adventitious substances are found. They then no longer appear accidental, but indicative of the transition of one mineral into others; they place clearly before us the progressive nature of those changes, whose ultimate results are recognisable more obviously in pseudomorphs, and show that those constituents of a mineral, which in a minimum proportion are regarded as accidental, may ultimately in a maximum proportion become essential.

There can be no doubt that the chemical analysis of minerals would acquire a much higher value if its object were not merely to establish chemical formulæ, but also to elucidate the formation of minerals. The fact that one mineral may appear with the outward form of another totally distinct mineral has been sufficiently well established by mineralogists, and it remains for chemists to trace the processes by which the alteration of the one into the other may take place. Time being so essential an element in the processes by which these changes are effected, it is not to be expected that they can be experimentally studied; so that the only course is to ascertain by analysis the increase of the non-essential, and the decrease of the essential constituents of mineral, until a point is reached at which the one takes the place of the other.

These processes may be considered to consist either in the direct conversion of one mineral into another, or in the production of a series of gradational changes, furnishing minerals more distinct from the original ones, and more resembling the final product of the alteration. Thus, magnetic iron ore may be directly converted into ferric oxide, while in the case of more complex minerals, such as silicates containing several bases, there would be a long series of transitions, as in the alteration of cordierite, terminating in the formation of mica, the minerals fahlunite, chlorophyllite, bonsdorffite, esmarkite, oolite, weissite, prasciolite, gigantolite and pinitite are pseudomorphous minerals, representing the different stages of alteration, and hence they cannot be regarded as individual mineral species.

With a knowledge of the substances removed and introduced at any stage of such alterations, it may be possible to arrive at some conclusions as to the means by which those alterations have been effected, which could not otherwise be accessible. It would not perhaps be possible to effect the conversion of augite, olivine, or hornblende into serpentine experimentally; but when serpentine is found with the forms of those minerals, that fact may be taken as evidence that such a conversion has taken place.

If it be ascertained that a crystalline mineral may undergo conversion into another mineral, which, as a pseudomorph, presents the crystal-form of the original mineral, it may be safely inferred that the former mineral, in an amorphous condition, might undergo the same alteration. In such a case, however, the indication afforded by the crystalline form of the original mineral, as to the origin of the product of alteration, would be wanting. So, besides the positive evidence afforded by pseudomorphs, they also furnish the probability that similar alterations may have taken place in amorphous masses without their being recognisable. Thus, serpentine may have been, in some instances, formed by the alteration of amorphous rocks possessing the composition of augite, olivine, or hornblende; and, on the other hand, minerals which, like mica, have an individual crystalline form, may in some instances, where they occur with their proper form, have been formed by the alteration of amorphous masses.

In seeking to arrive at a knowledge of the means by which these gradually progressive alterations of minerals and rocks are effected, it is necessary to take into account a variety of influences which, though infinitesimal in themselves, within ordinary periods of observation, are nevertheless capable of producing, by long continuance, effects which appear at first sight disproportionate. Chief among these are the actions exercised by water, and by the substances it contains in solution, upon the minerals and rocks with which it comes in contact.

The water, falling as rain, penetrates rocks, and yields up the oxygen and carbonic acid it contains to substances capable of combining with them. It also extracts from the rocks it traverses such substances as are soluble in water alone, or by the aid of carbonic acid. In some cases water, penetrating to great depths, meets with subterranean sources of carbonic acid, by absorbing which its solvent capability is greatly increased. The chief constituents of all rocks, excepting limestone, dolomite, and gypsum, are silicates, containing alumina, magnesia, the oxides of iron and manganese, and alkalis. The action of water upon these compounds consists, not merely in solution, but also in the decomposition of the silicates by the aid of the carbonic acid it contains. The porosity of rocks, which such a penetration of water presupposes, is a very general character even of the most compact rocks. In basalt, for instance, small ochrey spots are often found in the interior, consisting of hydrated oxide of iron, and in some cases carbonate of calcium is minutely disseminated throughout the entire

mass of a compact basalt. Both these substances must be regarded as resulting from the decomposition of the silicates of iron and calcium existing in the basalt, by carbonic acid and oxygen conveyed into it by water.

Silicate of calcium is readily decomposed both by solutions of carbonic acid and alkaline carbonates, but silicate of magnesium is not decomposed by either. This very different behaviour of the silicates of earths otherwise so analogous, is of considerable geological importance, and serves at once to account for the well-known facts of the ready disintegration of rocks containing silicate of calcium, and the extreme durability of those containing silicate of magnesium. It also explains why steatite and talc, consisting in their purest forms only of silicate of magnesium, are among the most unalterable minerals, and why they so often appear as the final products of the alteration of minerals.

The decomposition of silicate of calcium by alkaline carbonates, and the frequent presence of the latter in the water percolating through rocks, afford a clue to the conversion of wernerite into mica, a change consisting merely in the substitution of potash for lime. In like manner, most of the alterations indicated by pseudomorphs may be traced to reactions between constituents of the original minerals and alkaline carbonates, acid carbonate of calcium, or carbonic acid, substances which are very commonly present in water.

Of the substances present in water, some, such as earthy carbonates, are no doubt derived, by direct solution, from rocks with which it comes in contact; but there are others, such as the alkaline carbonates, which do not exist in any rocks. Such substances can only be supposed to originate from the decomposition of minerals contained in the rocks; and when water containing earthy or metallic carbonates issues from rocks consisting wholly of silicates, it is probable that those carbonates are also derived from the minerals contained in the rocks, by decomposition.

The uniformity in the characters of the water of mineral springs shows that such processes of alteration are continuous and of considerable magnitude. As illustrations of the effects of such decomposition of silicates in rocks, the conversion of felspar into kaolin and clay may be mentioned as one of the most important. The decomposition of ferruginous silicates by the action of carbonic acid and oxygen is also one of the chief causes of the alteration and disintegration of rocks. The effects thus produced by water and the substances contained in it are not always of a destructive nature. Water containing alkaline silicates or silicate of aluminium is capable of giving rise to the production of silicate of calcium by reacting with sulphate of calcium; silicate of magnesium may be formed by the reaction of such water with magnesian salts, and ferrous silicates may be formed by the reduction of ferric silicates by the carbonaceous substances in the sedimentary rocks. This change appears indeed to be an essential feature of the metamorphosis of rocks. The brown-coloured argillaceous deposits of rivers contain iron solely in the state of ferric oxide and ferric silicate, while the slate rocks, which have undoubtedly originated from such deposits, contain chiefly ferrous silicates. In this series of changes it will be seen that, as in the phenomena of vegetation and animal life, the atmosphere is also concerned. The oxidation of ferrous and manganous compounds which is so prominent a feature of the disintegration of rocks, is attended with an abstraction of oxygen from the atmosphere; while in the reduction of ferric and manganic compounds, under the influence of organic substances, the oxygen thus abstracted, is again restored to the atmosphere, either in the state of carbonic acid or in its original condition, after having passed through an intermediate phase of plant-nutrition: while the carbon, which has been the means of this restoration of the oxygen by the ferric oxide of iron, again assumes a condition in which it may eventually repeat the same function.

So, throughout all the various phenomena of mineral alteration, it is possible to trace for almost every process of decomposition, a compensatory reproductive process by which the substances concerned in the former change are reproduced. The changes of this latter kind are, however, less directly recognisable, since the chief seat of rock formation, in its earlier stage of sedimentary deposit, is to a great extent inaccessible to observation. In the bed of the ocean the materials continually carried down in solution, and mechanically suspended in the water of rivers, contribute, partly under the influence of chemical action, to the formation of new strata. Notwithstanding the large quantities of carbonate and sulphate of calcium thus carried into the sea, there is every reason for the opinion that the composition of sea-water is as little subject to change as the composition of the atmosphere; for as this is maintained constant by the balanced and mutually supporting functions of animal and vegetable life, so the composition of sea-water is maintained constant by the consumption of the carbonate of calcium carried into it by rivers, in the formation of the shells of fish and by coral animals, which appear to be the chief agents of the production of limestone strata. It is in the sea also that a great number of changes are effected in sedimentary deposits.

resulting in the conversion of such deposits as those situated beneath and in the neighbourhood of Amsterdam, into masses of slate, and probably of gneiss and similar rocks. There, the materials furnished by the mechanical and chemical disintegration of rocks still situated above water, are now undergoing the same changes as those which at some earlier period gave rise to the production of the former rocks, whose subaqueous formation is indicated by the fossil remains embedded in them.

This cyclical character of geological phenomena is very generally recognisable, not only in regard to the destruction and formation of rocks, but also in all the processes of mineral alteration; and though there are certain minerals which very generally appear as final products of alteration, such as mica, steatite, talc, quartz, &c., it is probable that they should be regarded in this light but relatively, and that, in reality, they only represent particular stages of wider cycles of alteration which are still unrecognised.

GEOMYRICIN.

GEORETIC ACID.

} See GEORETIC ACID.

GERMINATION OF PLANTS. To enable a seed to germinate, the following conditions are necessary:—

1. *Full maturity of the Seed itself.*—Only the ripe seed contains the necessary quantity of those constituents on which the nutrition of the young plant depends, before it has attained sufficient development to enable it to derive its nutriment from the air and from the soil. Some seeds contain peculiar compounds, not found in other parts of the plant; and, in all, certain proximate principles are developed in peculiar abundance, especially the azotised bodies, albumin, legumin, and gluten, with a corresponding quantity of earthy phosphates.

2. *A certain temperature.*—The temperature required for the germination of most seeds is from 10° to 30° C. (50° to 86° F.); some, however, will germinate at temperatures as low as 4° C. (40° F.) The vitality or germinating power is absolutely destroyed by exposure to too great a degree of heat, but not by cold. Seeds can withstand much greater extremes of temperature than the other parts of plants, their vitality not being destroyed by a cold of -50° C. (-58° F.), or by a heat of 62° C. (143° F.) in an atmosphere of steam, or of 75° C. (167° F.) in a dry atmosphere.

It is commonly stated that seeds will not germinate when exposed to light. This does not appear, however, to be strictly true. Germination takes place certainly more quickly in the dark; but Saussure found that mustard seeds when kept in moist atmospheres—some under a transparent, and others under an opaque shade—both germinated with equal rapidity; hence he concluded that the retarding action usually ascribed to light is really due to heat, which desiccates the seeds.

3. The presence of *water*, which dissolves certain constituents of the seed, and thus enables them to act upon the insoluble matters; whereas in the absence of moisture all the constituents of the seed remain in the solid state, and no chemical action can take place. Too much water, however, impedes germination, by completely removing the soluble matters.

All seeds contain a certain quantity of water within their own substance; but they do not lose their germinating power by being dried in vacuo over sulphuric acid—that is to say, they are still capable of germinating when placed in contact with water. Some seeds lose their vitality when dried by heat; others do not, provided the heat applied is only sufficient to expel the water. The seeds of *Phaseolus vulgaris*, *Portulaca oleracea*, *Campanula rapunculus*, and *Papaver somniferum*, lose their vitality when dried in the shade at 36° C.; but those of barley, maize, lentils, hemp, garden cress, mustard, and lettuce, retain it under the same circumstances. Wheat, rye, vetches and cabbage seeds, retain it even at 70° C. When a seed has once germinated, and is then dried, it remains dormant, after being moistened, for a longer time than those which have not germinated.

4. The presence of *oxygen*. Seeds will not germinate in a vacuum, in hydrogen, nitrogen, carbonic anhydride, or carbonic oxide, in water deprived of air by boiling, or covered with a layer of oil, or when buried too deeply in the soil. They often begin to germinate under these circumstances, but quickly decay. Germination takes place with peculiar facility in presence of water containing a little chlorine, probably because the chlorine decomposes the water, and sets oxygen free. In the absence of light, or at low temperatures, when this decomposition does not take place, the presence of chlorine is rather hurtful than otherwise. Strong chlorine-water completely destroys the vitality of seeds.

Gladstone found that the germination of onions was accelerated by the addition of 8 per cent. of marsh gas to the air (Jahresb. d. Chem. iii. 562). According to Violette (Compt. rend. xxxviii. 905), wood-charcoal is peculiarly favourable to germination.

in a dark place through the winter, germinated freely; while similar germs immersed in peat-ash, wood-ash, powdered gypsum, slaked lime or dry sand, were found in a state of putrefaction. According to A. Vogel, jun. (Ann. Ch. Pharm. lxxviii. 195), germination is completely arrested by arsenic and its compounds, by oxide and carbonate of copper, by mercurous chromate, and by Prussian blue; and retarded by fluor spar, mercuric oxide, *antimonium crudum*, stannic oxide, carbonate of magnesium, ammonio-magnesian phosphate, and smalt; whereas several other substances which exert a poisonous or a deleterious action on the animal organism—viz. mercury (metallic, or in the form of tin-amalgam), cinnabar, calomel, litharge, phosphate of lead, chromate of lead, *vitrum antimonii*, and carbonate of barium—do not interfere with the germination of seeds. The experiments were made with cross-seed. The statement that arsenic-compounds completely arrest germination is at variance with the well-known practice of steeping wheat-grain in a solution of arsenious acid for the purpose of destroying fungi.

The germination of seeds is accompanied by the following phenomena:—

1. The seed absorbs water, swells up and softens. The harder the seed-coatings, the more slowly does the absorption of water, and consequently the germination, take place. According to Stein (J. pr. Chem. lxiii. 42), different seeds absorb in 24 to 48 hours (by which time the maximum of water appears to be taken up) from 22 to 116 times their weight of water.

2. The seed pushes forth its germ to a slight extent, and gives off a little carbonic anhydride; these changes taking place whether oxygen is present or not.

3. It absorbs a certain quantity of oxygen. According to Saussure, bean and lettuce seeds absorb 1 per cent., barley and purselain from 0.1 to 0.2 per cent. of their weight of oxygen.

4. It gives off carbonic anhydride, the volume of which, according to Scheele and Saussure, is equal to that of the oxygen absorbed. According to Boussingault, on the other hand, the volume of carbonic anhydride evolved is sometimes less than that of the oxygen absorbed, part of the carbon being oxidised, only to carbonic oxide.

5. The oxidation-process just mentioned gives rise to a development of heat, sometimes, as in the malting of barley, sufficient to induce spontaneous combustion.

6. The chemical changes which take place in the seed during germination are attended with loss of weight. 100 pts. by weight of barley, which had lost 12 pts. by drying, yielded 80 pts. of dry malt. Of the 8 pts. thus lost, four were removed in the softening of the seed by water, the remaining four in the actual germination. (Thomson, Thoms. Ann. x. 388; Hermbstädt, Schw. J. 33, 249.)

7. The insoluble non-azotised matters in the seed—viz. the starch and fat—are converted into soluble compounds, and are thereby enabled to pass from the parts of the seed in which they were developed into the various cells and organs of the growing plant. In this process, the azotised matters of the seed appear to play the same part that bodies of similar constitution discharge in alcoholic fermentation: that is to say, they absorb oxygen, and, being thus thrown into a disturbed state, they communicate the disturbance to the non-azotised bodies with which they are in contact; the result of which is that the starch of the seed is converted into sugar and gum, and the fats appear to be resolved into fatty acids and glycerin. The heat evolved in germination is, perhaps, due in great part to the fixation of water by which these transformations are accompanied. (Rochleder, *Gmelin's Handbuch*, viii. [1] 147; Pelouze et Frémy, *Traité*, vi. 313.)

W. Knop (Rép. Chim. app. 1862, p. 249) has observed that the presence of free alkali is unfavourable to the germination and healthy development of plants. It is well known that when healthy seeds are sown in pure quartz-sand or pounded glass, and watered with saline solutions, the plants, though appearing green and vigorous at first, often turn yellow after a while, and ultimately perish. This etiolation is sometimes attributed to the absence of iron salts, which are necessary to the development of chlorophyll; it may, indeed, sometimes be remedied by watering the plants with weak iron solutions. But from Knop's experiments it appears that the chief cause of the etiolation is the development of alkali in the act of germination. Plants growing in solutions of nitre decompose the nitric acid, and set the alkali free. The juices expressed from the roots and green leaves of healthy plants are always slightly acid. Knop finds that plants growing under the circumstances above-mentioned may be rendered green and healthy by addition of a small quantity of free acid to the solutions with which they are watered, and attributes the beneficial effect of iron-salts rather to the acid which they contain than to the iron. The well-known fact that seeds germinate for the most part better in spring than in the middle of summer, is attributed by Knop to the more rapid production of ammonia in summer, by the decomposition of albuminous matters in the soil; this ammonia being absorbed by the roots, the sap becomes alkaline, and the leaves turn yellow and fade.

GERSDORFFITE. Syn. with NICKEL-GLANCE.

GYSERITE. Syn. with OPAL.

GIBBSITE. $(Al^3)^4H^+O^+ = Al^+O^3.3H^+O$.—Native trihydrate of aluminium, called also *Felsobanyite*, and in the crystallised form, *Hydrargyllite*. It is found at Gumuchdag in Asia Minor, at Richmond in Massachusetts, and other localities in the United States, usually in stalactitic masses, with smooth surface, and indistinctly fibrous structure, exhibiting a faint lustre on the surface. Specific gravity 2·3 to 2·4. Hardness 3 to 3·75. The crystallised variety (*hydrargyllite*), is found near Slatoust in the Ural, in small hexagonal prisms, with replaced lateral edges, and very distinct basal cleavage; specific gravity 2·287; pearly lustre on the base. Both varieties are translucent, tough, exhale a strong argillaceous odour when breathed upon, give off water when heated, and exhibit before the blowpipe the usual characters of aluminium-compounds. They yield by analysis 63·5 to 65·6 per cent. alumina, and 33·8 to 34·7 water (calculation, 65·6 Al^+O^3 , and 34·4 H^+O).

Herrmann found in the gibbsite of Massachusetts a large but variable quantity of phosphoric acid, whereas other analysts have found little or none; the discrepancy arises, most probably, from the occasional admixture of phosphate of aluminium with the hydrate. On this account, Rammelsberg (*Mineralchemie*, p. 145) applies the name *hydrargyllite* to the hydrate of aluminium, and *gibbsite* to the phosphate.

GIESECKITE. A pseudomorph of NEPHELINE (*q. v.*)

GIGANTOLITE. A hydrous dichroite (p. 320) found in a gneissoid granite at Tammela, in Finland. Crystalline form the same as that of dichroite, with basal cleavage usually perfect, and sometimes micaceous. Hardness = 3·5, but on the cleavage-surface, 2. Specific gravity 2·862—2·878. Colour greenish to dark steel-grey. Lustre vitreous and waxy, approaching to submetallic. Melts before the blowpipe, with intumescence, to a greenish slag. Contains, according to Wachtmeister's analysis: 46·27 per cent. SiO^2 , 25·10 Al^+O^3 , 14·04 Fe^+O^3 , 2·70 K^+O , 3·80 MgO , 6·00 H^+O , with 0·89 MnO , 1·20 Na^+O , and a trace of fluorine. If the greater part of the iron be regarded as protoxide (Fe^+O^3 2·83, FeO 11·61), the composition of the mineral will be that of dichroite + 4 at. water. (Dana, ii. 216.)

GILBERTITE. A variety of BIAxIAL MICA.

GILDING. See GOLD.

GILLINGITE. Syn. with HISINGERITE.

GIN. An ardent spirit prepared from corn, and generally flavoured with juniper-berries. (See *Ure's Dictionary of Arts, &c.*, ii. 337.)

GINGER. There are two varieties of this root, the black or grey, and the white. Both are prepared from the root-stocks of *Zingiber off.*, about a year old; the former by scalding them in hot water and drying in a stove, the latter by peeling and drying them in sunshine without previous immersion in hot water. White ginger contains, according to Bucholz, volatile oil, 1·56 per cent.; extract soluble in alcohol, 0·06; extract insoluble in alcohol, 10·50; gum, 12·50; starch, 19·75; mucilage, 8·36; woody fibre, 8·00; matters insoluble in potash, 26·00; water, 11·90; resin, 3·60. (Pelouze et Frémy, *Traité*, vi. 370).

GINSENG. A root found in China, and said by the Chinese to possess extraordinary medicinal virtues. It appears, however, to be identical with the *Panax quinquefolium*, a plant which is likewise found in North America, and does not possess any such qualities. From the root of the American ginseng, Garrigues has obtained a neutral substance called PANACQUILONE (*q. v.*)

GIOBERTITE. Syn. with MAGNESITE.

GIRASOL. A variety of OPAL.

GISMONDIN. Syn. with ABRAXITE.

GITHAGIN. See SAPONIN.

GLAIADIN or **GLIADIN.** See GLUTEN.

GLAIRIN. See BAREGIN (i. 500).

GLANCE. A name applied to minerals having a metallic or pseudometallic lustre; e. g., *glance-coal*, *iron-glance*, *antimony-glance*, &c.

GLASSRITE. Native sulphate of potassium. (See SULPHATES.)

GLASS. (Gm. iii. 377.)—Glass is a mixture of silicate of potassium or sodium, or of both, with one or more silicates insoluble in water, as silicate of barium, strontium, calcium, magnesium, aluminium, manganese, iron, or lead. Pure silicate of potassium or sodium, or a mixture of the two, even with a sufficient quantity of silica to form a

very infusible glass, would still be attacked by water and acids. Silicate of calcium is likewise acted on by acids; but a mixture of it with silicate of potassium or sodium resists their action. Such mixtures of silicate of sodium or potassium with silicate of calcium, &c., are more fusible than the simple salts, and require a smaller amount of silica to render them capable of resisting the action of water and of acids. They contain between 2 and 3 atoms of silica to 1 atom of base, and still less when alumina is also present. The glass is less fusible, and offers greater resistance to the action of water and of acids, the larger the proportion of silica and alumina it contains; and, on the contrary, it is more easily fused, and attacked by water and acids, the more the potash, soda, baryta, lime, magnesia, or oxide of lead predominates; an excess of the last-mentioned oxide renders it particularly fusible, of a high specific gravity, soft, easily scratched, and corroded by acids. According to Baudrimont and Pelouze (*J. Chim. méd.* ix. 277), the lustre and refractive power of glass increase with the atomic weight of the bases contained in it; thus these qualities are possessed in the highest degree by lead-glass, next by baryta, next by potash, and least of all by soda-glass.

The following substances yield the ingredients necessary for the formation of glass:

Silica: Ground quartz or flint, or quartz-sand, which is sometimes treated with hydrochloric acid to free it from adhering sesquioxide of iron.—*Potash*: Pearlash and wood-ashes (this likewise yields lime and sesquioxide of iron).—*Soda*: Carbonate of sodium; sulphate of sodium with charcoal (which decomposes the sulphuric acid); native and artificially prepared soda (which at the same time yields lime); common salt, by which the potash-glass—produced by using carbonate of potassium—is decomposed into soda-glass and chloride of potassium.—*Baryta*: Heavy spar mixed with charcoal, or carbonate of barium; rarely employed. According to Baudrimont and Pelouze, 1 at. of heavy spar with 3 at. of sulphate of sodium and 4 at. of charcoal yields a peculiarly brilliant, fusible, and easily worked glass, resembling flint-glass.—A mixture of 70 pts. (1 at.) of carbonate of potassium, 54 pts. (1 at.) of carbonate of sodium, 99 pts. (1 at.) of carbonate of barium, and 224 pts. (7 at.) of silica yields a very transparent glass, which scratches window glass (Döbereiner, *Pogg. Ann.* xv. 243).—*Strontia*: Sulphate of strontium with charcoal, or carbonate of strontium. 70 pts. (1 at.) of carbonate of potassium, 54 pts. (1 at.) of carbonate of sodium, 47 pts. (1 at.) of carbonate of strontium, and 224 pts. (7 at.) of silica yield a remarkably beautiful glass, specifically heavier, more refractive, and much more fusible than crown glass (Döbereiner).—*Lime*: Lime after being burned and slaked, in powder; chalk marl (which also yields alumina), wood-ashes; the same exhausted with water; ball-soda.—*Oxide of lead*: Litharge, minium, white lead, or 1 at. of galena with 3 at. of sulphate of sodium, whereby 4 at. of sulphurous anhydride are evolved.—*Alumina*: Quartz-sand containing clay, marl, felspar, basalt, pumice-stone, and other minerals containing silicate of aluminium and an alkali-metal: they must not however be added in too large quantity, because the presence of too much alumina produces in the glass a tendency to crystallise. The mass of fused glass dissolves alumina from the pots.

Oxidising agents, as nitre, arsenious acid, and peroxide of manganese, are added in the preparation of white glass, partly to oxidise the carbon contained in the wood-ashes or ball-soda,—which would render the glass brown,—partly to convert the protoxide of iron into sesquioxide, inasmuch as a quantity of iron which in the state of protoxide would give the glass a dark bottle-green colour, will, if converted into sesquioxide, impart to it a light yellow tint of much less intensity. If too much sesquioxide of manganese is added, so that the carbon and the protoxide of iron cannot reduce it all to the state of protoxide, which dissolves in the glass without producing any colour, a portion is taken up in the state of sesquioxide, which stains the glass red; an excess of arsenious acid imparts to the glass a white turbidity.

Substances causing turbidity.—Bone-ash produces a milkiness in the glass, forming what is called Bone-glass; stannic oxide renders lead-glass opaque, and converts it into Enamel.

Colouring agents.—Blood-red: cuprous oxide. Carmine-red: purple of Cassius. Violet-red: peroxide of manganese. Blue: oxide of cobalt, oxide of copper. Green: the same substances, together with sesquioxide of iron; sesquioxide of chromium. Yellow: oxide of antimony, sesquioxide of iron. Yellow with a greenish cast: sesquioxide of uranium.—Aventurin glass contains, according to Wöhler (*Pogg. Ann.* lviii. 286), fine octohedral segments of metallic copper. (See AVENTURIN GLASS, i. 476.)

The above ingredients, powdered and mixed in the proper proportions, constitute the Glass-frit. This is in most cases first exposed in the frit-oven to a gentle heat, which expels water and part of the carbonic acid, and diminishes the subsequent swelling or frothing up of the mass. It is then put into large crucibles called glass-pots, made of very refractory clay, six of which are commonly arranged on ledges in a circular or oblong furnace, and exposed to a continually increasing heat for twelve or

more hours, till the mass becomes free from bubbles, grains of quartz, and streaks. Chloride of potassium, chloride of sodium, sulphate of potassium, and sulphate of sodium float on the surface in the form of a thin fluid stratum, which is skimmed off: the scum is called Glass-gall, or Sandivir. The glass is then formed into the required shapes, and afterwards cooled from a red heat, as slowly as possible, in the *annealing furnace*.

Bottle-glass.—Specific gravity about 2.732; very infusible on account of the small proportion of potash and soda, and the large quantity of alumina which it contains.—*a.* From *Souvigny*. Prepared from quartz-sand, marl, elutriated wood-ashes, and a portion of common salt. The phosphoric acid present in the glass arises from the phosphate of calcium in the wood-ashes (Berthier). Its composition is nearly $3(\text{CaO} \cdot 3\text{SiO}_2) + \text{Al}_2\text{O}_3 \cdot \text{SiO}_2$.—*b.* From St. Etienne. In the preparation of this glass heavy spar is employed (Berthier).—*c.* From Epinac. Prepared by simply fusing together two different kinds of sand, one of which contains 61.7 per cent. of carbonate of calcium, 35.6 of carbonate of barium, and 1.2 of clay, the other (a mixture of quartz-sand and felspar), 6 per cent. of potash, 2 of sesquioxide of iron, 0.7 of sesquioxide of manganese, 11 of alumina, and 80 of silica (Berthier).—*d.* From Sèvres. This glass is with difficulty reduced to a white mass, which is neither crystalline nor fibrous in its texture (Dumas).—*e.* Of unknown origin; easily converted into fibro-crystalline sort of Reaumur's porcelain. (Dumas.)

Pale green Glass used for Medical Bottles and Chemical Apparatus.—Hard; bears changes of temperature better than white glass. *a, b, c, d,* are four French varieties analysed by Berthier.

	Bottle glass.					Glass for medical bottles.

German Window-glass generally consists of a double silicate of calcium and potassium, *e.g.* 100 pts. of quartz-sand, 50 pts. of pearlash, from 25 to 30 pts. of chalk, and 2 pts. of nitre. In many mixtures, however, common salt is an ingredient; or it is really a *Glauber's salt glass*, which, according to Gehlen, is prepared with 100 pts. of quartz-sand, 50 pts. of dry Glauber's salt, 17.5 to 20 pts. of lime, and 4 pts. of charcoal.

French Mirror-glass.—Specific gravity, 2.488—2.506. About = $2(\text{Na}_2\text{O} \cdot 3\text{SiO}_2) + \text{CaO} \cdot 3\text{SiO}_2$. The variety *a* examined by Berthier, *b* by Tassaert, *c* and *d* by Dumas. All the varieties have a bluish tinge arising from the soda (*d* the least), from which the glass containing potash is free.

Venetian Mirror-glass.—About = $\text{K}_2\text{O} \cdot 3\text{SiO}_2 + 2(\text{Na}_2\text{O} \cdot 3\text{SiO}_2) + 3(\text{CaO} \cdot 2\text{SiO}_2)$; *e* obtained from an old mirror of a somewhat yellow colour. (Berthier.)

Bohemian Glass.—Specific gravity, 2.396; containing about $2(\text{K}_2\text{O} \cdot 3\text{SiO}_2) + 3(\text{CaO} \cdot 3\text{SiO}_2)$; *f* obtained from a goblet from Neufeld in Bohemia, transparent and colourless (Berthier); *g* from Neufeld (Gros); *h* from an old cup of Bohemian glass, perfectly transparent (Dumas); *i*, ordinary Bohemian glass. (Peligot.)

k **English Crown-glass**, of specific gravity 2.487, has a composition similar to that of Bohemian glass.

	99.1	100.0	100.0	100.50	98.2	98.1	101.2	100.0	100	100.0

Crystal glass.—Specific gravity, 2.9 to 3.255, from trisilicate to tetrasilicate of lead and potassium. Pure silicate of lead is yellow; but when it is combined with a sufficient quantity of silicate of potassium, the mixture is colourless. This glass is obtained from 100 pts. of pure quartz-sand, 60 to 70 pts. of minium or litharge, and 30 to 40 pts. of purified pearlash; sometimes an addition is made of 4 pts. of borax, 3 pts. of nitre, 0.15 pts. of arsenious acid, and 0.2 pts. of peroxide of manganese.

a. *London Crystal glass.*—Transparent and colourless; used in the construction of philosophical instruments; containing about $2(\text{K}^2\text{O}.4\text{SiO}^2) + 3(\text{PbO}.4\text{SiO}^2)$; examined by Berthier.

b. From Vonêche in Belgium; $\text{K}^2\text{O}.4\text{SiO}^2 + 2(\text{PbO}.4\text{SiO}^2)$, nearly. (Berthier.)

c. From Newcastle; $2(\text{K}^2\text{O}.3\text{SiO}^2) + 3(\text{PbO}.3\text{SiO}^2)$, nearly. (Berthier.)

d. Origin unknown; $2(\text{K}^2\text{O}.3\text{SiO}^2) + \text{CaO}.3\text{SiO}^2 + 3(\text{Pb}^2\text{O}.3\text{SiO}^2)$, nearly; analysed by Dumas.

e. English; $\text{K}^2\text{O}.3\text{SiO}^2 + \text{PbO}.3\text{SiO}^2$, nearly; analysed by Faraday.

Flint-glass.—Acid silicate of lead and potassium, prepared from the purest materials possible: for example, 100 pts. of quartz, 50 pts. of pearlash, 100 pts. of minium, 3 pts. of borax, 0.15 pt. of arsenious acid, and 0.2 pt. of peroxide of manganese. Guinand's flint glass has a specific gravity of 3.3 to 3.6; Fraunhofer's, a specific gravity of 3.77. a. Flint glass examined by Faraday. b. Guinand's flint glass, analysed by Dumas, $= 2(\text{K}^2\text{O}.2\text{SiO}^2) + 3(\text{PbO}.2\text{SiO}^2)$. Döbereiner (Schw. J. liv. 424) recommends the proportions of 1 at. of potash to 2 at. of oxide of lead and 7 at. of silica. Faraday's flint glass (Pogg. Ann. xviii. 515), specific gravity = 5.44, has a very different composition, being a compound of oxide of lead with silicic and boracic acids.

	Crystal glass.					Flint glass.		Strass.
	a.	b.	c.	d.	e.	a.	b.	
K ² O	9.0	6.6	9.4	8.9	13.67	11.75	11.7	7.9

	97.8	98.0	100.2	100.0	98.88	99.10	100.0	100.0

The *Mentz Flux*, or *Pierre de Strass*, used in the formation of artificial gems consists of flint glass with a smaller proportion of silicate of potassium, prepared likewise with the purest ingredients: e.g. 100 parts of quartz or rock-crystal, 32 to 52 parts of hydrate of potassium purified by alcohol, 154 to 157 parts of minium, or 171 parts of pure white lead, 6 to 9 parts of borax, $\frac{1}{2}$ to $\frac{1}{3}$ part of arsenious acid. Dumas analysed the *Strass* manufactured by Donault-Weiland, the composition of which is nearly $= \text{K}^2\text{O}.2\text{SiO}^2 + 3(\text{PbO}.2\text{SiO}^2)$.

The flint glass b contains also a trace of arsenious acid, and the *Strass* a trace of borax in addition.

Aventurin glass.—A brownish-coloured glass, interspersed with small spangles, which give it a peculiar shining appearance. (See vol. i. p. 476.)

Ruby glass, containing Gold.—Splittgerber (Pogg. Ann. lxi. 144) gives the following proportions, as affording an excellent glass of this kind: 3 lbs. $4\frac{1}{2}$ oz. of fine white sand, 1 lb. 14 oz. of nitre, 1 lb. 13 oz. of pure white soda, 4 oz. of carbonate of calcium, $2\frac{1}{2}$ oz. of arsenious acid, $4\frac{1}{2}$ oz. of minium, 4 oz. of antimony-glass (i. 322), and the solution of a Dutch ducat, weighing 3.41 grammes, in aqua regia. The gold-solution is first poured into the sand; the remaining ingredients are then added, and the whole is put into a glass-pot and exposed for more than three hours to a white heat. This method differs from former ones, in not having any purple of Cassius or oxide of tin added. The glass

thus obtained is perfectly colourless, but on being heated to a temperature of 600° C. (932° F.), assumes an intense ruby colour. The colour, when once produced, cannot be again destroyed by exposure to heat, even in an atmosphere of oxygen or hydrogen, or in a close crucible surrounded with sand, powdered charcoal, or oxide of zinc, or by throwing the glass into a flux of nitre or chlorate of potassium; before the oxyhydrogen blow-pipe, however, it loses its colour, but regains its original tint on cooling and subsequent exposure to heat. Splittgerber accounts for the peculiarities of this glass, by assuming that the gold in the colourless variety is in the form of trioxide; and that, when heated a second time, it is converted into the ruby-red oxide described by Berzelius, in consequence of a portion of its oxygen combining with one or more of the other substances present—probably with the antimonious oxide. The slight increase in bulk consequent on the second heating appears to be in favour of this view. Splittgerber likewise succeeded in obtaining a coloured glass with purple of Cassius, but of a violet rather than a ruby tint. Rose (Pogg. Ann. lxxii. 556) gives the following proportions for ruby-coloured glass: 46 lbs. of fine quartz, 12 lbs. of borax, 12 lbs. of nitre, 1 lb. of minium, 1 lb. of white arsenious acid, and a solution of 8 ducats in aqua regia. The whole is then mixed and fused as before. The resulting glass is colourless, but when again heated to redness acquires a ruby colour; Rose has likewise observed that the red colour is produced, whether the glass is heated in atmospheric air, oxygen, or carbonic acid gas. If exposed to a heat at which it softens, it becomes opaque and liver-coloured. When it is fused before the oxyhydrogen blowpipe, colourless drops are obtained, which Rose could not again obtain of a red colour by heating. Rose is of opinion that the colourless glass contains silicate of gold, and that this compound, when heated, is decomposed, with separation of oxide of gold, which imparts the red colour to the glass; moreover, that the liver-coloured glass probably contains metallic gold.

a. Aventurin from Venice, analysed by Gahn. b. Analysed by Peligot. c. By Kersten. d. Ruby-glass, analysed by Splittgerber, the gold found by experiment amounting to less than one-half the quantity per cent. added. e. Venetian ruby-glass, in the form of flattened round masses, distinguished from the ordinary varieties by being very fusible, and not losing its red colour when melted; analysed by Böhme. (J. pr. Chem. xxxviii. 335.)

Enamel is, for the most part, a double silicate of lead and potassium, rendered opaque by stannic oxide. In one specimen of enamel, Dumas found 8.3 per cent. of potash, 60.3 of oxide of lead, 9.8 of stannic oxide, and 31.6 of silica. Antimonious or arsenious acid produces a similar effect to the stannic oxide. By adding colouring agents, principally metallic oxides, to white enamel, the coloured varieties are obtained (p. 487).

For further details on the composition and manufacture of glass, see *Ure's Dictionary of Arts, Manufactures and Mines*, ii. 339; Payen, *Précis de Chimie Industrielle*, 4me édition, i. 489; Regnault, *Cours de Chimie*, ii. 332; Pelouze et Frémy, *Traité de Chimie Générale*, 3me édition, ii. On porcelain colours for enamel, Wächter (Ann. Ch. Pharm. lxi. 99).

Decomposition of Glass.—1. Water extracts potash or soda from glass, together with a portion of silica, the decomposition taking place with greater ease in proportion as the glass is richer in these alkalis, and more minutely divided, and the temperature of the water higher. The powder filed off from a tube of white glass reddens moistened turmeric-paper (Bischof, Kastn. Arch. i. 443). Finely powdered plate-glass

acts in a similar manner (Faraday, Pogg. Ann. xviii. 469). Water triturated with powdered glass in an agate mortar becomes alkaline, and on the addition of sal-ammoniac deposits flakes of silica (Fuchs, Kastn. Arch. v. 306). Water becomes alkaline after long digestion with glass at the boiling heat, and likewise turbid, from separation of an insoluble silicate of calcium (Dumas). An alkaline reaction is exhibited by the powder of bottle-glass, and of Reaumur's porcelain, formed from it; also of plate-glass, crown-glass, flint-glass, and white enamel. After sufficient washing it no longer reddens turmeric-paper, unless it be recrushed in a mortar. One hundred parts of finely divided flint-glass boiled for a week with water, lose 7 pts. of potash, which may be obtained in the solid state by evaporation (Griffiths, Quart. J. of Sc. xx. 258). The moisture in the atmosphere produces a similar alteration, separating the potash and soda, and leaving the greater part of the silica with the lime on the surface of the glass; glass thus decomposed often exhibits prismatic colours on its surface. Sometimes this superficial decomposition is scarcely visible; but, on warming the glass, numerous fine scales peel off, and leave the surface dull, opaque, and wrinkled. This fault shows itself in glass, to which, for the sake of economising fuel, too small a quantity of silica has been added. The pearly stratum with which specimens of antique glass found buried in the earth are covered consists almost wholly of silica (Griffiths). Glass which has lain in pits at least ten feet deep in the ground, is soft when dug up, and may be bent and indented, and even cut in two with a knife; but after exposure to the air for a few hours, it again hardens, and if it has been previously bent or twisted, it becomes extremely brittle, like unannealed glass. (Colladon, J. Chim. méd. xvi. 579.)

2. All kinds of glass are corroded by *hydrofluoric acid*, with formation, partly of fluoride of silicium, and partly of the double fluorides of silicium and potassium, sodium, calcium, &c. A hot concentrated solution of phosphoric acid also decomposes every variety. Glass which is poor in silica is attacked by boiling *oil of vitriol*; and glass of yet inferior quality—that, namely, which becomes dull on exposure to heat (Dumas)—is acted on by boiling *hydrochloric* and *nitric acids*, and *aqua-regia*, a dull spot remaining after evaporation of the acid (Berzelius). The acids dissolve out potash, soda, lime, and other bases, and separate the silica. On powdered glass they act with far greater energy. From pulverised flint-glass boiling hydrochloric acid extracts potash only, not the oxide of lead (Griffiths). Many kinds of bottle-glass which resist the action of acetic acid are decomposed by the stronger mineral acids; thus a bottle filled with sulphuric acid will sometimes, at ordinary temperatures, gradually become covered with warty depressions, which at last penetrate through the substance of the glass (Dumas). In distilling hydrochloric acid from a green glass retort, Hess (Pogg. Ann. xx. 540) obtained a crystalline sublimate [?] of silica, while chloride of potassium, sesquioxide of iron, and silica were dissolved. Many anhydrous salts of ammonia containing the stronger acids, also attack glass—especially lead-glass—when heated in contact with it; such is the case with a mixture of hydrochlorate and nitrate of ammonium (Silliman), or the neutral or acid sulphate of ammonium. (Marchand, Pogg. Ann. xlii. 556.)

3. Solutions of *potash* and *soda* dissolve out the silica of glass with greater ease in proportion to their temperature and degree of concentration. Even at ordinary temperatures, the alkaline liquid partially dissolves the glass bottle in which it is preserved, frequently causing it to crack. Even ammonia attacks many kinds of glass; a bottle made of flint-glass, and containing a solution of carbonate of ammonia, became so fragile that, on shaking it, pieces of glass were detached. (Griffiths.)

4. Glass containing lead blackens when heated in the flame of a lamp or in hydrogen gas, from reduction of the lead—and when heated in sulphuretted hydrogen, from formation of sulphide of lead. On this account Guinand's flint-glass (p. 841) becomes tarnished in dwelling-houses (Faraday). A bottle made of French glass, in which sulphhydrate of ammonium had been kept, acquired a metallic lustre, from formation of sulphide of lead. (Bischof, Br. Arch. xvii. 242.)

Crystallised or Devitrified Glass.—a. Many kinds of glass, when slowly cooled in the pots, separate into two portions, the one crystallising in opaque prisms and needles, the other retaining its vitreous character. According to the following analysis by Dumas, it appears that the portion which crystallises gives up soda to that which remains in the vitreous state.

	Crystallised portion.	Vitreous portion.
Na ² O	14.9 . .	19.8 . .

Al ² O ³	4.9 . .	3.5 . .
SiO ²	68.2 . .	64.7 . .
	100.0	100.0

b. Reaumur's Porcelain.—Many kinds of glass, after exposure for several hours to a heat at which they become soft—for example, in a potter's furnace—pass into a condition resembling porcelain. Bottle glass is the most disposed to undergo this change, doubtless from the greater quantity of alumina which it contains; next in order is the more common sort of green window glass; white glass rich in lime is also liable to this change, but not pure silicate of potassium or sodium, or lead-glass. (Lewis, Dartigues.)

The devitrification takes place just as well if the glass vessels are surrounded within and without with an infusible powder or cement, to prevent them from losing their shape—*e. g.* sand, a mixture of sand and gypsum, bone-ash, clay, powdered bricks, lime, sesquioxide of iron, charcoal, or soot,—as when they are heated by themselves; but in the former case, a longer time is required (Lewis, Dartigues, Morveau). It occurs also in a similar manner with glass enveloped in a lava-stream (Morveau). This change may either be regarded, according to Dartigues' supposition, as arising simply from the amorphous glass passing without change of composition into the crystalline state—the long continued state of softness affording the atoms an opportunity of uniting together in crystalline molecules; or we may suppose with Lewis, Morveau, and Dumas, that the glass, in undergoing this change, loses a portion of its alkali, which, when the glass is ignited by itself, passes off in vapour, and when it is surrounded by a powder during ignition, is absorbed by the powder. Dumas is likewise of opinion that the protoxides of manganese and iron present in the glass are peroxidised at the same time. According to Lewis, the sand surrounding the glass as cement becomes caked together by absorbing alkali. Dumas found in a devitrified specimen of bottle glass only 2 per cent. of potash, together with 27·4 per cent. of lime, 6·6 of the peroxides of manganese and iron, 12·0 of alumina, and 52·0 of silica. [The behaviour of Reaumur's porcelain in fusing is also in favour of this theory; *vid. seq.*]

In this change, the following facts are to be distinguished:—1. The glass first becomes cloudy, and appears blue by reflected and yellow by transmitted light (Lewis, Fournet), still, however, exhibiting a vitreous fracture. The blue colour is also seen at the fractured edges, and consequently cannot proceed from oxidation (Fournet). The opacity doubtless arises from the separation of fine particles, whose composition differs from that of the rest of the mass. Many iron slags behave in a similar manner (especially the double silicate of aluminium and calcium). Many slags which appear green when cooled rapidly, become blue within and yellow by transmitted light when slowly cooled, even if they are green on the outside, but the powder again assumes a green colour. This fact would appear to explain the action of the test which is employed to distinguish a great many earths and heavy metallic oxides by the blowpipe; viz. that the bead obtained by fusing them with borax or microcosmic salt, remains clear when rapidly cooled, but becomes turbid and opaque by exposure to *interrupted blasts*, or *flaming*, whereby it is kept for a long time in a soft state, and crystalline compounds are produced and separated. (Fournet, *Ann. Ch. Phys.* lxxix. 370; also *J. pr. Chim.* xxvi. 331.)

2. After this stage, white, opaque needles are formed, proceeding from the inner and outer surfaces of the glass, and finally meeting in the centre. The place of contact is often marked by a brown line. The mass thus far changed is *Reaumur's porcelain*. When burnt between pipe-clay, it has a smooth surface, but if burnt between lime or bone-ash, it acquires a rough, wrinkled, or blistered surface. When burnt between powdered charcoal, its surface becomes black or grey (Lewis). It is white and nearly opaque, appearing at the fractured surface to possess a straight fibrous texture; it is specifically heavier than glass, and so hard that it scratches glass and sometimes even rock-crystal, and emits sparks with steel; it does not crack so readily with changes of temperature as glass, or even as porcelain, and conducts heat and electricity better than the former, so that, unless insulated, it does not become electrical by friction. Reaumur's porcelain may be used instead of ordinary porcelain in the fabrication of vessels. It fuses with much greater difficulty than glass, and is thereby converted into a white or grey enamel, transparent only at the edges—having a conchoidal fracture, harder than glass, but softer than Reaumur's porcelain. The specific gravity of this enamel is to that of the substance before fusion as 2·625 : 2·801; it does not become electrical by friction. (Morveau.)

3. If the baking be too long continued, the threads of the fasciculated or fibrous structure become separated by fissures, and the whole is converted into a fine-grained and subsequently a coarse-grained mass, loose, greyish, and still more difficult of fusion. When the porcelain has begun to change from the fibrous to the granular condition, it may still be fused by the heat of a forge to a pearly, porous mass, which contains green glass enclosed within. If the change to the fine-grained con-

dition is complete, it fuses to a spongy mass; but when the coarse-grained state is arrived at, it no longer fuses, but cakes together to an exceedingly hard mass, having a dense fracture.

GLAUBAPATITE. A mineral from the Mongo islands on the Mosquito coast, where it occurs in geodes of small yellowish-green or brown crystals, consisting of 74 per cent. phosphate of calcium, 15.1 sulphate of sodium, and 10.3 water. (*Kammelsberg's Mineralchemie*, p. 984.)

GLAUBER SALT. Sulphate of sodium. (See SULPHATES.)

GLAUBERITE. Native sulphate of sodium and calcium, $\text{Na}^2\text{Ca}^2(\text{SO}_4)^2$. It is found crystallised in four-sided prisms, belonging to the monoclinic system, Colour greyish-white and wine-yellow. Lateral planes transversely striated; terminal planes smooth. Fracture foliated or conchoidal, Hardness = 2.5 to 3. Specific gravity = 2.64 to 2.85. Lustre vitreous. Streak white. Taste slightly saline. Before the blowpipe it decrepitates, and melts to a white enamel. Becomes opaque when immersed in water. It is found in crystals in rock-salt at Villa Rubia, near Oçana, in New Castile; also at Aussee, in Upper Austria, in Bavaria, at the salt mines of Vic in France, and in the province of Tavapaca, Peru. (*Dana*, ii. 374.)

GLAUCENE. $\text{C}^2\text{H}^2\text{N}^2$ (?). According to Völkkel, sulphocyanate of ammonium heated to 300° C. yields, among other products, a compound called *poliene*, $\text{C}^2\text{H}^2\text{N}^2$; and this, when heated, gives off 1 at. ammonia, NH_3 , and is converted into glaucene. (See SULPHOCYANATES.)

GLAUCIC ACID. The name originally given to the acid of *Glaucium flavum*, now known to be fumaric acid.

GLAUCINE. An alkaloïd obtained by Probst from the leaves of the yellow horned poppy (*Glaucium flavum*), a plant growing on sandy sea-shores. It is not contained in the flowers or the root of the plant. It may be extracted by macerating the leaves with acetic acid; boiling the acid juice to coagulate the chlorophyll; treating the clarified liquid with nitrate of lead; decomposing the precipitate with sulphuretted hydrogen; precipitating the filtered liquid with decoction of oak-bark; mixing this precipitate with lime while still moist, after washing and pressing; treating the mixture at a gentle heat with alcohol; passing carbonic acid gas through the alcoholic filtrate, to precipitate the lime; driving off the alcohol by evaporation; and treating the residue with water. Glaucine then remains undissolved, and may be purified by solution in boiling water.

From its aqueous solution it separates by spontaneous evaporation in colourless crusts, composed of nacreous scales; the ethereal solution deposits it in a pitchy mass. From the solutions of its salts it is precipitated by ammonia, as a curdy mass, which after some time becomes pitchy, and melts to an oil at the temperature of boiling water. Its taste is harsh and bitter. It is moderately soluble in hot water, freely in alcohol and ether; the solution blues reddened litmus.

Glaucine decomposes at high temperatures; heated with sulphuric acid, it assumes a fine violet colour; the product forms with water a deep red solution, from which ammonia throws down a deep indigo-blue precipitate. Glaucine is quickly decomposed by nitric acid.

Glaucine forms neutral salts, which have an acrid burning taste, and are precipitated by tincture of galls. The *hydrochlorate* and the *sulphate* are crystalline, very soluble in water and alcohol, insoluble in ether. The *phosphate* crystallises readily (Probst, *Ann. Ch. Pharm.* xxxi. 241.)

GLAUCIUM FLAVUM. The yellow horned poppy. The seeds of this plant, after drying in the air, give off 8 per cent. water at 110° C. The seed dried at this temperature contains 42.5 per cent. oil. The stems (air-dried?) yielded 4.5 per cent., the seeds, 9.32 per cent. ash, containing in 100 parts:

	CO_2	SO_3	P_2O_5	SiO_2	NaCl	K_2O	Na_2O	CaO	MgO	Fe^2O_3	Mn^2O_3	Sand & loss.
Stem .	6.39	5.89	2.40	4.15	29.14	13.82	..	29.00	3.35	0.82	0.02	5.02
Seed .	22.39	0.76	11.29	2.76	1.07	5.86	1.59	38.22	5.95	5.22	0.70	4.19

(Cloez, *Institut.* 1860, p. 124; *Ann. Ch. Phys.* [3] lix. 129.) The plant contains fumaric acid and two alkaloids—viz. glaucine in the leaves, glaucopierine in the root.

GLAUCODOTE. $(\text{Co}; \text{Fe})\text{S}^2$. $(\text{Co}; \text{Fe})\text{As}^2$.—A mineral resembling mispickel in crystalline form and in composition, excepting that the iron is partly replaced by cobalt. It crystallises in prisms belonging to the rhombic system. Cleavage very distinct, parallel to the base, less so parallel to the prismatic faces; also massive. Hardness

= 5. Specific gravity = 5.975 to 6.003. Lustre metallic. Colour greyish tin-white. Streak black. It occurs in chlorite slate with cobaltine in the province of Huasco, Chile, and with a pale yellow calcite at Orowitz, in the Bannat. It contains:

	S	As	Co	Fe	Ni	
From Chile . . .	20.21	43.20	24.77	11.90	trace	= 100.08 Plattner.
„ Orowitz. . .	19.78	43.63	32.02	4.56	..	= 99.99 (Patena).

Before the blowpipe it gives the reactions of sulphur, arsenic, cobalt, and iron. (Dana, ii. 63.)

GLAUCOLITE. Syn. with **SCAPOLITE**.

GLAUCOMELANIC ACID. A product of the decomposition of ellagic acid (p. 484).

GLAUCONITE. A silicate of iron, occurring in green, translucent, opalescent rounded grains in the greensand of various localities. According to Ehrenberg (Berl. Akad. Ber. 1854, pp. 374–384; 1855, pp. 86–172; Jahresb. f. Chem. 1854, p. 885), these grains consist of the stony nuclei and silicified shells of polythalamine. Their composition is somewhat variable, as the following analyses will show:—*a.* From Gay Head, Massachusetts, by S. L. Dana (*Dana's Mineralogy*, ii. 288); *b.* From Cauley's Pits, Woodtown, New Jersey, H. B. Rogers (*ibid.*); *c.* From the green sandstone between Dortmund and Witten, Westphalia. (Von der Marck, Jahresb. f. Chem. 1855, p. 1007.)

	SiO ₂	Al ₂ O ₃	FeO	MgO	CaO	K ₂ O	H ₂ O	
<i>a.</i> 56.70	13.32	20.10	1.18	1.52	= 92.92
<i>b.</i> 48.45	6.30	24.31	..	trace	12.01	8.40	..	= 99.47
<i>c.</i> 53.46	5.00	21.78	6.21	..	8.79	4.76	..	= 100.00

A green ferrous silicate imbedded in the calcspar of Tākli, near Nagpur, in Central India, appears to have the composition of glauconite. (T. L. Haughton, Phil. Mag. [4] xvii. 16.)

GLAUCOPHANE. See **WICHTYN**.

GLAUCOPICRINE. An alkaloid contained in the root of *Glaucium flavum*. It is extracted by exhausting the root with acetic acid; precipitating by ammonia; redissolving the precipitate in acetic acid; precipitating the solution with decoction of oak-bark; treating this precipitate with lime and alcohol, as described in the preparation of glaucine; exhausting the alcoholic residue with ether; evaporating the ethereal solution; treating the residue with a very small quantity of ether, which leaves pure glaucopierine undissolved; and crystallising from boiling water.

Glaucopierine forms granular crystals soluble in water and alcohol, especially when hot; less soluble in ether. Its salts have an extremely bitter and nauseous taste. Animal charcoal removes the glaucopierine from their solutions. Glaucopierine, or any of its salts, heated with strong sulphuric acid, yields a dark green pitchy product, insoluble in water, acids, and ammonia.

Hydrochlorate of glaucopierine crystallises in rhomboidal plates or in bundles of prisms, soluble in water, insoluble in ether. The *sulphate* and *phosphate* are likewise crystallisable. (Probst, Ann. Ch. Pharm. xxxi. 254.)

GLAUCOSIDERITE. Syn. with **VIVIANITE**.

GLECHOMA. The herb of ground ivy (*Glechoma hederacea*) at the flowering time contains a tannic acid which turns iron-salts green, also acetic acid, tartaric acid, sugar, gum, volatile oil, waxy and oily substances, an acid and a slightly bitter substance, &c. 1000 pts. of the flowering herb lost by drying, 824 pts. water; the residue yielded to ether 24 pts., then to alcohol 8 pts., then to water 56 pts., to hydrochloric acid 16 pts., and there remained 72 pts. of insoluble vegetable fibre (J. B. Enz, Vierteljahrsschr. pr. Pharm. x. 11.)

GLIADIN. See **GLUTEN**.

GLINKITE. A greenish variety of olivine from a talcose slate in Perm, Russia; also occurring in gneiss at Tunaberg in Sweden, with augite and garnet, and in veins 3 inches thick in the mica slate of Kytsebimsk, north of Miask in the Ural. (See **OLIVINE**.)

GLOBULARIA. According to G. F. Walz (N. Jahrb. Pharm. xiii. 281), the leaves of *Globularia Alypum* contain a yellow colouring matter, a peculiar tannic acid, globularitannic acid, whose lead-salt dried at 100° C. contains C¹²H¹²PbO⁷; a resin, globularresin, C¹²H¹²O⁸, having a very strong and fragrant odour, and a bitter principle, globularin, C¹²H¹²O¹¹, which is resolved by dilute sulphuric acid into globularetin, C¹²H¹²O⁹ (a white pulverulent substance which melts to a resin when heated), para-globularetin, C¹²H¹²O⁴ (a slightly coloured pulverulent substance insoluble in ether

and precipitated by water from its alcoholic solution), and glucose, with elimination of 1 st. water:

For details respecting these compounds, see *Gmelin's Handbook*, xv. 38; xvi. 82.

GLOBULIN, or CRYSTALLIN. (Lehmann, *Physiol. Chem.* i. 366; Handw. 2^{te} Aufl. ii. 134.—Gerh. iv. 450.)—An albuminous substance existing in the crystalline lens of the eye, and, according to Berzelius and others, in the corpuscles of the blood. As however it has never been obtained from the latter source free from colouring matter, the identity of the two substances cannot be considered as quite established, more especially as the albuminous substance obtained from the blood-corpuscles by Lehmann's latest process differs essentially from that in the crystalline lens. (See HEMATO-CRYSTALLIN.)

From the crystalline lens, globulin is obtained by triturating this body with water, evaporating the filtered liquid at a temperature below 50° C. and purifying the dry residue by digestion, first with ether, then with dilute alcohol. In the lens of the human eye, Berzelius found 35.9 per cent. of dry globulin.

Globulin thus prepared is a yellowish transparent mass which swells up in water and dissolves, for the most part, forming a gummy liquid. The solution becomes opaline at 73° C., and deposits a coagulum at 93°, therefore at a temperature considerably above that at which albumin coagulates (i. 65). Mixed with a small quantity of acetic acid, it becomes opaline, and deposits a coagulum at 50°; but a larger quantity of acetic acid either prevents the coagulation altogether, or renders a temperature of 100° necessary to produce it. The aqueous solution has a slight alkaline reaction and behaves with mineral acids and metallic salts, in most respects, like a solution of albumin. According to Lehmann, the solution acidulated with acetic acid is precipitated by ammonia, and a solution mixed with ammonia gives a precipitate when cautiously neutralised with acetic acid. Moreover, on passing carbonic acid gas through the aqueous solution, a precipitate is obtained which is soluble in pure water.

The chemical composition of globulin is sensibly the same as that of albumin. Mulder found it to contain on the average, 54.35 per cent. C, 7.0 H, 16.5 N, and 0.3 to 1.2 S. Lehmann found 1.1 per cent. sulphur.

According to Lehmann, globulin from the crystalline lens yields by incineration 0.24 per cent. phosphates, and 1.55 per cent. soluble salts, consisting of alkaline chlorides, sulphates, and phosphates, but no alkaline carbonate (whereas the albumin of serum or white of egg always yields alkaline ash). But the liquid separated by filtration from coagulated globulin yields an ash containing alkaline carbonate. According to the same chemist also, globulin when coagulated by heat gives off ammonia, and the filtered liquid, instead of exhibiting increased alkaline reaction, like white of egg similarly heated, is found to have an acid reaction. Hence Lehmann concludes that soluble globulin contains ammonio-sodic phosphate, which is resolved by heat into ammonia and acid phosphate of sodium. He is also of opinion that globulin contains, in combination with soda, an organic acid—probably lactic acid—to which is due the alkaline ash obtained from the liquid filtered from coagulated globulin. The presence of different mineral salts in albumin and in globulin may perhaps account for the slight differences observed in the characters of the two bodies.

According to Valenciennes and Frémy (*Compt. rend.* xlv. 1122), the outer and inner portions of the crystalline lens of the eyes of mammalia contain different modifications of albumin, and those of fishes contain another albuminous substance called phaeonin. (See EYE, p. 615.)

GLOCKERITE. A basic ferric sulphate, $2\text{Fe}^3\text{O}^3.\text{SO}^3 + 6 \text{ aq.}$, occurring in stalactites of considerable size at Obergund near Zuckmantel in Austrian Silesia. (See SULPHATES.)

GLONIN. Syn. with NITROGLYCERIN. (See GLYCERIN.)

GLOSSECOLITE. (Shepard, *Sill. Am. J.* [2] xxiv. 124; Pisani, *Compt. rend.* 41, 310.)—A silicate of aluminium from Rising Fawn, in Dade County, Georgia, compact, with conchoidal fracture, dull, of white, yellowish, or brownish colour, with shining streak; adheres to the tongue. Hardness = 2 to 2.5. Specific gravity = 2.2 (or if protected from penetration of water, 1.7). Soft to the touch and very brittle. Heated in a tube, it gives off water (17 per cent. according to Shepard, 21.8 according to Pisani), and turns bluish-grey. Infusible before the blowpipe; exhibits a fine blue colour with cobalt-solution. Decomposed by heating with sulphuric acid. Shepard regarded it as an opal; but according to Pisani's analysis, it contains 40.4 per cent. SiO_2 , 37.8 Al_2O_3 , 0.5 MgO , and 21.8 water (= 100.5).

LOTTALITE. A mineral from the greenstone near Port Glasgow, on the Clyde; occurring in cubes with the angles truncated; colourless or white, with vitreous

lustre. According to Thomson's analysis (*Outlines of Mineralogy*, i. 328), it contains 27.01 SiO₂, 16.31 Al₂O₃, 0.50 Fe²O₃, 23.93 CaO and 21.25 water (= 99.00), agreeing approximately with the formula

Greg (*Minerals of Great Britain*, p. 171) regards the mineral as chabasite, a view which does not accord with Thomson's analysis. The existence of the mineral as a distinct species cannot, however, be considered as positively established. (*Rammelsberg's Mineralchemie*, p. 781.)

GLUCIC ACID. C¹²H¹⁸O⁹ = C²⁴H¹⁸O¹⁸ (Peligot), or C¹⁶H¹⁸O¹¹ · 2HO (Rochleder and Kawalier). *Kalisaccharic acid.* (Peligot, Ann. Ch. Phys. lxxvii. 154; Mulder, Ann. Ch. Pharm. xxxvi. 243; Gerh. ii. 563.)—An acid produced by the action of acids and alkalis on sugar. A solution of dextroglucose (grape- or starch-sugar), saturated with lime or baryta, and left to itself for several weeks, gradually loses its alkaline reaction, and the base which it contains is no longer precipitable by carbonic acid. It then gives with basic acetate of lead, a bulky white precipitate of basic glucate of lead, which, when decomposed by sulphydric acid, yields glucic acid (Peligot). An easy mode of preparing the acid is to mix grape-sugar melted at 100° C. in its water of crystallisation, with a warm concentrated solution of caustic baryta, potash, or soda. Great rise of temperature then takes place; and if the action be stopped before it has gone too far, a large quantity of glucic acid is obtained, which may be extracted with basic acetate of lead as above. (Persoz.)

Glucic acid may also be prepared by boiling cane-sugar, in contact with the air, with dilute sulphuric acid; filtering; saturating with chalk; evaporating to dryness; and digesting the residue in a very small quantity of water. The brown syrupy liquid thus obtained, which contains acid glucate of calcium, together with the calcium-salt of *apogluic acid*, a small quantity of sulphate of calcium, and uncrystallisable sugar, is treated with alcohol to precipitate the apogluicate, and decolorised with animal charcoal; then mixed with caustic lime in sufficient quantity to destroy the acid reaction; and again with alcohol, which throws down neutral glucate of calcium in white flakes. From this salt the acid may be obtained by precipitating its solution with basic acetate of lead, as above. (Mulder.)

According to Rochleder and Kawalier (J. pr. Chem. lxxiv. 28, 299; Jahresb. 1858, p. 257), gallotannic acid boiled with baryta-water yields glucic and gallic acids, and if the liquid, when cold, be filtered to separate the precipitate of gallate of barium, the filtrate shaken up with air, and the rusty-brown precipitate thereby formed be removed, a solution is obtained free from gallic acid; and on removing the baryta by sulphuric acid, precipitating with basic acetate of lead, decomposing the precipitate with sulphydric acid, and evaporating in vacuo, glucic acid remains in the form of a thick acid syrup.

Glucic acid (from sugar), obtained from its solution by evaporation in vacuo, is a colourless, amorphous body, resembling tannin, very soluble in water and in alcohol; that obtained from tannic acid does not solidify (Kawalier). According to Mulder it does not absorb moisture from the air, but according to Peligot, it is highly hygroscopic when dry. It has a very fresh taste. Heated to 100° C., it decomposes, turning brown, and giving off a large quantity of water. The aqueous solution turns brown when boiled in contact with the air, or with dilute sulphuric or hydrochloric acid, forming apogluic acid. With the same acids in the concentrated state, it forms a brown ulmic substance insoluble in water.

The *glucates*, both acid and neutral, are soluble in water. The *neutral calcium-salt*, dried at 100°, is permanent in the air, and appears to contain C²⁴H³⁰(Ca²)²O¹⁸ + H²O (Analysis by Mulder, 38.4 per cent. C, 4.5 H, and 23.2 Ca; calculation, 38.8 C, 4.0 H, and 22.6 Ca). It is very soluble in water, sparingly in alcohol. The aqueous solution is decomposed by carbonic acid, yielding acid glucate and carbonate of calcium.

The *acid calcium-salt* crystallises in needles, soluble in alcohol. It is produced by the action of aqueous glucic acid on carbonate of calcium.

Basic glucate of lead is insoluble in water, and appears to contain C²⁴H³⁰(Pb²)²O¹⁸. 3PbO + H²O. (Analysis by Peligot, 14.8 and 14.2 C, 1.9 H, 69.3 and 70.5 Pb; calculation, 15.0 C, 1.7 H, and 70.0 Pb.)

Apogluic acid, the product formed from glucic acid by oxidation in the air (p. 848), may be separated from the solution of its calcium-salt by precipitating with acetate of lead, and decomposing the lead-salt with sulphydric acid. In the dry state it forms a brown amorphous mass easily soluble in water, sparingly soluble in alcohol, insoluble in ether. According to Mulder, it contains, when dried at 120° C., C¹⁶H¹⁰O⁹ + HO. It is perhaps identical with assamar. (See ASSAMAR, CARAMEL, HUMIC ACID, SUGAR, ULMIC ACID.)

GLUCINUM. *Glycium, Beryllium.* Symbol G; atomic weight 9.1: or Symbol Be; atomic weight 14.

This somewhat rare metal, the oxide of which was discovered by Vauquelin in 1798, occurs as a silicate, either alone, as in phenacite, or associated with other silicates, in beryl, euclase, leucophane, helvite, and several varieties of gadolinite; also as an aluminate in chrysoberyl or cymophane.

Wöhler and Bussy, in 1828, first obtained metallic glucinum, though in an impure and pulverulent state, by fusing the chloride with potassium in a platinum crucible. Becquerel afterwards reduced it in steel-grey crystalline scales by electrolysis a solution of the chloride; and Debray, in 1854 (*Ann. Ch. Phys.* [3] xlv. 5), obtained it in the compact state by reducing the chloride with sodium, in a manner similar to Deville's first process for the reduction of aluminium. A small dish containing chloride of glucinum is introduced into a combustion-tube, and after the air has been expelled by a current of hydrogen, another small dish containing metallic sodium, previously well cleansed from naphtha by pressure between filtering paper, is likewise introduced. Heat is then applied, first to the sodium to melt it, and then to the chloride of glucinum, which volatilises, and coming in contact with the melted sodium, is thereby decomposed. A black mass consisting of glucinum and chloride of sodium is thus obtained, from which the metal may be separated in distinct globules, by melting the mass in a small crucible with an additional quantity of chloride of sodium, and washing out the soluble salts with water. The improved methods of reducing chloride of aluminium with sodium (i. 160) might doubtless be applied with advantage to the preparation of glucinum.

Glucinum, as obtained by Debray's process, is a white metal, of specific gravity 2.1. It may be forged, and rolled into sheets like gold. Its melting-point is below that of silver. It may be melted in the outer blowpipe-flame, without exhibiting the phenomenon of ignition presented by zinc and iron under the same circumstances; it cannot even be set on fire in an atmosphere of pure oxygen, but in both experiments becomes covered with a thin coat of oxide, which seems to protect it from further change. It does not appear to combine with sulphur under any circumstances, but unites directly with chlorine and iodine with the aid of heat. It unites readily with *silicon*, forming a hard brittle substance susceptible of a high polish; this alloy is always formed when glucinum is reduced in porcelain vessels. Glucinum does not decompose *water* at a boiling heat, or even when heated to whiteness. *Sulphuric* and *hydrochloric acids* dissolve it, with evolution of hydrogen. *Nitric acid*, even when concentrated, does not act upon it at ordinary temperatures, and dissolves it but slowly at the boiling heat. Glucinum is not attacked by *ammonia*, but dissolves readily in caustic *potash*.

The above-mentioned properties differ considerably from those of the metal which Wöhler obtained by igniting chloride of glucinum with potassium in a platinum crucible, the metal thus produced being a grey powder, very refractory in the fire, but combining with oxygen, sulphur, and chlorine much more energetically than Debray's metal. The differences appear to be due, partly to the different states of aggregation, and partly to the contamination of Wöhler's metal with platinum and potassium.

Compounds of Glucinum.—Glucinum forms but one class of compounds, and into these it was supposed by Berzelius to enter as a triatomic radicle (with the atomic weight 7) the chloride being Be^3Cl^3 , and the oxide B^3O^3 , this view being based upon certain resemblances between the chlorides and hydrates of glucinum and aluminium, and upon the supposed capability of glucinum and aluminium to replace one another in indefinite proportion in minerals, *e.g.* in chrysoberyl. This, however, has been completely disproved by the researches of Awdejew and Damour, from which it appears that the proportions of glucinum and aluminium in chrysoberyl are quite constant, from whatever locality the mineral may be derived. Moreover, glucina bears, on the whole, a much closer resemblance to the protoxides than to the sesquioxides. It forms a carbonate and double carbonates, which alumina does not. When strongly heated it volatilises like magnesia, without fusing, whereas alumina melts; and it cannot be fused with lime, as alumina can, without the presence of another body, such as silica or alumina.

Again, chloride of glucinum does not form definite compounds with the alkaline chlorides as chloride of aluminium does. For these reasons Debray regards glucinum as diatomic, that is, as replacing 2 at. of hydrogen, and assigns to glucina the formula GO .

This view of the atomicity of glucinum is further recommended by the greater simplicity of the formulæ which it affords for many of the compounds of the metal; take for example the phosphates analysed by Scheffer (*Ann. Ch. Pharm.* cix. 144):

Orthophosphates.

G = 9.4.

Be = 14.

Pyrophosphate.

On the other hand, H. Rose (Pogg. Ann. xvi. 445) is disposed to regard glucina as a sesquioxide, partly from certain considerations relating to its specific volume, and further, because when heated with alkaline carbonates, it decomposes them, which no protoxide is known to do. It must also be observed that many compounds of glucinum are not isomorphous with the generality of substances, which, if glucinum be monatomic, must be represented by similar formulæ. Thus glucina is not isomorphous with lime or magnesia; chrysoberyl, if expressed by the formula $(\text{Al}^2)^{\text{O}}\text{G}^{\text{O}}\text{O}^4$, will be included, so far as composition goes, in the class of *spinel*s; but in crystalline form it differs essentially from all other minerals of that class. The emerald, $\text{G}^{\text{O}}\text{O}^4\text{Si}^{\text{O}}\text{O}^3$, also differs completely in crystalline form from the generality of silicates of the form $\text{M}^{\text{O}}\text{Si}^{\text{O}}\text{O}^3$. Ordway (Sill. Am. J. [2] xxvi. 197) finds that glucina has a great tendency to form basic salts with three and six at. of metal to 1 at. of acid radiæ, and adduces this tendency as an argument in favour of the trivalent of the metal; inasmuch as aluminium and ferricum exhibit the same tendency;—but as lead, which is certainly not trivalent, forms a great number of basic salts of similar constitution, this argument has not much force.

On the whole, the question as to the equivalent value of glucinum cannot be regarded as decided, but the balance of evidence perhaps inclines in favour of the tri-equivalent value.

The affinity of glucina for acids is less than that of the alkaline earths and of yttria, but stronger than that of alumina; for the hydrate decomposes ammoniacal salts at the boiling heat. The hydrate dissolves readily in acids, the ignited oxide slowly; but it may be rendered easily soluble by fusion with sulphate of potassium. The salts are colourless, unless the acid itself is coloured: many of them crystallise well. Most neutral glucinum salts are soluble in water; the solutions have a sweet, astringent taste, and redden litmus. Many glucinum salts which are insoluble in water, *e.g.* the borate, phosphate, carbonate, &c., dissolve readily in acids. The silicates dissolve in acids only after ignition with sulphate of potassium; by fusing them with caustic alkalis or alkaline carbonates, the glucina is separated, and is then soluble in acids. Ignited salts containing volatile acids, even the sulphate, give off the acid when ignited; the anhydrous chloride volatilises without decomposition.

Glucina has a great tendency to form basic salts. According to Ordway the neutral nitrate, $\text{G}^{\text{O}}(\text{NO}^3)^2 + 3\text{H}^{\text{O}}\text{O}$, or $\text{Be}^{\text{O}}\text{O}^3.3\text{N}^{\text{O}}\text{O}^3 + 9\text{H}^{\text{O}}\text{O}$, heated for 20 hours over the water-bath, leaves a soluble basic nitrate containing $\text{G}^{\text{O}}\text{O}.\text{G}^{\text{O}}(\text{NO}^3)^2 + 3\text{H}^{\text{O}}\text{O}$ or $2\text{Be}^{\text{O}}\text{O}^3.3\text{N}^{\text{O}}\text{O}^3 + 9\text{H}^{\text{O}}\text{O}$; the same salt remains in solution when an aqueous solution of the neutral nitrate is treated in the cold with carbonate of barium, but on boiling, the whole of the glucina is precipitated in the form of a salt containing a great excess of base. The neutral nitrate, formate, chloride, bromide, and iodide of glucinum may be almost wholly converted into tribasic salts by digestion with hydrate of glucinum. The neutral nitrate may also be converted into the tribasic salt by partial neutralisation of the acid with ammonia: the sulphate also in like manner, but the solution does not bear dilution. The solution of the acetate dissolves hydrate of glucinum, till it is converted into a sexbasic salt.

GLUCINUM, ALLOYS OF. But little is known of the alloys of glucinum. An alloy of this metal with iron is obtained by heating glucina to whiteness in contact with iron and charcoal (Stromeyer), or with iron and potassium (H. Davy); also by decomposing glucina, in an atmosphere of hydrogen, by the current of a powerful voltaic battery, the negative pole of which is formed of an iron wire, which is fused by the current (H. Davy). The alloy obtained by Stromeyer is white and less malleable than iron, and dissolves in acids, forming a glucinum-salt and a ferrous salt.

GLUCINUM, BROMIDE OF. GBr^2 or Be^2Br^2 .—Glucinum takes fire when heated in bromine-vapour, forming a bromide, which sublimes in long colourless prisms, is fusible, volatile, and dissolves in water, with great rise of temperature. — Hydrate of glucina dissolves in aqueous hydrobromic acid, and the solution, when evaporated, yields deliquescent crystals of a hydrated bromide, which when ignited leave a residue of glucina. (Berthémot.)

GLUCINUM, CHLORIDE OF. GCl^3 or Be^2Cl^3 .—Formed by heating the metal in chlorine or in hydrochloric acid gas, and by the action of aqueous hydrochloric acid on the metal or its oxide. The anhydrous chloride is prepared by passing dry chlorine gas over an ignited mixture of glucina or pulverised beryl with charcoal. It then collects in the colder parts of the tube, or in the receiver, in silky needles and flakes, thickly interwoven or caked together into a dense mass. It melts at a gentle heat, and at a higher temperature again sublimes in needles. It is less volatile than chloride of aluminium. Heated with potassium or sodium, it yields glucinum.

Chloride of glucinum dissolves in water, with considerable rise of temperature and a hissing noise; it is very deliquescent. The solution, which may also be obtained by dissolving glucina, or the metal, in hydrochloric acid, deposits on evaporation a crystalline mass, consisting of the hydrated chloride, $GCl^3 \cdot 2H^2O$. A basic chloride, or oxychloride, is obtained by boiling the aqueous solution with glucina, or by treating it with a quantity of ammonia not sufficient for complete precipitation.

GLUCINUM, DETECTION AND ESTIMATION OF. 1. Reactions.—

Glucinum is not precipitated from neutral or acid solutions by *sulphydic acid*.

Alkaline sulphides throw down hydrate of glucinum as a bulky white precipitate, with evolution of sulphydric acid.

Caustic potash and *soda* form a gelatinous precipitate of hydrate of glucinum, soluble in excess of the alkali, but completely precipitated on boiling, if the solution is dilute, and redissolving only to a very slight extent on cooling; if the caustic alkali-solution was very concentrated, the hydrate does not separate from the boiling solution till water is added, but the precipitation then takes place immediately.

Ammonia also precipitates the hydrate, even in presence of ammoniacal salts; the precipitate is not soluble in excess of ammonia.

The *alkaline earths*, and likewise *magnesia* and *yttria*, precipitate glucinum as a hydrate. The *normal* and *acid carbonates* of *potassium* and *sodium* throw down a bulky precipitate of carbonate of glucinum, soluble in a large excess of the reagent. *Carbonate of ammonium* produces a similar precipitate, but soluble in a much smaller excess.

Carbonate of barium precipitates glucina completely at the boiling heat; in the cold, according to H. Rose (Handb. d. Chem. Anal. ii. 61), no precipitate is formed; but according to Awdejew (Pogg. Ann. lvi. 101) and Weeren (*ibid.* xcii. 91), partial precipitation takes place. Ordinary *phosphate of sodium* throws down a flocculent precipitate. *Ferrocyanide of potassium* produces no precipitate at first, but the liquid becomes gelatinous after a while. *Alkaline succinates* form a white precipitate; *tincture of galls* throws down yellow flakes. Glucinum salts are not precipitated by sulphate of potassium, hydrofluosilicic acid, carbonate of calcium, oxalic acid, alkaline oxalates or tartrates, or by ferricyanide of potassium.

The reactions of glucinum are in most respects similar to those of aluminium. A sufficient distinction between the two is, however, afforded by the reaction with *carbonate of ammonium*, which dissolves the precipitates of glucinum formed by alkalis and alkaline carbonates, but not the corresponding precipitates of aluminium. A further distinction is that glucinum-compounds, moistened with nitrate of cobalt and heated before the blowpipe, do not give the blue colour which is characteristic of aluminium-compounds.

2. *Quantitative Estimation and Separation.*—Glucinum is precipitated from its solutions for quantitative estimation by ammonia, or better by sulphide of ammonium. The precipitate, when washed and ignited, yields pure anhydrous glucina.

The methods of separating glucinum from other metals are for the most part the same as those for the separation of aluminium.

When glucinum and aluminium occur together in solution, the best mode of separating them is that given by Berzelius, viz. to boil the precipitated hydrates with a highly concentrated solution of sal-ammoniac as long as ammonia continues to escape. The whole of the glucina then dissolves, and the alumina remains behind. To ensure complete separation, it is necessary to add the sal-ammoniac solution before precipitating, and continue the boiling for a considerable time, renewing the water as it evaporates, to prevent the solution becoming too concentrated. When the evolution of gases ceases, the solution is to be diluted with a large quantity of hot water, then filtered hot, and the glucina precipitated by sulphide of ammonium. The method

usually given for effecting this separation—viz. by digestion in a cold strong solution of carbonate of ammonium—is not satisfactory, because a portion of the alumina dissolves together with the glucina, although by itself it is quite insoluble in carbonate of ammonium. Neither does precipitation with carbonate of barium give satisfactory results, a portion of the glucina always going down with the alumina. (Weeren.)

According to V. Hofmeister, on the contrary (J. pr. Chem. lxxvi. 1), the method of digestion in carbonate of ammonia is the best of all methods of separating glucina from alumina, provided it be carried out as follows:—The mixture of the two earths precipitated by caustic ammonium and washed, is digested in a quantity of solution of carbonate of ammonium not much more than sufficient to dissolve the whole of the glucina, this quantity having been approximately determined beforehand. The alumina which remains is then perfectly free from glucina. The solution contains the whole of the glucina, together with a certain quantity of alumina; if the quantity of alumina thus dissolved is rather large, the solution becomes spontaneously turbid, after standing for 6 to 12 hours. The solution is acidulated with hydrochloric acid, heated till all the carbonic acid is expelled, and precipitated by caustic ammonia. The well-washed precipitate, if treated with a quantity of carbonate of ammonium *smaller* than that previously used, yields a residue of alumina, which may contain glucina; and in that case the resulting solution is free from alumina. The same treatment is now to be applied to this undissolved residue (or to the solution, if the residue is free from glucina); and in this manner a complete separation of the two earths is effected. The best way of precipitating the glucina from its solution in carbonate of ammonium is to supersaturate with hydrochloric acid, and then with ammonia mixed with a little sulphide of ammonium. (See also Scheffer, p. 853.)

3. *Atomic weight of Glucinum.*—The atomic weight of glucinum has not yet been determined with the same degree of accuracy as those of most other metals. The early determinations, founded on analyses of the chloride and sulphate, were much too high, the error having apparently arisen from the formation of basic salts in the precipitations, so that the separation of the base and acid was not complete.

Awdejew (Pogg. Ann. lvi. 101) found in chloride of glucinum prepared by the action of chlorine on a mixture of glucina and charcoal, from 86.7 to 88.3 per cent. of chlorine; whence, for the formula GCl_2 , he finds $\text{G} = 9.64$, and for Be^2Cl^4 , $\text{Be} = 14.6$.

From the analysis of the sulphate of glucinum, G^2SO^4 , Awdejew found for the atomic weight of glucinum ($\text{S} = 32.2$) values ranging from 9.13 to 9.444, mean $\text{G} = 9.3$, which, if reduced to the value which it should have for $\text{S} = 32$, becomes $\text{G} = 9.24$ or $\text{Be} = 13.96$.

From these determinations, the atomic weight of glucinum may be estimated approximately as $\text{G} = 9.4$ or $\text{Be} = 14$.

GLUCINUM, FLUORIDE OF. GF^2 or Be^2F^4 .—The anhydrous fluoride is not known. The solution of hydrate of glucinum in aqueous hydrofluoric acid dries up to a colourless, transparent, gummy mass, which remains clear at 60°C ., but gives off water and becomes milk-white at 100° , then swells up, and at a red heat gives off part of its acid, provided the whole of the water has not previously been driven off. It dissolves readily in water, even after it has been heated. (Berzelius.)

Fluoride of Glucinum and Potassium. 2KF.GF^2 , or $6\text{KF.Be}^2\text{F}^4$.—Precipitated in small scaly crystals on mixing the solutions of the component fluorides. If the fluoride of potassium be added in excess to the solution of chloride of glucinum, the compound separates in the form of a jelly, but its solution in hot water yields crystalline scales on cooling. (Berzelius.)

GLUCINUM, IODIDE OF. GI^2 or Be^2I^4 .—Glucinum takes fire when heated in iodine vapour, the iodide subliming in colourless prisms easily soluble in water (Wöhler). It is less volatile than the chloride, and is decomposed by oxygen, even at the heat of a spirit-lamp, yielding iodine and glucina. (Debray.)

GLUCINUM, OXIDE OF. *Glucina. Beryllia, Beryllerde, Süsserde, GO*, or Be^2O^4 .—Glucina may be prepared from beryl or either of the other silicates of glucinum by calcination with alkaline hydrate or carbonate, or with quicklime. Weeren fuses an intimate mixture of 1 pt. finely pounded beryl and 3 or 4 pts. carbonate of potassium in a hessian crucible, keeping the mixture at a full white heat for two hours; treats the fused mass with hydrochloric acid in the usual way, to separate silica; precipitates the glucina, alumina, and ferric oxide with ammonia; and boils the precipitate with a strong solution of sal-ammoniac as long as ammonia continues to escape, frequently renewing the water. By this means the glucina alone is dissolved, and may be precipitated by ammonia or sulphide of ammonium.

Debray prepares glucina from the emerald of Limoges by the following process. The mineral, finely pounded (levigation with water is quite superfluous), is fused with half its weight of quicklime in an air-furnace, and the glass thus obtained is treated, first with

dilute, and then with strong nitric acid, till it is reduced to a homogeneous jelly. The product is then evaporated to dryness, and heated sufficiently to decompose the nitrates of aluminium, glucinum, and iron, and a small portion of the nitrate of calcium; and the residue, consisting of silica, alumina, glucina, sesquioxide of iron, nitrate of calcium, and a small quantity of free lime, is boiled with water containing sal-ammoniac, which dissolves the nitrate of calcium immediately, and the free lime after a while, with evolution of ammonia (if no ammonia is evolved, the calcination has not been carried far enough, and must be repeated). The liquid is then decanted; the precipitate, after thorough washing, treated with boiling nitric acid; and the resulting solution of alumina, glucina, and iron poured into a solution of carbonate of ammonium mixed with free ammonia. The earths are thereby precipitated without evolution of carbonic acid, and the glucina redissolves, after seven or eight days, in the excess of carbonate of ammonium. As the carbonate of ammonium may also dissolve a small quantity of iron, it should be mixed with a little sulphide of ammonium to precipitate the iron completely. Lastly, the carbonate of ammonium is distilled off, and the carbonate of glucinum which remains yields pure glucina by calcination.

According to G. Scheffer (*Ann. Ch. Pharm.* cix. 144), the preceding processes are attended with considerable loss of glucina: the following gives better results. A mixture of 7 pts. beryl and 13 pts. fluorspar is digested at 100° — 200° C. with about 18 pts. sulphuric acid, in a leaden capsule (or in a porcelain capsule, especially if a somewhat smaller quantity of fluorspar be used), a large quantity of fluoride of silicon being thereby evolved. The mass is then heated nearly to redness in a capacious porcelain crucible, and dissolved in water acidulated with sulphuric acid, and the solution is mixed with 1.7 pts. sulphate of ammonium, or an equivalent quantity of sulphate of potassium, and left to itself till the greater part of the alumina contained in it has crystallised out in the form of alum. To separate the alumina still remaining in solution from the glucina, the liquid decanted from the alum-crystals is diluted with 6 or 8 times its volume of water, and digested for two or three days with granulated zinc, then heated with the zinc and filtered. The whole of the alumina is thereby precipitated as basic sulphate, while the glucina remains in solution, also as basic sulphate ($G^2O.G^2SO^4$) together with sulphate of zinc. The greater part of the latter may be crystallised out as zinc-potassic sulphate by addition of sulphate of potassium (1.4 pts. of that salt to 1 pt. of zinc dissolved); the decanted liquid mixed with excess of acetate of sodium; the remaining zinc precipitated by sulphydric acid; the filtrate neutralised with ammonia; and the whole of the glucina precipitated by sulphide of ammonium. Common beryl treated by this process yields from 11 to 12.5 per cent. pure glucina.

Glucina is a soft, light, very bulky white powder, of specific gravity 2.967. It is tasteless and adheres to the tongue. It is not hardened by heat like alumina, but merely rendered less soluble in acids. When very strongly heated, it volatilises, like magnesia, without fusing. Ebelmen has obtained it in hexagonal prisms by exposing a solution of glucina in fused boracic acid to a powerful and long-continued heat. It may be more easily obtained in microscopic crystals, apparently of the same form, by decomposing the sulphate at a high temperature in presence of sulphate of potassium, also by calcining the double carbonate of glucinum and ammonium.

Hydrate. $G^2H^2O^2$ or $G^2O.H^2O$.—This is the precipitate formed in glucinum-salts by caustic alkalis. It resembles trihydrate of aluminium when moist, but forms a powder when dry. It parts with its water at a high temperature, but without becoming incandescent. It dissolves in caustic potash and soda like alumina, but is precipitated by boiling, when the solution is diluted to a certain extent with water. According to Weeren, it dissolves slightly in ammonia, unless chloride or sulphide of ammonium is present. It absorbs carbonic acid from the air, in the dry, as well as in the moist state.

GLUCINUM, OXYGEN-SALTS OF. See p. 849; also the several Acids.

GLUCINUM, PHOSPHIDE OF. Glucinum burns in vapour of phosphorus, forming a grey powder, which is decomposed by water, with evolution of spontaneously inflammable phosphoretted hydrogen gas.

GLUCINUM, SELENIDE OF. Produced, with vivid incandescence, when glucinum is fused with selenium. It forms a crystalline brittle mass, grey on the fractured surface; is slowly dissolved and decomposed by water; but oxidises quickly, with separation of selenium, in contact with the air.

The precipitate formed by selenide of ammonium in solutions of glucinum-salts is probably impure hydrate of glucinum containing selenium.

GLUCINUM, SULPHIDE OF. Formed, with vivid incandescence, when glucinum is ignited in sulphur vapour; it is not produced by igniting glucina in

vapour of sulphide of carbon. It is a grey unfused mass, which dissolves slowly in water, without evolution of sulphuric acid, and is easily decomposed by acids, sulphuric acid being then evolved.

GLUCINUM, TELLURIDE OF. Produced, without emission of light, when glucinum is heated with tellurium; it is a grey powder, which decomposes gradually in contact with the air, and immediately in contact with water, giving off tellurhydric acid.

GLUCOSAN. $C^6H^{10}O^5$.—The anhydride of dextroglucose. Dextroglucose dried between 100° and 110° C. gives off water at 170° , becoming coloured at the same time, and is converted into glucosan, mixed, however, with small quantities of caramel and unaltered glucose, the latter removable by yeast, the former by charcoal. Glucosan is a colourless mass, scarcely sweet to the taste. It turns the plane of polarisation to the right, somewhat less strongly than dextro-glucose. It does not ferment immediately in contact with yeast, but only after being treated with dilute acids, which convert it into glucose. (Gélie, Compt. rend. li. 331.)

Glucosan may be regarded as a hexatomic alcohol, containing the tetratomic radicle $(C^6H^4)^{iv}$, and represented by the formula $\left. \begin{matrix} (C^6H^4)^{iv} \\ H^6 \end{matrix} \right\} O^5$; in fact, by treating glucose with acids and with alcohol, compound ethers are obtained, related to glucosan in the same manner as the mannitanides and dulcitanides (p. 521) are related to mannitan and dulcitan. (Berthelot, Ann. Ch. Phys. [3] lx. 96 *et seq.*)

Aceto-glucosan. $C^{12}H^{22}O^{11} = \left(\begin{matrix} (C^6H^4)^{iv} \\ (C^2H^2O)^2 \end{matrix} \right) O^5 = C^6H^{10}O^5 + 6C^2H^4O^2 - 6H^2O$. *Glucose acetique, Hexacetoglucose.*—Obtained by heating glacial acetic acid with dextro-glucose or with cane-sugar to 100° C. for fifty hours; purified like the corresponding butyric compound. Trehalose and starch at 180° C., and dextrin at 100° , form with acetic acid, compounds similar to or identical with this.

Aceto-glucosan is a pale yellow or colourless neutral oil, having a bitter taste and faint odour. It dissolves abundantly in water, but not in all proportions, and is precipitated from the solution by chloride of calcium. It is soluble in alcohol and ether (Berthelot). It becomes acid in contact with the air, turns brown when heated, and burns with an odour of caramel. It is carbonised by oil of vitriol; slowly decomposed by boiling with dilute sulphuric acid, into acetic acid and dextro-glucose, which is further partly resolved into humous substances. With alcoholic hydrochloric acid, it forms acetate of ethyl and dextroglucose. Aceto-glucosan reduces potassio-cupric tartrate.

Benzo-glucosan. $C^{26}H^{18}O^7 = \left(\begin{matrix} (C^6H^4)^{iv} \\ (C^2H^2O)^2 \end{matrix} \right) O^5 = C^6H^{10}O^5 + 2C^2H^4O^2 - 2H^2O$. *Glucose benzoïque or dibenzoïque, Dibenzoyl-glucose.*—Obtained by heating benzoic acid with dextro-glucose or cane-sugar to 100° C. for fifty hours, and purified like butyro-glucosan. The same or a similar compound is produced by heating benzoic acid with trehalose to 180° , or with cotton to 200° ; also at ordinary temperatures in a mixture of cotton, oil of vitriol, and benzoic acid; in all cases, however, only in small quantity. It is a neutral, semi-fluid oil, which produces grease-spots on paper, and has a bitter, pungent taste. It dissolves sparingly in water, easily in alcohol and ether. It burns with an odour of caramel when heated; is carbonised by oil of vitriol. With alcoholic hydrochloric acid, at a moderate heat, it yields benzoate of ethyl and dextro-glucose. It reduces potassio-cupric tartrate.

Butyro-glucosan. $C^{11}H^{22}O^7 = \left(\begin{matrix} (C^6H^4)^{iv} \\ (C^2H^2O)^2 \end{matrix} \right) O^5 = C^6H^{10}O^5 + 2C^2H^4O^2 - 2H^2O$. *Glucose butyrique, Dibutyryl-glucose.*—This compound is produced from cane-sugar, dextro-glucose, or trehalose, and in small quantity from dextrin, by heating with butyric acid. Traces of the same or a similar compound are obtained when cotton or paper is heated with oil of vitriol and butyric acid. To prepare it, butyric acid is heated with cane-sugar or anhydrous dextro-glucose to 100° C. for fifty or sixty hours; the mass is exhausted with alcohol, and the solution filtered and evaporated. The residue is mixed with concentrated aqueous carbonate of potassium, a lump of caustic potash being added to neutralise it completely; the mixture is shaken up with ether; the ethereal layer is decolorised with animal charcoal, and the filtrate is evaporated over the water-bath.

Butyroglucosan is a pale yellow, viscid oil which produces grease-spots on paper. It is neutral, very bitter, with a slightly aromatic odour; retains water obstinately. It dissolves sparingly in water, easily in alcohol and ether. It burns when heated, emitting an odour of caramel. It is carbonised by oil of vitriol, and resolved, by heat-

mg with dilute sulphuric acid, into butyric acid and dextro-glucose. With alcoholic hydrochloric acid it yields dextro-glucose and butyrate of ethyl. From potassio-cupric tartrate, it reduces cuprous oxide.

Ethyl-glucosan. $C^{10}H^{18}O^8 = \left\{ \begin{array}{l} (C^6H^8)^{1\frac{1}{2}} \\ (C^2H^2)^2 \\ H^4 \end{array} \right\} O^8 = C^6H^{10}O^5 + 2C^2H^2O - 2H^2O$.—Pro-

duced when a mixture of cane-sugar, bromide of ethyl, and hydrate of potassium is heated in a sealed tube to $100^\circ C$. for several days, and the product, when cold, is treated with ether; ethyl-glucosan is thereby dissolved, and may be obtained by evaporation as a colourless oil. It has a bitter taste and a faint, agreeable odour, and is not volatile. It is nearly insoluble in water. From the ethereal solution it is almost completely precipitated by animal charcoal (Berthelot). By heating with dilute sulphuric acid, it is resolved into alcohol and dextro-glucose. From potassio-cupric tartrate it reduces cuprous oxide.

Glucosotartaric acid, $C^{12}H^{20}O^{23}$ (p. 872), may be represented by the formula $\left\{ \begin{array}{l} (C^6H^8)^{1\frac{1}{2}} \\ (C^2H^2)^2 \\ H^4 \end{array} \right\} O^8.C^4H^6O^6.2H^2O$, and *Glucosocitric acid*, $C^{12}H^{16}O^{16}$, by the formula $\left\{ \begin{array}{l} (C^6H^8)^{1\frac{1}{2}} \\ (C^2H^2)^2 \\ H^4 \end{array} \right\} O^8.C^4H^6O^7.5H^2O$.

GLUCOSE. $C^6H^{12}O^6$ or $C^{12}H^{24}O^{12}$.—A species of sugar produced, by the action of acids, certain ferments, and other reagents, and by processes going on in living plants, from cane-sugar, dextrin, starch, cellulose, and other carbohydrates; also by the decomposition of glucosides (p. 866); also by certain transformations of mannite and glycerin, and by the action of sodium-amalgam on oxalate of ethyl. There are two varieties of it, distinguished by their action on polarised light, viz. dextroglucose, which turns the plane of polarisation to the right; and lævoglucose, which turns it to the left.

Dextroglucose. *Ordinary glucose, Granular sugar (Krümelzucker)*, and, according to its origin, *Grape-sugar, Fruit-sugar, Honey-sugar, Starch-sugar, Diabetic sugar, Sugar of Urine, Chestnut-sugar, Rag-sugar*, some of which names are also used to denote glucose in general. It was first recognised as a distinct substance by Lowitz (Crell. Ann. 1792), and Proust (J. Phys. lxiii. 257); first prepared from starch by Kirchhoff (Schw. J. xiv. 389); from linen by Braconnot (Ann. Ch. Phys. [2] xii. 181). Its combinations with bases have been investigated chiefly by Peligot (*ibid.* lxvii. 136); those with organic acids by Berthelot (*ibid.* [3] liv. 74, lx. 95), who has likewise investigated its fermentation in contact with chalk and cheese (*ibid.* l. 322), and its formation from mannite and glycerin (*ibid.* l. 369). Our knowledge of glucose has been further extended by Dubrunfaut (Ann. Ch. Phys. [2] liii. 73; [3] xxi. 169, 178; Compt. rend. xxiii. 38; xxv. 308; xxix. 51; xxxii. 249; xlii. 228 and 739), who has eliminated much that does not properly belong to it, and more exactly characterised its properties.

Occurrence. *a. In the Mineral kingdom.*—Impressions of ferns from the clay-slate of Petit-cœur, in Savoy, contain a sweet substance, which smells like caramel when burnt on charcoal, and perhaps consists of glucose (Calloud, Compt. rend. xxxiii. 511). On the alleged occurrence of sugar or dextrin in vegetable mould see Verdeil and Risler, Compt. rend. xxxv. 97, and the counter-statement of Petzholdt (J. pr. Chim. lx. 368.)

b. In the Vegetable kingdom.—Dextroglucose occurs abundantly in sweet fruits, frequently together with cane-sugar, and always with such a quantity of lævotatory fruit-sugar that the mixture exhibits lævotatory power, and is thence called inverted sugar (p. 863). The isolated occurrence of dextroglucose has been observed only in the following cases:—

A thick viscid liquid which, in the summer of 1842, covered the upper surface of the leaves of lime-trees, and at certain times of the day fell down like rain, contained cane-sugar and dextroglucose (Biot, Ann. Ch. Phys. [3] vii. 337; Langlois, *ibid.* vii. 348). Dextroglucose is contained in the manna of the ash-tree; a false manna, of unknown origin, was found to contain a peculiar sugar not invertible by acids, and having a molecular rotatory power equal to $\frac{2}{3}$ of that of cane-sugar; perhaps maltose (Biot, Compt. rend. xiv. 49). Whether the sugar occurring in many other parts of plants should be considered as dextroglucose, is not yet decided. According to Buig's researches (p. 712), cane-sugar and inverted sugar (which may be regarded as a peculiar substance, at least with reference to its origin), appear to be the most widely diffused; and the imperfectly investigated granular sugar (*Krümelzucker*) of many chemists appears to be inverted sugar, formed either in the plant, or during the process to which it is subjected for the extraction of the sugar.

In Honey.—This substance contains cane-sugar (which is gradually inverted by keeping), inverted sugar, and an excess of dextroglucose. (Dubrunfaut, Compt. rend. xxix. 51.)

c. In the Animal body.—In many animal liquids and tissues; in the liver, in the amniotic and allantoic liquids, in the blood, in the chyle, in the transudates, in the yolk and white of hens' eggs. In large quantity, to the amount of 8 or 10 per cent., in diabetic urine; in small quantity also in the urine of healthy men (Brücke; Bence Jones, Chem. Soc. Qu. J. xiv. 22). The urine of a fox fed exclusively on meat contained glucose (Vintschgau, Wien. Akad. Ber. xlii. 523). Compounds of glucose are likewise found in the animal body. (See GLUCOSIDES.)

Formation.—Of dextroglucose and fermentable sugars in general isomeric therewith, in so far as they cannot with certainty be referred to other species.

A. *By the transformation of Carbo-hydrates, with assumption of Water.* 1. Glucosan, $C^6H^{10}O^5$ (p. 853), is converted into dextroglucose by boiling with dilute acids. (Géllis.)

2. Dextrin is converted into dextroglucose by boiling with dilute acids (Biot and Persoz). Diastase acts in like manner, according to Payen and Persoz; according to Musculus, it does not.—3. Under the same circumstances, soluble starch and common starch are converted into dextroglucose, after they have been previously converted wholly or partially into dextrin or other intermediate products. Dextroglucose is also formed from starch by continued boiling with water, by prolonged contact with glutin, saliva, animal gelatin, the pancreatic juice, the substance of the kidneys, mucous membrane, urine, bile, semen, blood-serum; and by watery infusions, prepared at $40^{\circ} C.$, from the heart, brain, lungs, liver, kidneys, spleen, and muscles. (See *Gmelin's Handbuch*, viii. [2] 21.)

4. *Glycogen* is converted into dextroglucose under the same circumstances as starch.

5. In like manner, *lichenin* and *paramylone* are converted into glucose by boiling with acids.

6. *Cellulose* treated with strong sulphuric or hydrochloric acid (i. 819), or a concentrated aqueous solution of chloride of zinc, yields products which are converted into glucose when their aqueous solution is boiled with water. Glucose is likewise produced in the decomposition of *lignosulphate of lead*, and by the action of alkalis on *pyroxylon*. But it is doubtful also whether this sugar should be regarded as dextroglucose. According to Béchamp (Ann. Ch. Phys. [3] xlviii. 502), it yields, when treated with alcohol, two sorts of crystals, one having the hardness of cane-sugar, the others resembling dextroglucose.

The skin of the silk-worm, and that which remains in the cocoons when the butterflies escape, are capable of yielding a substance isomeric with cellulose, which may be converted into glucose. When the caterpillars are boiled for several hours with strong hydrochloric acid, and this treatment is repeated three times with the residue, and this residue is washed with strong potash-ley, then with water, and dried between 100° and $110^{\circ} C.$, a white light substance nearly free from nitrogen is obtained, which gradually diffuses in oil of vitriol, forming a colourless gummy liquid. This solution, added by small quantities to boiling water, and boiled for an hour or two, yields fermentable sugar, which reacts, like glucose, with common salt and potassio-cupric tartrate. (De Luca, Compt. rend. liii. 102.)

7. *Tunicin* is decomposed by sulphuric acid, under the same circumstances as cellulose, into dextroglucose and a second substance.

8. *Maltose*, *mlezitose*, *trehalose* and *mycosc*, are completely converted into dextroglucose by boiling with dilute acids.

B. Another class of compounds yield by their decomposition dextroglucose and another product. This latter body is either isomeric with glucose: thus melitose is resolved, by dilute acids, yeast, and other bodies, into dextroglucose and eucalin; cane-sugar into dextro- and levoglucose;—or it belongs to the class of non-saccharine bodies, in which case the compound which yields this second product and dextroglucose belongs to the class of *Glucosides* (p. 866).

C. In the decomposition of *dulcite* ($C^6H^{10}O^6$) by nitric acid, there is formed, amongst other products, a sugar, $C^6H^{12}O^6$, which reacts with alkalis, potassio-cupric tartrate, basic nitrate of bismuth, and indigo, in the same manner as dextroglucose. (Carlet, Compt. rend. li. 137.)

D. *From Oxalate of Ethyl.*—When this compound is brought in contact with sodium-amalgam at low temperatures, and the product is agitated with ether, a solution is obtained from which a greasy mass separates on addition of water. This mass is a mixture of oxalate of sodium, another sodium-salt, and fermentable sugar. (Löwig, J. pr. Chem. lxxiii. 183.)

E. *From Mannite or Glycerin.*—When a moderately concentrated aqueous solution of mannite, dulcite, or glycerin, is left for some time in contact with the testicles of man, or of the horse, dog, or cock, a peculiar fermentable sugar is produced, the form-

ation of which likewise takes place in certain cases, when, instead of the testicle, albumin, casein, fibrin, gelatin, or the tissue of the kidneys or pancreas, is employed. (Berthelot, *Ann. Ch. Phys.* [3] 1. 369.)

When to a solution of mannite or glycerin in 10 pts. water there is added such a quantity of comminuted testicle that its dried substance amounts to $\frac{1}{50}$ of the mannite, and the mixture, contained in an open flask, is exposed to diffused daylight between 10° and 20° C., the liquid, after an interval varying from a week to three months, is found to contain (without the occurrence of putrefaction, which, indeed, is incompatible with the success of the experiment) a substance which reduces cupric tartrate. The testicular tissue, if separated at this time from the liquid by decantation and thorough washing, then again introduced under similar circumstances into a solution of mannite or glycerin, produces therein, in the course of a few weeks, a considerable quantity of sugar. This sugar is formed, sometimes in extremely small, sometimes in larger, quantity, amounting to $\frac{1}{10}$ of the mannite or glycerin, and is partly further altered during the operation. It is not formed by the substance of the testicle, inasmuch as this substance is recovered for the most part unaltered, and gives up to the liquid, chiefly salts and albuminous substances, amounting to less than the weight of the sugar. The sugar is probably laevo-rotatory. It is deliquescent, uncrystallisable, and cannot be separated from the glycerin. It is apt to alter during the evaporation of its solution, is turned brown by alkalis, easily fermented by yeast, and reduces potassio-cupric tartrate. It is very soluble in water, alcohol, and glycerin, and slightly precipitable by ammoniacal sugar of lead. (Berthelot). On the formation of sugar in the muscles and lungs of the foetal calf, see *Gmelin's Handbuch*, viii. [2] 489.

Preparation.—1. *From the juice of various kinds of fruit, especially of Grapes.*—The juice is boiled and skimmed; the free acid is neutralised with chalk or marble; and the liquid is concentrated to one-half, clarified by deposition and decantation, or further with white of egg, and evaporated to a syrup, not too thick. From this the grape-sugar separates after some weeks, and is purified by repeated solution in water and crystallisation.

2. *From Honey.*—1. White granular honey is diffused in $\frac{1}{2}$ pt. of cold strong alcohol, which dissolves the more soluble levoglucose, and leaves the dextroglucose for the most part undissolved; the solution is separated from the sediment after a few hours; the sediment strongly pressed; the residue again triturated with $\frac{1}{10}$ pt. alcohol; again pressed, and the undissolved portion is purified by solution in water and crystallisation (Braconnot, *Bull. Pharm.* iii. 360.) A similar process is followed by Proust, also by Canvezalli (Scher. J. vii. 714), and Trommsdorff (N. Tr. ix. 1, 287).—2. Sieglé spreads granular honey on dry porous bricks, whereby the liquid portion is absorbed, leaving, after a few days, a granular residue, which is recrystallised from warm alcohol with help of animal charcoal (J. pr. Chem. lxi. 148). The dextroglucose obtained by either of these processes will be contaminated with cane-sugar, if the honey contained that substance.

3. *From Starch by the action of dilute Sulphuric acid.*—1 pt. of starch is boiled with 4 pts. water, and a quantity of oil of vitriol weighing from $\frac{1}{100}$ to $\frac{1}{10}$ as much as the starch, the liquid being stirred and the water continually renewed till the liquid is no longer precipitated by alcohol. To bring it to this state, the boiling must be continued for a longer time in proportion as less sulphuric acid has been used; with the above proportions, from 6 to 36 hours' boiling is required. The dextroglucose then contained in the solution is separated and purified in the same manner as that from grape-juice (Kirchhoff). In preparing starch-sugar on the large scale, the ebullition is produced by passing over-heated steam into the mixture contained in closed casks. When starch is boiled with water and 2 per cent. oil of vitriol, the liquid being evaporated after 5 or 7 hours, at which time it is no longer precipitated by alcohol, an uncrystallisable syrup is obtained. It is only after longer boiling that the whole of the dissolved matter is converted into dextroglucose, part of which moreover undergoes further alteration, so that the liquid does not easily yield crystals by evaporation (Anthon, *Dingl. pol. J.* cli. 218). After the sulphuric acid has been neutralised by chalk, a small quantity of acetic acid must be added before boiling the liquid, since an excess of lime leads to the formation of bitter products of decomposition. (*Polyt. Centr.* 1854, p. 252.)

4. *From Starch, by the action of Glutin, Malt, or Diastase.*—2 pts. of starch well mixed by stirring with 4 pts. of cold water are diffused in 20 pts. of boiling water, and the paste thus formed is digested for eight hours at 50° to 70° C. with 1 pt. of dried and pulverised wheat-gluten. From the syrup obtained by evaporation, alcohol extracts the sugar, leaving the starch which is still but slightly altered, and the solution yields the sugar by evaporation.

* The product thus obtained is perhaps not dextroglucose, but maltose (q. v.)

100 pts. of starch are suspended in 400 pts. of cold water; the mixture is poured into 2000 pts. of boiling water, and after the whole has cooled to 65°C ., 2 pts. of diastase dissolved in 20 pts. of cold water are added. The mass, which in a few minutes becomes perfectly fluid, is kept for $2\frac{1}{2}$ hours at a temperature between 60° and 65°C .; evaporated as quickly as possible at 60° , or better in vacuo, to 34°Bm ., and left to itself for some days in shallow vessels. By treating the syrup, which is sometimes crystalline, with alcohol of 95 per cent., at a temperature of 75°C ., cooling the solution out of contact of air, filtering, reducing the filtrate to a syrup by distillation and concentration, and leaving the syrup to itself in vacuo, crystals are obtained which may be purified by pressure, renewed treatment with alcohol, and recrystallisation from 4 pts. water at 65° , with help of animal charcoal. The diastase may be economically replaced by 18 times the quantity of malt. (Guérin-Varry.)

5. *From Linen*.—(See i. 819.) To 12 pts. of linen purified as completely as possible by treatment, first with potash-ley, then with water, and dried, 17 pts. oil of vitriol are very slowly added, so that no heating may take place; the mass is kneaded together, left to itself for 24 hours, then dissolved in a very large quantity of water; the solution is boiled for 10 hours; the acid is saturated with chalk; the liquid is filtered and evaporated; and the glucose which separates after some days is purified by recrystallisation (Braconnot). Vogel uses sulphuric acid of sp. gr. 1.8, which blackens the linen less than the strongest acid, and leaves the mass to itself for two days.

6. *From the Urine of diabetic patients*.—The crystals obtained by evaporating the urine are pressed (after being separated from the chloride-of-sodium compound of glucose) and purified by crystallisation from boiling alcohol (Chevreul), or by digestion with cold alcohol and subsequent recrystallisation (Prout). Addition of ether to the alcoholic solution favours the crystallisation (Peligot, Hünefeld). The urine is evaporated to a syrup on the water-bath; the residue exhausted with alcohol; the tincture precipitated with basic acetate of lead; the lead separated from the filtrate by sulphuretted hydrogen; and the clear liquid evaporated to a syrup and allowed to stand till it deposits crystals (Hünefeld, J. pr. Chem. viii. 560). Frequently nothing but crystals of the chloride-of-sodium compound of glucose are obtained on evaporating diabetic urine. (Lehmann, *Gmelin's Handbook*, viii. [2] 568.)

Properties.—Dextroglucose separates from its aqueous solution by slow evaporation in white, opaque, granular, hemispherical or cauliflower-shaped masses, consisting of a hydrate $\text{C}^6\text{H}^{12}\text{O}_6 \cdot \text{H}_2\text{O}$; but from alcohol of 95 per cent. or upwards, it separates in anhydrous, microscopic, sharply-defined needles, which melt at 140°C . to a colourless, transparent mass (O. Schmidt, *Dissertation über Traubenzucker*, Göttingen, 1861). These anhydrous crystals are, however, frequently mixed with small portions of the hydrate. Anhydrous glucose is also obtained as a white powder by heating the hydrate to 55° or 60°C . in a stream of dry air, and as a fused transparent mass by heating the hydrate to 100° .

Dextroglucose is much less soluble in water than cane-sugar, requiring for solution $1\frac{1}{2}$ times its weight of cold water; in boiling water it dissolves in all proportions, forming a syrup which has a very sweet taste, but is not so ropy as the syrup of cane-sugar. Pulverised glucose placed on the tongue produces a pungent and mealy taste, becoming slightly saccharine as the substance dissolves. $2\frac{1}{2}$ pts. glucose according to Prout, 2 pts. according to Dubrunfaut, sweeten as much as 1 pt. of cane-sugar.

The following table, calculated by Pohl (Wien. Akad. Ber. xi. 664), from determinations by Graham, Hofmann, and Redwood, exhibits the quantities of anhydrous glucose contained in aqueous solutions of different specific gravity:

Quantity of anhydrous glucose in 100 pts. solution.	Specific gravity of solution.	Quantity of anhydrous glucose in 100 pts. solution.	Specific gravity of solution.
2	1.0072	15	1.0616
6	1.0200	17	1.0693
7	1.0275	20	1.0831
10	1.0406	22	1.0909
12	1.0480	26	1.1021

Dextro-glucose is also less soluble than cane-sugar in alcohol: the solution, saturated at the boiling heat, deposits crystals which retain a portion of alcohol with considerable force.

The molecular rotatory power of anhydrous glucose ($\text{C}^6\text{H}^{12}\text{O}_6$), for the transition-tint (see LIGHT, POLARISED), is $[\alpha] = +53.2^{\circ}$ (Dubrunfaut), 57.44° (Béchamp), 55.15° (Pasteur); for the monohydrate ($\text{C}^6\text{H}^{12}\text{O}_6 \cdot \text{H}_2\text{O}$), $[\alpha] = +48^{\circ}$ (Dubrunfaut), 53.03 (Béchamp). A freshly prepared solution of hydrated glucose (also of the crystals of anhydrous glucose obtained from absolute alcohol, or of dehydrated glucose prepared without fusion) shows a rotatory power equal to twice the above; but it gradually sinks to this point and then remains constant; but if the glucose has been

dehydrated by fusion, its solution, even when freshly prepared, possesses the same rotatory power as that acquired by a solution of the crystals after long standing. Dubrunfaut distinguished the glucose contained in a freshly-prepared solution as *glucose birotatoire*. The solution of the crystals in wood-spirit retains its rotatory power for a longer time than the aqueous solution.

Decompositions.—1. When dextroglucose dried at 110° C. is heated to 170° , it gives off one at. water, and is converted into glucosan, $C^6H^{10}O^5$ (Géllis, p. 854). When heated for a long time to 150° , it turns brown, and is then hygroscopic after cooling (O. Schmidt). Between 210° and 220° C., it swells up more than cane-sugar, gives off a larger quantity of water, and yields caramel (Peligot). The products formed at high temperatures are similar to those obtained from cane-sugar (i. 747), but are somewhat more fusible, more easily soluble in water, and less soluble in alcohol.

2. Glucose froths up in the open fire, evolves a smell of burned sugar, and burns away with flame.

3. When oxygen is passed over glucose mixed with spongy platinum, formation of water and carbonic anhydride commences between 140° and 150° C., and at 250° the glucose is completely decomposed (Roiset and Millon, Ann. Ch. Phys. [3] viii. 258). Aqueous glucose in contact with platinum-sponge does not absorb oxygen; but, if potash-ley is also added, it becomes heated, and is oxidised to carbonic anhydride and water (Döbereiner). It yields formic acid when heated with *chromic acid* and sulphuric acid, or with *peroxide of manganese* and sulphuric acid (Hünefeld). Aqueous glucose does not alter *acid chromate of potassium* when heated with it (Reich). By distilling 1 pt. glucose with 1 pt. oil of vitriol, 1 pt. peroxide of manganese, and 30 pts. water, a distillate is obtained which exhibits the reactions of aldehyde, and possesses also the smell of acrolein (Liebig). Glucose is not altered by boiling with peroxide of manganese alone (Stürenberg), neither is it altered by permanganate of potassium (Monier). It takes fire when triturated with 6 pts. *peroxide of lead* (Böttger). On adding small quantities of glucose to a boiling pulp of peroxide of lead and water, carbonate and formate of lead are obtained: $C^6H^{12}O^6 + 8PbO^2 = 2C^2H^2PbO^4 + 2PbCO^2 + 4PbO + 4H^2O$. (Stürenberg.)

4. Dextroglucose behaves like milk-sugar when its *aqueous solution* is heated, that is to say, it turns yellow, and finally dark brown, and, if afterwards left to evaporate, leaves an acid deliquescent syrup, which does not crystallise, even after several months (Hoppe, Chem. Centr., 1860, p. 54). The rotatory power of the aqueous solution does not alter by standing for ten months (Maumené, Compt. rend. xxxix. 916). A concentrated aqueous solution becomes yellow when heated in a chloride-of-sodium bath, but its rotatory power is scarcely altered in 40 to 80 hours. (Soubeiran.)

5. Its aqueous solution, mixed with 1 at. acid carbonate of potassium, and then with 1 at. *iodine*, and warmed, yields iodoform. (Millon.)

6. Heated in a sealed tube with *bromine* in presence of water, it yields hydrobromic acid, a dark-brown liquid, and humus-like products. (Barth and Hasiwetz.)

7. *Chlorine* converts glucose into a brown or black mass containing caramel, i. 748 (Maumené). *Stannic chloride* acts upon glucose in the same way as upon cane-sugar, converting it into Maumené's caramel (i. 749).

8. Fuming *nitric acid* converts glucose into nitro-glucose (Flores Domonté and Ménard). When heated with common, or moderately diluted nitric acid, glucose yields saccharic acid (Heintz) and oxalic acid, but no tartaric acid. (Liebig.)

9. By heating glucose with syrupy aqueous *phosphoric acid* to 140° , a small quantity of a saccharide is obtained. (Berthelot.)

10. Glucose dissolves without coloration when triturated with cold oil of vitriol, forming glucoso-sulphuric acid. This reaction distinguishes glucose from cane-sugar, which is quickly blackened by oil of vitriol. It chars when gently heated with 4 pts. oil of vitriol, and evolves carbonic oxide and carbonic anhydride (Fihol). When glucose is boiled with dilute sulphuric acid, the liquid becomes brown and yields a deposit of ulmin and ulmic acid; when air has access, formic acid is also produced. (Malaguti, Ann. Ch. Phys. liv. 417.)

11. Glucose long boiled with *hydrochloric acid* becomes unfermentable. (Böcker.)

12. When heated with aqueous *iodic acid*, it is slowly decomposed into carbonic anhydride and water. (Millon.)

13. Mixed with water and an equal quantity of *arsenic acid*, and exposed to the sun, it becomes red or brown after three or four days. (Böttger.)

14. Honey behaves with *oxalic acid* in the same way as cane-sugar. (Döbereiner.)

15. The rotatory power of aqueous glucose is but very slightly altered by long heating in a chloride-of-sodium bath with *acetic acid*. (Soubeiran.)

16. By heating dextroglucose with *organic acids*, compounds are formed, with elimination of water, which belong to the class of *Saccharides*, and no longer possess the properties of the acid and of sugar, but are capable of breaking up again, by

assimilating water, into the acid and dextroglucose (Berthelot). See GLUCOSIDES and SACCCHARIDES.

17. Gaseous ammonia passed over dextroglucose heated in a water-bath, or to 100° C., is rapidly absorbed; water holding carbonate of ammonium in solution distilling over, while a brown tasteless nitrogenous residue is left. (P. Thenard, Rep. Chim. pure, 1861, p. 20.)

18. Glucose is decomposed by long contact with *alkalis*, *alkaline earths*, and some *metallic oxides*, forming glucic acid (Peligot). When it is heated with *potash-ley*, the solution becomes dark brown, evolves a smell of caramel, and contains, besides glucic acid, Peligot's melassic acid.

19. A thick syrup of glucose distilled with *lime* yields an oil from which metacettone and phorone can be obtained by fractional distillation. (Liéss-Bodart, Ann. Ch. Pharm. c. 354.)

20. Aqueous glucose heated with *nitrate of barium* to 180° C. for 48 hours in a sealed tube, yields a body which is insoluble in water, and contains a small quantity of nitrogen, while an acid colourless solution remains, which quickly becomes coloured on exposure to the air, and contains neither nitric acid nor ammonia, but evolves a large quantity of ammonia when fused at a red heat with hydrate of barium. (P. Thénard, Bull. Soc. Chim., 1861, p. 61.)

21. By heating aqueous glucose with aqueous carbonate of sodium and *basic nitrate of bismuth*, a black-brown liquid and greyish-brown precipitate are obtained (Böttger, Jahrb. pr. Pharm. xxii. 29). Glucose can be detected in cane-sugar or in urine by this reaction. (Böttger, J. pr. Chem. lxx. 432.)

22. Crystallised glucose, evaporated with excess of *oxide of lead*, loses 11·14 per cent. (10·4 per cent. according to Guérin-Varry) of its weight, but the residue is brown, and smells of burnt sugar (Berzelius). A mixture of crystallised glucose with oxide of lead loses in weight 28 per cent. at 110° C., the sugar being converted into melassic acid. (Peligot.)

23. *Ferric sulphate* and *chloride* are reduced to ferrous salts by boiling with aqueous glucose (Hünefeld, J. pr. Chem. vii. 44). *Ferric hydrate* is reduced in the cold, still more easily on boiling (Kuhlmann, Compt. rend. xlix. 257). An aqueous mixture of 6 pts. tartaric acid, 240 pts. crystallised carbonate of sodium, and 5 or 6 pts. crystallised ferric chloride, if heated to boiling, filtered hot, and then mixed with glucose, becomes darker coloured, and deposits a precipitate containing ferrous oxide. (Löwenthal, J. pr. Chem. lxxiii. 71.)

24. A concentrated solution of glucose mixed with *nitrate of cobalt* and a small quantity of fused caustic potash, remains clear on boiling, or, if very concentrated, deposits a light-brown precipitate (Reich). The presence of glucose in a solution of cane-sugar prevents the production of the violet-blue precipitate, which solutions of pure cane-sugar give with solutions of cobalt and potash. (Reich, J. pr. Chem. xliii. 72.)

25. An aqueous solution of glucose mixed with *potash-ley*, and then with *cupric sulphate*, dissolves the cupric hydrate which separates at first, with a deep blue colour, and deposits cuprous oxide after some time in the cold, immediately if heated. The production of this precipitate makes it possible to detect and distinguish $\frac{1}{100,000}$ pt. glucose from cane-sugar, starch, or gum; by the reddish coloration of the solution, $\frac{1}{1,000,000}$ pt. glucose can be detected (Trommer, Ann. Ch. Pharm. xxxix. 361). Under the same conditions, 1 at. glucose reduces 5 at. cuprous oxide (formed from 10 at. cupric oxide) from a solution of cupric sulphate mixed with a sufficient quantity of tartaric acid and then with potash: a solution usually called *potassio-tartrate of copper*. A similar reduction takes place when *cupric acetate* is boiled with a solution of glucose; cuprous hydrate is then deposited, acetic acid is given off, and the solution retains a copper salt which has not yet been examined. Nitrate of copper is not reduced by glucose.

26. *Mercurous nitrate* is not altered by aqueous glucose at 100° C. (Baumann.)

27. Glucose throws down metallic silver from aqueous *nitrate of silver*, as a black precipitate, on boiling; from aqueous ammonio-nitrate of silver, as a dirty-grey precipitate (Baumann). Ammoniacal glucose throws down silver as a metallic mirror from aqueous silver-salts, in the cold or when heated (Liebig). The metal is also separated when a mixed solution of nitrate of silver and glucose is allowed to stand for 14 days (Schwertfeger, Jahrb. pr. Pharm. vii. 292). A solution of glucose, mixed with carbonate of sodium, or with potash-ley, reduces chloride of silver to the metallic state on boiling; it reduces carbonate of silver even at 66°—70° (Schiff, Ann. Ch. Pharm. cix. 68). On heating glucose with oxide of silver and potash-ley, oxalic acid is formed. (Liebig, *ibid.* cxiii. 12.)

28. Glucose is not changed by ebullition with aqueous *platinic chloride*. (Baumann.)

29. If solution of glucose mixed with *indigo*, or with solution of indigo, is boiled, and carbonate of sodium dropped in, the liquid is decolorised by the conversion of the indigo-blue into indigo-white. (E. Mulder, N. Br. Arch. xcv. 268.)

30. An aqueous solution of 1 pt. *ferricyanide of potassium (red prussiate)* mixed with $\frac{1}{2}$ pt. hydrate of potassium, and heated to 60° or 80° C., is decolorised when aqueous glucose is dropped in. Inverted sugar behaves in the same way, but cane-sugar and dextrin prepared by roasting (the latter not even after being boiled for a short time with acids) do not decolorise the solution. 100 c.c. of a solution containing in that bulk 10.98 grms. ferricyanide and $5\frac{1}{2}$ grms. hydrate of potassium, is decolorised by the inverted sugar formed from 1 grm. of cane sugar. (Gentile, Dingl. pol. J. clii. 68; Jahresb. d. Chem. 1859, 698.)

31. Dextroglucose is capable of undergoing *vinous fermentation* (p. 729). It is not thereby first converted into another kind of sugar, certainly not into levoglucose; for the liquid has, at every stage of the process, a dextro-rotatory power proportional to the quantity of glucose contained in it, and yields crystals of dextroglucose by evaporation. (Ventzke, J. pr. Chem. xxv. 78; Mitscherlich, Pogg. Ann. lix. 94; Dubrunfaut, Ann. Chim. Phys. [3] xxi. 171.)

32. In the *lactous fermentation* (p. 630) of dextro-glucose, the rotatory power diminishes constantly in the proportion corresponding to the quantity of acid formed (Dubrunfaut). *Erythrozym* acts on glucose in the same way as upon sugar. (Schunck, J. pr. Chem. lxiii. 222. See also p. 267.)

Left to itself in contact with *chalk* and *cheese*, or *gelatin*, or other nitrogenous animal substances, at 40° C. for weeks or months, an aqueous solution of glucose is capable, according to Berthelot, of undergoing a decomposition, different from fermentation properly so called (which takes place under the influence of yeast), whereby the nitrogenous substance as well as the sugar suffers decomposition, and nitrogen, carbonic anhydride, and hydrogen, are evolved, while alcohol, and butyrate and lactate of calcium are formed. Yeast is not produced under these circumstances, unless air has access to the liquid. In other cases, cells resembling yeast make their appearance without any alcohol being produced; so that, under these particular conditions, yeast and alcohol are independent of each other. The chalk may be replaced by many other carbonates—50 grms. glucose, 800 grms. water, 50 grms. chalk; and 20 grms. cheese, left to stand at the mean temperature, produced at first lactate of calcium, but after five months this had disappeared, and the liquid contained butyrate of calcium, and a quantity of alcohol amounting to 2 per cent. of the glucose used. Alcohol was also formed after addition of fatty oil, or of oil of turpentine, but there was no lactate of calcium; addition of sulphide of carbon prevented the destruction of the sugar. A mixture of 1 pt. glucose, 10 pts. water, $\frac{1}{2}$ pt. cheese, and 1 pt. *magnesia alba* contained, after five months, alcohol, lactate, and a small quantity of butyrate of magnesium, the sugar being completely destroyed. In this and in some of the following cases, it remained doubtful whether or not yeast was formed. Similar products were formed when an equal quantity of carbonate of barium was used instead of the *magnesia*. Alcohol was obtained when the carbonate of zinc, manganese, iron, nickel, and lead, or peroxide of manganese, oxide of zinc, cupric oxide, metallic iron, and metallic zinc were used instead of the *magnesia*; with oxide of lead and carbonate of copper no alcohol was obtained. Alkaline carbonates, or borate, phosphate, or hyposulphite of sodium added in equal quantity, did not prevent the production of alcohol. By caustic soda, the sugar was destroyed without yielding alcohol; with sulphite of sodium or calcium, it remained unaltered. When the *magnesia* was replaced by carbonate of ammonium, alcohol was formed together with a peculiar acid, the calcium-salt of which was deliquescent, and contained at 110° C., 36.6 per cent. carbon, 5.2 hydrogen, and 18.9 lime, nearly corresponding to the formula $C^4H^{14}Ca^2O^8$. (Berthelot, Ann. Ch. Phys. [3] l. 351.)

33. When strong sulphuric acid is gradually added to aqueous solution of *ox-bile*, until the precipitate at first produced is re-dissolved, the liquid assumes, on addition of a small quantity of solution of glucose, a violet-red colour, similar to that of a solution of permanganate of potassium. Cane-sugar and starch also act in the same way (Pettenkofer, Ann. Ch. Pharm. lii. 90). According to Pettenkofer, this reaction is applicable to the detection of sugar in urine, and also in blood, after removal of albumin by boiling with alcohol. Many other protein-compounds, likewise oil-fat, oil of almonds, and many other oils, behave like bile (M. S. Schultze, Ann. Ch. Pharm. lxxi. 266). The extractive matter of healthy urine, employed in place of sugar, produces the same coloration, which may sometimes be obtained with ox-bile, sulphuric acid, and a small quantity of water only (Van den Broek, J. pr. Chem. xxxix. 362). According to Schunck (Phil. Mag. [4] xxiii. 179), the extractive matters in healthy urine yield, when decomposed in aqueous solution by means of strong acids, a sugar possessing the composition and some of the properties of glucose, but uncrystallised and insipid.

Combinations of Dextroglucose.

A. With Water.—Melted glucose deliquesces at first in the air by absorption of water (7·5 per cent. according to Guérin-Varry), and solidifies as soon as the quantity of water is sufficient for the formation of crystals, to a crystalline, granular mass. Glucose dried without being melted absorbs no water when exposed to the air (Béchamp, *Compt. rend.* xlii. 900).—The crystals of anhydrous glucose, obtained from alcohol, if dissolved in a small quantity of water and evaporated over oil of vitriol, are found to have taken up a quantity of water amounting to only 3·1 per cent. of their weight. Anhydrous glucose appears, therefore, capable of existing for some time in aqueous solution (O. Schmidt). An aqueous solution evaporated to a thin syrup solidifies after a few days to a granular mass; if evaporated to a thick syrup it does not solidify, owing to absence of sufficient water, until it has absorbed more water from the air.

a. Hemi-hydrated glucose. Anthon's hard-crystallised glucose.—Prepared on the manufacturing scale by a process which is kept secret. In the crystallised state, air-dried, it contains $2C^6H^{12}O^6 \cdot H^2O$, and does not diminish in weight when placed over oil of vitriol at 13° . (Anthon, *Chem. Centr.* 1859, p. 289.)

b. Mono-hydrated glucose. Crystallised glucose. $C^6H^{12}O^6 \cdot H^2O$. This hydrate is generally obtained in white, opaque, granular hemispherical or cauliflower-shaped masses, with occasional shining surfaces. The crystals are seen under a magnifying glass to be six-sided tables, whose lateral faces cut each other at angles of about 120° . Mitscherlich obtained on one occasion transparent well-formed crystals, as much as 0·5 millimetre long, which showed double refraction (Biot, *Compt. rend.* xxiii. 909).—The crystals are brittle and grate between the teeth. Specific gravity 1·3861. (Guérin.)

The mono-hydrate becomes soft at $60^\circ C$. more so still at 65° , losing a small quantity of water; at 70° it becomes doughy; at 90° — 100° , it deliquesces to a thin syrup, and loses in all 9·8 per cent. water (Guérin-Varry). It melts between 70° and 80° ; if dried in vacuo, between 90° and 100° (Béchamp), at 86° (C. Schmidt) loses 9—9·1 per cent. water (3 at. = by calculation 9·09 per cent. water) (Peligot). In a stream of dry air it loses only hygroscopic water at 50° , but between 55° and 60° part of its water of crystallisation, and, if kept at this temperature for a few hours, it may be heated to 80° or 100° without melting. (Béchamp, *Compt. rend.* xlii. 898.)

B. With Metallic oxides. GLUCOSATES.—Dextroglucose unites with the alkalis, alkaline earths, and oxide of lead, forming compounds which may be regarded as glucose in which the hydrogen is more or less replaced by a metal. These compounds are more easily decomposed than the corresponding compounds of cane-sugar. An aqueous solution of glucose takes up a large quantity of baryta, strontia or lime, forming yellow solutions precipitable by alcohol, which, even when protected from the air, become darker and decomposed when kept or heated. Their taste is bitter and slightly alkaline, and when evaporated in vacuo, they leave transparent, brittle masses, sometimes containing unaltered glucose. Dextroglucose also forms definite compounds with bromide and chloride of sodium.

Glucosates of Barium.—*a.* $C^{12}H^{22}Ba^2O^{12}$.—An alcoholic solution of hydrate of barium is added to excess of glucose dissolved in alcohol, and the precipitate is washed with strong alcohol and dried in vacuo over sulphuric acid. It is a nearly white, loose powder, having a caustic taste; easily soluble in water. (W. Mayer, *Ann. Chim. Pharm.* lxxxiii. 138.)

b. $2C^{12}H^{22}Ba^2O^{12} \cdot Ba^2O + 6aq$.—A solution of glucose in wood-spirit is mixed with a solution of baryta (not in excess) in aqueous wood-spirit; the precipitate is washed with wood-spirit and dried in vacuo, first over quicklime, then over oil of vitriol (Peligot). Soubeiran precipitated a mixture of baryta-water and excess of glucose with alcohol. The salt acquires a bright yellow colour at $100^\circ C$. in vacuo without undergoing further alteration; at a higher temperature it froths up and chars. (Peligot.)

Glucosate of Calcium. $C^6H^{12}Ca^2O^6 + aq$.—A freshly prepared solution of hydrate of calcium in aqueous glucose is precipitated by alcohol (Peligot). Soubeiran ngitates glucose with milk of lime, adds a small quantity of glucose to the filtrate to neutralise the excess of lime, and precipitates with alcohol. The salt does not become perfectly dry till it has stood a long time in vacuo. (Soubeiran.)

Glucosates of Lead.—*a.* $C^{12}H^{22}(Pb^2)^2O^{12} + 2aq$.—An ammoniacal solution of neutral acetate of lead is added to excess of glucose-solution till the precipitate becomes permanent. The white precipitate washed out of contact with carbonic acid and dried in vacuo, turns yellow at $150^\circ C$. without further alteration. (Peligot.)

b. $C^6H^{12}(Pb^2)^2O^6$.—25 pts. aqueous ammonia are added to the mixed solution of 20 pts. dextroglucose (or inverted sugar, according to Soubeiran) and 35 pts. neutral acetate of lead in 400 pts. water, and the precipitate is dried, first in vacuo, then at 100° . (Soubeiran.)

Glucosate of Bromide of Sodium, $2C^6H^{12}O^6 \cdot NaBr$.—This compound, prepared by

leaving a solution of 1 at. bromide of sodium and 2 at. glucose to evaporate in a warm place, washing the crystals which separate with cold water, and recrystallising from alcohol, forms anhydrous rhombohedral crystals which are perhaps isomorphous with the following compound; when examined by polarised light they exhibit the characters of uniaxial crystals. (Stenhouse, Chem. Soc. J. xvi. 297.)

Glucosates of Chloride of Sodium.—a. $2\text{C}^6\text{H}^{12}\text{O}^6\text{NaCl} + \text{aq.}$ —This compound, discovered by Calloud (J. Pharm. xi. 562), crystallises out when diabetic urine is evaporated, also from solutions containing 1 at. or less of chloride of sodium to 2 at. glucose; according to Brunner, from solutions of glucose saturated with chloride of sodium. When a layer of ether-alcohol is poured upon diabetic-urine syrup, and the whole allowed to stand quietly, transparent crystals of this compound are obtained (Hünefeld, J. pr. Chim. vii. 46). Glucose from diabetic urine yields this compound far more easily than glucose of different origin (Erdmann and Lehmann). It is purified by crystallisation from water at the common temperature. (Brunner.)

It forms transparent, colourless, lustrous crystals, attaining half an inch in length, and belonging, according to Kobell and Schabus, to the hexagonal system, and consisting of hexagonal prisms and rhombohedrons. According to Pasteur, on the other hand (Ann. Ch. Phys. [3] xxxii. 92), they belong to the dimetric or rhombic system, forming hemihedral rhombic prisms $+ \frac{P}{2} - \frac{P}{2} \cdot \tilde{P} \infty$, resembling double pyramids of the hexa-

gonal system, but having the angles at the base = $120^\circ 12'$ and $119^\circ 54'$. On cutting a crystal into laminae with parallel faces perpendicular to the axis which joins the summits of the two six-sided pyramids, and sending a ray of polarised light through these laminae, they do not exhibit the optical properties which belong to crystals of the hexagonal system (Pasteur). For further details respecting the crystalline form, see *Gmelin's Handbook*, xv. 236.

The aqueous solution, when freshly prepared, exhibits dextro-rotatory power corresponding to the quantity of glucose contained in it, viz. for the transition-tint, $[\alpha] = 47.14^\circ$; but the rotatory power continually diminishes, especially if the solution is hot, just like that of a pure solution of glucose (p. 858).

b. $\text{C}^6\text{H}^{12}\text{O}^6\text{NaCl} + \frac{1}{2} \text{aq.}$ —Calloud obtained from glucose and common salt crystals containing 25 per cent. chloride of sodium, the existence of which was afterwards called in question. The slow evaporation of diabetic urine saturated with common salt furnishes well-formed crystals, but without sufficient lustre to admit of measurement. They contain on an average 23.01 per cent. chloride of sodium, and lose 3.35 per cent. water at 130°C. (Städeler.)

Instead of the crystals b, crystals are sometimes obtained containing between 1 and 2 at. glucose to 1 at. chloride of sodium: probably because the compounds b and c crystallise together. (Städeler.)

c. *With more than 1 at. chloride of sodium.*—By evaporating diabetic urine saturated with common salt, very small crystals are sometimes obtained, which contain $1-1\frac{1}{2}$ per cent. water, and more chloride of sodium than the crystals of b, corresponding nearly to the formula $\text{C}^6\text{H}^{12}\text{O}^6 \cdot 2\text{NaCl}$. (Städeler, Pharm. Centr. 1854, 930.)

Lævoglucose. This sugar, isomeric with dextroglucose, but distinguished from it by turning the plane of polarisation the opposite way, occurs, together with dextroglucose, in honey, in many fruits, and in other sacchariferous vegetable organs; the mixture of these two sugars in equal numbers of atoms constitutes fruit sugar, or inverted sugar, which is itself lævo-rotatory, because the specific rotatory power of lævoglucose is greater than that of dextroglucose. This lævo-rotatory inverted sugar was recognised as a substance distinct from cane-sugar, even in the last century, by Lowitz and others, but no certain mode of discrimination was known, till Biot showed that the different kinds of sugar may be distinguished from one another by their optical rotatory power.

Lævoglucose was first obtained as a distinct substance by Dubrunfaut (Ann. Ch. Phys. [3] xxi. 169). Its isolated occurrence has not been demonstrated with certainty; nevertheless some kinds of apple and pear contain more lævo- than dextroglucose, perhaps because the mixture of these two substances in equal numbers of atoms, first produced by the inversion of cane-sugar, has already suffered an alteration chiefly affecting the dextroglucose. (Buignet, Ann. Chym. Phys. [3] lxi. 264.)

Formation.—1. A solution of cane-sugar left to itself, or warmed with dilute acids, loses its dextro-rotatory power, and acquires a lævo-rotatory power, which, when the transformation, or *inversion*, is complete, amounts to 38° for every 100° of the original rotation to the right. This alteration depends on the assimilation by the cane-sugar of 5 per cent. (1 at.) water, whereby it is resolved into dextro- and lævoglucose:

The same decomposition is brought about by contact with yeast, or with the peculiar ferment of fruits (pectase).

864 GLUCOSE—DETECTION AND ESTIMATION OF.

2. Lævoglucose is also produced by boiling lævulosan ($C^6H^{12}O^6$) with water or with dilute acids. (Géllis, Compt. rend. xlviii. 1662.)

3. Inula, the amylaceous matter obtained from the roots of *Inula Hellenium*, and many other plants of the composite order, which also has the composition $C^6H^{12}O^6$, yields, when boiled with dilute acids, or for a long time with water, a lævo-rotatory sugar, which, according to Dubrunfaut, is identical with the lævoglucose obtained by method 1.

Preparation of Lævoglucose from inverted sugar.—When 10 grms. of inverted sugar, prepared from cane-sugar by the action of acids as above mentioned, are intimately mixed with 6 grms. hydrate of lime and 100 grms. water, the mass, which is liquid at first, solidifies after a certain amount of agitation, and yields, by strong pressure, a solution of the calcium-compound of dextro-glucose; while the solid residue, washed and decomposed with oxalic acid, yields lævoglucose (Dubrunfaut). The inverted sugar occurring in fruits may be decomposed in the same manner.

Properties.—Lævoglucose is a colourless uncrystallisable syrup (Dubrunfaut), an amorphous solid mass (Bouchardet). After being heated to $100^\circ C.$, it exhibits the composition $C^6H^{12}O^6$. It is as sweet as cane-sugar, and acts as a purgative. It is more soluble in alcohol than dextroglucose. Its rotatory power varies with the temperature. For the transition-tint, $[\alpha] = -106^\circ$ at $14^\circ C.$; $= -79.5^\circ$ at $52^\circ C.$; $= -53^\circ$ at $90^\circ C.$ (Dubrunfaut.)

Decompositions.—Lævoglucose, when heated, yields a product analogous to the glucosan (p. 864) of dextroglucose, but more easily decomposable (Géllis, Compt. rend. li. 331); probably, therefore, lævulosan. Lævoglucose in contact with yeast undergoes vinous fermentation without previous conversion into another kind of sugar (Dubrunfaut). The other reactions of lævoglucose have been studied only with fruit-sugar containing dextroglucose; they agree with those of dextroglucose.

When sodium-amalgam is added to an aqueous solution of cane-sugar inverted by the action of dilute sulphuric acid, the excess of acid having been removed, evolution of hydrogen ceases altogether as soon as the liquid has become slightly alkaline; heat is evolved; and, when the action is complete, the solution is found to contain mannite. (Linnemann, Ann. Ch. Pharm. cxliii. 136.)

Combination.—With Lime.—Lævoglucose forms with lime a soluble basic compound analogous to that of dextroglucose (p. 862), which absorbs oxygen from the air and decomposes. A second compound containing 3 at. lime to 1 at. lævoglucose forms sparingly soluble microscopic needles, and is decomposed by water when exposed to light and air, the compound deliquescing and the sugar undergoing decomposition. (Dubrunfaut.)

Lævulosan. $C^6H^{12}O^6$. (Géllis, Compt. rend. xliii. 1062; Ann. Ch. Phys. [3] lvii. 234; Jahresb. 1859, p. 547).—Cane-sugar quickly heated to $160^\circ C.$, and kept in the melted state at that temperature for a moderate time, is converted into a mixture of equal numbers of atoms of lævulosan and dextro-glucose, the latter of which may be removed by fermentation:

The remaining liquid, which has a lævo-rotatory power $= 15^\circ$ for the transition-tint, leaves, when evaporated, a syrup, which does not crystallise even when kept for years, but contains lævulosan, partly unaltered, partly metamorphosed.

Lævulosan is converted by boiling water and by dilute acids into a fermentable lævo-rotatory sugar, which reduces copper-solution, and is probably identical with lævoglucose.

GLUCOSE, DETECTION AND ESTIMATION OF. The reactions best adapted for the detection of glucose (dextro- or lævo-) in solution, either alone or in presence of cane-sugar, are:—1. The dark brown coloration with *potash-ley* (18, p. 860), cane-sugar not exhibiting any sensible coloration when thus treated.—2. The black-brown coloration and greyish brown precipitate forming by *basic nitrate of bismuth* in the solution mixed with carbonate of sodium (21, p. 860).—3. The reduction of *cuprio salts*. It is necessary to observe, however, that cane-sugar reduces cuprous oxide from an alkaline solution of cupric sulphate after prolonged boiling, being in fact partly converted thereby into glucose; but with glucose the reduction is immediate (25, p. 860).—4. The decoloration of an alkaline solution of *ferricyanide of potassium* (30, p. 861), an effect not produced by cane-sugar.—5. The non-production of a violet-blue precipitate with *nitrate of cobalt* and caustic alkali, indicates the presence of glucose in a solution previously known to contain cane-sugar (24, p. 860).—6. In the solid state or in that of strong syrup, glucose and cane-sugar may be distinguished

by their different behaviour with strong *sulphuric acid* (10, p. 959), glucose simply dissolving, without coloration, whereas cane-sugar is blackened and completely decomposed. This reaction will not, however, serve to indicate the presence of glucose when mixed with cane-sugar.

For the detection of sugar in urine, see URINE.

Quantitative Estimation.—1. By reduction of *cupric salts*. A known measure of potassio-tartrate of copper mixed with potash-ley is heated to boiling in a capsule, and the liquid containing sugar is dropped in until the copper-solution has become colourless by the separation of red cuprous oxide. The quantity of glucose required to reduce the quantity of copper-solution employed must be ascertained by a preliminary experiment. Barreswil (J. Pharm. vi. 361) prepares the copper-solution by dissolving 400 grms. carbonate of sodium, 500 grms. cream of tartar, 300 grms. sulphate of copper, and 400 grms. hydrate of potassium, in half a litre of water. Fehling (Ann. Ch. Pharm. lxxii. 106; cvi. 75) adds to a solution of 160 grms. neutral tartrate of potassium (or better, 192 grms. tartrate of potassium and sodium) in a small quantity of water, 600 or 700 c.c. soda-ley of sp. gr. 1.12, then a solution of 40 grms. crystallised sulphate of copper in about 160 c.c. water, and dilutes the mixture until it measures 1154.4 c.c. at 16° C. Five milligrammes of dry glucose can reduce 1 c.c. of this solution. The solution must be kept in well closed vessels, to protect it from carbonic acid and air; it ought not to give any precipitate of cuprous oxide when boiled by itself. The sugar-solution to be tested is best employed free from acid.

2. When a solution contains no optically active substance besides glucose, or only cane-sugar in addition, the quantity of dextroglucose may be deduced from its rotatory power. (See SACCHARIMETRY.)

3. Glucose, as well as cane-sugar, may also be estimated by the quantities of carbonic anhydride and alcohol produced from it by fermentation with yeast. According to Pasteur, 100 pts. cane-sugar, or 105 pts. glucose, yield by fermentation 49.12 pts. carbonic anhydride and 51.01 pts. absolute alcohol. (See SUGAR and SACCHARIMETRY.)

GLUCOSE FERMENT. The conversion of cane-sugar into glucose (inversion of sugar) which takes place in vinous fermentation, is regarded by Pasteur as a secondary effect, depending on the action of the succinic acid, which is always produced in small quantity in that process. According to Berthelot, on the other hand (Compt. rend. li. 980; Jahresb. 1860, p. 518), the change is due to the action of a peculiar ferment, contained in or produced from yeast. That it does not depend on the action of a free acid, is shown by the fact that when yeast is added to a solution of cane-sugar made alkaline by addition of acid carbonate of sodium, a considerable quantity of inverted sugar is produced, although the fermentation is retarded by the presence of the alkali. When the liquid obtained by diffusing yeast in a twofold quantity of water, leaving it to stand for several hours in the cold, and filtering, is added to a solution of cane-sugar mixed with a small quantity of acid carbonate of sodium, the inversion of the sugar takes place, though the liquid does not become acid, and no vinous fermentation is set up. On mixing this same liquid with an equal volume of alcohol, white flocks are precipitated, which, when washed with alcohol and dried at ordinary temperatures, form a yellow horny mass, consisting, according to Berthelot, of a nitrogenous substance analogous to diastase and pancreatin, which may be redissolved in water, and afterwards coagulated by heat or by nitric acid. One part of this substance is sufficient to convert from 50 to 100 pts. of cane-sugar into glucose. It appears to be formed from the yeast itself; for if yeast which has been washed for any length of time with water—provided it has not become putrid—be left for some time in contact with water, it still gives up to the water this so-called glucose-ferment. (Berthelot.)

GLUCOSIDES. *Glucosamides, Saccharogens.*—These terms were applied by Laurent (Ann. Ch. Phys. [3] xxxvi. 330) to substances which, when decomposed by dilute acids, yield, on the one hand, dextroglucose or another saccharine substance isomeric therewith, and, on the other, a product differing in character according to circumstances, but not belonging to the class of carbohydrates $C_nH_{2n}O_n$. These bodies are natural products occurring frequently in the bodies of plants, less frequently in those of animals; none of them have been prepared artificially.

Berthelot's class of *Saccharides* includes, besides these, certain artificially prepared compounds of the carbohydrates with acids. (See SACCHARIDES.)

The resolution of glucosides into glucose, or a corresponding product, and a second body, takes place for the most part on boiling with dilute *mineral acids*; or it is produced by heating the glucoside with aqueous *alkalis* or *baryta-water*. In this latter case, according to Rochleder (Wien. Akad. Ber. xxiv. 32), crystallisable sugar is sometimes obtained, whereas the decomposition with acids yields only uncrystallisable

sugar. Or the separation is effected at mean temperature, and in presence of water, by nitrogenous substances occurring either in the same plants as the glucosides, or in others. Emulsin decomposes amygdalin and many other glucosides; myrosin decomposes myronic acid; erythrozym decomposes rubian. Some glucosides are likewise decomposed by yeast and by saliva. The products of the decomposition are often further altered by the action of the air or of the acid employed.

For the separation of the decomposition-products of the glucosides, Rochleder gives the following method. The substance, contained in a flask, is treated with dilute hydrochloric acid, the flask being connected, on the one side with a carbonic acid apparatus, on the other with a Liebig's condensing tube. The air contained in the flask is displaced by carbonic anhydride, and the flask is heated in the water-bath, or, if necessary, in a chloride-of-calcium bath. As soon as the decomposition is complete, the contents of the flask are left to cool in a stream of carbonic anhydride; any product that may have separated out is collected; and the filtrate containing the sugar, hydrochloric acid, and sometimes other soluble products of the decomposition, is mixed with pure carbonate of lead, the addition of which is continued as long as effervescence ensues, after which it is washed, and white lead (prepared by precipitating basic acetate of lead with carbonic acid, and washing) is added, whereby basic chloride of lead is precipitated. The precipitate is collected on a filter and carefully washed; and moist phosphate of silver is added to the filtrate as long as any reaction ensues between this salt and the dissolved chloride of lead, and till the yellow colour of the phosphate of silver remains visible. The liquid is then filtered; any silver that may be dissolved in the filtrate is precipitated with a very small quantity of white lead; the liquid is heated till the white colour of the precipitate passes into cream-colour, then cooled, filtered, treated with sulphydric acid, and filtered again; and the filtrate is evaporated. Colourless sugar then remains, in case such sugar was formed by the decomposition of the glucosides, whilst the second decomposition-product, even if originally soluble in water, is generally rendered insoluble by the white lead.

The distilled liquid obtained by heating a glucoside with hydrochloric acid, contains, together with hydrochloric acid, any volatile product that may have been formed in the decomposition. It is neutralised with baryta or carbonate of barium, heated to decompose acid carbonate of barium, and concentrated by evaporation; the greater part of the chloride of barium is removed by crystallisation, the rest by sulphate of silver; and the filtrate is further examined.

The following enumeration of glucosides and their modes of decomposition is taken from *Gmelin's Handbook*, xv. p. 341.

Asculin is resolved by heating with dilute acids, into asculetin and sugar:

Zwenger and Delffs give other formulæ.

The sugar forms crystals, which melt at 100° C., are sweeter than grape sugar, and, like that substance, reduce potassio-cupric tartrate. It is fermentable.

Amygdalin, in contact with emulsin and water, is resolved into sugar, bitter almond-oil, and hydrocyanic acid:

(Liebig and Wöhler, 1837). The sugar thus produced is identical in every respect with dextroglucose. (O. Schmidt.)

Apiin, boiled with dilute acids, is decomposed, with separation of flocks. The filtrate freed from acid leaves, on evaporation, a sweetish syrup, which, when boiled with potassio-cupric tartrate, separates cuprous oxide, but does not give off the odour of caramel when burnt, does not ferment in contact with yeast, cannot be made to crystallise, and dissolves but partially in alcohol, with separation of yellow flocks. Von Planta and Wallace cannot see in these results any evidence of decomposition, and therefore do not regard apiin as a glucoside.

Arbutin boiled with dilute acids, or in contact with emulsin, is resolved into hydroquinone (Kawalier's arctivin) and grape-sugar (Kawalier):

The sugar forms crystals which exhibit the properties of grape-sugar, and when dried at 100° C., or in vacuo, contain 36.64 per cent. carbon, 7.05 hydrogen, and 56.31 oxygen, corresponding to the formula $C^6H^{12}O^6.H^2O$. (Kawalier, *Wien. Akad. Ber.* ix. 293.)

Arnicin ($C^{18}H^{16}O^7$ or $C^{24}H^{20}O^8$) is decomposed by heating with dilute acids, with separation of dark flocks and formation of a substance which reduces cupric oxide. (Walz)

Benzohelicin is resolved, by boiling with dilute acids or aqueous alkalis (not by emulsin), into benzoic acid, salicylic acid, and grape-sugar:

Bryonin is resolved by boiling with dilute acids, into bryoretin, hydrobryotin, and sugar:

Cañcin ($C^{16}H^{26}O^7$) is resolved in like manner, into thiococcic acid and sugar. (Rochleder and Hlasiwetz.)

Chitin, boiled for twelve hours or longer with a mixture of 1 vol. oil of vitriol and 4 vol. water, is resolved, with evolution of ammonia, into amorphous sugar and a second body not yet isolated. Perhaps in this manner:

The sugar is fermentable, and reduces cupric tartrate. (Berthelot, Compt. rend. xlvii. 230.)

Colocynthin is resolved by boiling with dilute acids into colocynthin and sugar:

Convallarin is decomposed in like manner into convallaretin and sugar:

Convallamarin yields under the same circumstances convallamaretin and sugar:

Convolvulin is resolved by sulphuric or alcoholic hydrochloric acid, with assumption of 11 at. water, into convolvulinolic acid and sugar:

Convolvulin-sugar. — When Kayser (Ann. Ch. Pharm. li. 98) decomposed convolvulin by passing hydrochloric acid gas into the alcoholic solution, and after leaving the mixture to itself for ten days, extracted the resulting convolvulinol with ether, there remained an acid liquid, which was neutralised with carbonate of lead, filtered and evaporated. From the residue, absolute alcohol extracted a sticky, translucent, sweetish mass, which reduced cupric oxide, yielded crystals when brought into contact with common salt, fermented with yeast, and exhaled the odour of sugar when burnt on platinum-foil. Mayer, after decomposing convolvulinic acid with dilute sulphuric acid, and removing the convolvulinol, saturated the liquid with carbonate of lead; treated the filtrate with sulphuretted hydrogen; evaporated it to $\frac{1}{10}$; removed the separated convolvulin by agitation with ether; evaporated further; and thus obtained a brown sweetish syrup, which behaved like grape-sugar when burnt, also with an alkaline cupric solution, with bile, with sulphuric acid, with water, and with alcohol whether aqueous or absolute, but did not form a crystalline compound with common salt, and could not itself be made to crystallise. This syrup mixed in alcoholic solution with an alcoholic solution of baryta not in excess, formed a precipitate composed like monoglucosate of barium (p. 862). (Mayer, Ann. Ch. Pharm. lxxxiii. 138.)

Crocin is resolved by dilute acids into crocetin and crocin-sugar:

Crocin-sugar, obtained by decomposing crocin in the manner described above, is easily crystallisable, sweet, and reduces from potassio-cupric tartrate half as much cuprous oxide as dextro-glucose. (Rochleder and L. Mayer, Wien, Akad. Ber. xxix. 6.)

Cyclamin solidifies when heated with aqueous hydrochloric acid, with formation of sugar and separation of a second product. (De Luca.)

Daphnin is resolved by boiling with dilute acids, into daphnetin and sugar:

Datiscin, treated in the same manner, yields datiscetin and sugar:

The sugar is obtained by evaporation, after removal of the datiscetin and the sulphuric acid, as a sweet syrup, which solidifies in the semi-crystalline form after standing for some time, and reduces potassio-cupric tartrate at 100° C. (Stenhouse, Ann. Ch. Pharm. xcviii. 171.)

Walz's *Digitalin* is resolved by boiling with dilute sulphuric acid, into digitaliretin, paradigitalatin and sugar. Walz supposes the reaction to consist of two stages:

a. Resolution of digitalin into digitalatin and sugar:

b. Further decomposition of the digitalatin, partly, with abstraction of 2 at. H^2O , into paradigitalatin, partly into digitaliretin and sugar:

Walz's digitalatin decomposed by dilute acids yields the products above mentioned (Walz, Delffs). Kosmann's *digitalin* and *digitalic acid*, which differ from Walz's compound in composition and properties, are resolved by dilute acids into digitaliretin (which however is not the same as Walz's) and sugar. Decomposition of digitalin:

Euxanthic acid ($C^{21}H^{18}O^{11}$) is, according to W. Schmidt (Ann. Ch. Pharm. xciii, 88), a glucoside, which is decomposed by sulphuric acid into euxanthone and sugar. According to Erdmann, the products formed in this reaction are euxanthone and hamathionic acid (lead salt = $C^{14}H^{17}O^{12}.SO^2.3PbO$); on the other hand, euxanthic acid decomposed by heat yields euxanthone, $C^{20}H^{12}O^8$, carbonic anhydride, and water. The latter decomposition, as well as the formulæ of euxanthic acid and euxanthone, is inconsistent with Schmidt's supposition; nevertheless, Erdmann's hamathionic acid bears some resemblance to sulphamidonic acid and other compounds of like nature. (Kraut.)

Fraxin, heated with acids, yields fraxetin and crystallisable sugar:

Gallotannic acid is resolved by boiling with acids into gallic acid and glucose:

The sugar exhibits the reactions and composition of dextroglucose. (Strecker, Ann. Ch. Pharm. xc. 331.)

By heating 50 grms. gallotannic acid with 50 grms. oil of vitriol and 450 grms. water to $90^\circ C$. for three days, and filtering off the gallic acid, a black saccharine solution is obtained which when neutralised with carbonate of lead, mixed with a slight excess of neutral acetate of lead, concentrated, freed from lead by sulphuretted hydrogen, and decolorised by animal charcoal, agrees perfectly with grape-sugar in rotatory power, fermentation, and reaction with potassio-cupric tartrate. (Buignet, Ann. Ch. Phys. [3] lxi. 287.)

The iodine-compound of a tannin occurring in sweet fruits is likewise decomposed, with formation of dextroglucose, by boiling with dilute sulphuric acid. (Buignet.)

Gelatin.—When isinglass is boiled for some days with dilute sulphuric acid, sulphate of ammonia is formed together with a fermentable sugar (Gerhardt, *Traité* iv. 509). Hyalin-cartilage and rib-cartilage, boiled with hydrochloric acid, yield large quantities of glucose. (Fischer and Bodeker, Ann. Ch. Pharm. cxvii. 111.)

Globularin, boiled with dilute sulphuric acid, yields globularetin (part of which changes into paraglobularetin) and sugar:

Glycyrrhizin is resolved, when its aqueous solution is boiled with hydrochloric acid, into glycyrretin and glucose. Perhaps in this manner:

Gratiolin is resolved by boiling with dilute sulphuric acid into gratioletin, gratiolaretin, and sugar:

Gratioletin. Gratiolaretin.

Gratiosolin in contact with aqueous acids or alkalis is resolved into gratiosoletin and sugar:

The *gratiosoletin* thus formed is further resolved by boiling into hydrogratiosoleretin and sugar:

Part of the hydrogratiosoleretin is further converted, with elimination of 2 at. water, into gratiosoleretin, $C^{16}H^{26}O^8$. (Walz.)

Helianthic acid.—This name is applied by Ludwig and Kromayer (N. Ba. Arch.

xcix. 1, 286) to a substance obtained from the seed of the sunflower (*Helianthus annuus*), which is insoluble in cold water and in alcohol, not fermentable, and reduces potassio-cupric tartrate only after boiling with acids.

Helicin heated with acids or alkalis, or in contact with emulsin or yeast, is resolved into salicylous acid and dextroglucose:

Chlorhelicin ($C^{18}H^{13}ClO^7$) exhibits a similar reaction, yielding, however, chlorosalicylous instead of salicylous acid. (Piria.)

Helicoidin is resolved by emulsin into saligenin, salicylous acid, and glucose:

Indican is resolved by acids or alkalis, *indicanin* by acids, into indiglucon and other products (Schunck). See INDICAN.

Jalappin in contact with dilute mineral acids is resolved into jalappinol and sugar:

Jalappic acid, which contains 3 at. water more, is decomposed in like manner, with assumption of 8 at. water. (W. Mayer.)

The *Lycopodium-bitter* of Kamp and Budeker reduces potassio-cupric tartrate after boiling with dilute acids, but not in its unaltered state, and should therefore perhaps be regarded as a glucoside.

Menyanthin, boiled with dilute sulphuric acid, is resolved into sugar and an oil which smells like bitter almonds. (Ludwig, N. Br. Arch. cviii. 84.)

Myronate of potassium is decomposed in contact with myrosyn and water, yielding oil of mustard, sugar, and other products (Ludwig and Lange, Zeitschr. Ch. Pharm. iii. 577). The formula $C^{20}NH^{10}S^4O^{18}.KO$ ($= C^8NH^4S^2 + KO.S^2O^4 + C^{12}H^{14}O^{14}$) given by Ludwig and Lange, is, according to Will and Körner (Ann. Pharm. cxix. 376), more correctly $C^{20}NH^{10}KS^4O^{18}$, and contains the elements of oil of mustard, $C^8NH^4S^2$, glucose, $C^{12}H^{12}O^{12}$, and acid sulphate of potassium, S^2KHO^6 . Ludwig and Lange also found sulphate of potassium among the products of the reaction, but no sulphate.

Ononin is resolved by boiling with dilute acids, into formonetin and glucose (Hlasiwetz):

Onospin is resolved under similar circumstances into ononetin and sugar (Hlasiwetz):

Such is the view of the reaction given by Limpricht (Grundr. d. org. Chem. Braunsch. 1864, 680.) For Hlasiwetz's formulae, see FORMONETIN (p. 695) and ONONIN.

The sugar formed from ononin and onospin by the action of dilute sulphuric acid, remains in solution after the second product of the decomposition has been removed by filtration, the sulphuric acid by carbonate of lead, and the excess of lead by sulphuretted hydrogen, and is obtained by evaporation as a very sweet fermentable syrup, in which granular crystals form after a few days. These crystals melt at the heat of the water-bath to a viscid syrup which remains soft after a day's drying, and exhibits all the reactions of grape-sugar. (Hlasiwetz, Wien. Akad. Ber. xv. 153.)

Paristyphein boiled with dilute sulphuric acid is resolved into paridin and sugar:

The *paridin* thus produced is resolved by boiling with a larger quantity of dilute sulphuric acid into paridol and sugar:

Phillyrin is resolved, by boiling with dilute hydrochloric acid, into phillygenin and sugar; by lactic fermentation into phillygenin and the products of the decomposition of sugar:

From the solution freed from phillygenin and hydrochloric acid by carbonate of lead, the sugar crystallises, after evaporation and re-solution in alcohol, in warty masses, exhibiting the properties of grape-sugar. (Bertagnini, Ann. Ch. Pharm. xcii. 110.)

Phlorizin is decomposed by dilute acids, not by emulsin, yielding phloretin and sugar (Staeg):

Schunk's *Rubianic acid* splits up into alizarin and sugar when boiled with dilute sulphuric acid, or with aqueous alkalis, or by contact with water and erythrozym. $C^{22}H^{10}O^{21} + 5H^2O = 2C^{14}H^8O^4 + 2C^{12}H^{12}O^{12}$.—Rochleder's *Ruberythric acid*, $C^{18}H^{10}O^{10}$ or $C^{16}H^{11}O^{11}$, perhaps identical with the last substance, yields the same products when heated with hydrochloric acid, $C^{18}H^{10}O^{10} = 3C^{10}H^{10}O^8 + C^{12}H^{12}O^{12} + 10H^2O$, or $C^{16}H^{11}O^{11} = 2C^{10}H^{10}O^8 + 1\frac{1}{2}C^{12}H^{12}O^{12} + 3H^2O$. (Rochleder.)

In the complicated decomposition of Schunk's *Rubian* by the same reagents and by chlorine, sugar is obtained together with various other bodies. *Rubidehydran* and *Rubidehydran* behave in the same way. (Schunck.)

Salicin is decomposed into saligenin and glucose by contact with emulsin:

The sugar is in every respect identical with dextroglucose (Schmidt). By boiling with dilute acids, saliretin is obtained in place of saligenin. (Piria.)

Saponin is decomposed into sapogenin and saponin-sugar, or glucose when boiled with dilute acids (Overbeck, Rochleder and Schwarz). *Saugin* (isomeric with saponin, according to Bolley) yields, besides sapogenin, a substance which reduces potassio-cupric tartrate. (Bolley.)

Saponin-sugar remains in solution after the sapogenin has been filtered off, the acid removed by carbonate or oxide of lead, and the excess of lead by sulphydric acid and by treatment with animal charcoal and evaporation is obtained as a tasteless, yellowish brown residue, easily soluble in water (Rochleder and Schwarz, Wien. Akad. Ber. xi. 339). When saponin is decomposed with dilute sulphuric acid, glucose remains in solution, after removal of the excess of acid, and may be obtained crystallised by evaporation. It has a sweet taste, and reduces an alkaline solution of cupric oxide in the cold (Overbeck, N. Br. Arch. lxxvii. 135). Crawford obtained gum, but no sugar from saponin, by means of dilute sulphuric acid (Pharm. Viertelj. vi. 361). Saponin-sugar dried at $100^\circ C$. contains, according to Rochleder and Schwarz, 41.99 per cent. C, 6.55 H, and 51.46 O, corresponding to the formula $C^{12}H^{20}O^{11}$.

Scammony resin ($C^{34}H^{50}O^{16}$) and *Scammonic acid* ($C^{14}H^{26}O^{16} \cdot \frac{3}{2}H^2O$) split up into scammonolic acid and sugar when boiled with dilute acids (or with baryta-water):

Like jalappin (p. 869), therefore, but with this difference, that instead of the product corresponding to jalappinol (which is converted by strong bases into jalappic acid) a product containing 1 at. water less is formed. (Spirgatis.)

The sugar remains in solution after separation of the scammonolic and sulphuric acids, and can be obtained in sweet-tasting laminae grouped in cauliflower-like shapes, which behave like glucose with sulphate of copper and potash-ley, when heated and when fermented. (Spirgatis, Ann. Ch. Pharm. cxvi. 305.)

Smilacin is slowly decomposed when boiled with hydrochloric acid, with separation of a jelly and formation of sugar. (O. Gmelin, Delffs, Walz.)

Solanin boiled with dilute acids splits up into solanidin and glucose:

The sugar crystallises well, and possesses the reactions and compositions of dextroglucose (Zwenger and Kind, Ann. Ch. Pharm. cxviii. 149). Rotatory power not determined.

Thujin is decomposed by heating its alcoholic solution with dilute acids, into thujetin and sugar:

When it is heated for a shorter time, thujinenin, $C^{11}H^{12}O^7$, may also be formed in place of the thujetin. Thujin heated with baryta-water yields thujetic acid and sugar:

When thujin has been decomposed by acids, the sugar remains in solution after removal of the thujetin and sulphuric acid (by carbonate of barium), and, by evaporation and drying at $100^\circ C$, is obtained as a colourless mass, which is easily reduced to a white powder when cold, and contains 39.83 per cent. C, and 6.81 H, corresponding to the formula $C^9H^{12}O^6$; its aqueous solution does not crystallise even after standing for several months; it reduces the same quantity of cupric oxide as dextroglucose. The sweet sugar of the same composition produced by the action of baryta-water solidifies (after the removal of the baryta by dilute sulphuric acid, of the excess of sulphuric acid by basic acetate of lead, and of the lead by sulphydric acid) to a crystalline mass when its solution is allowed to stand a short time after evaporation on the water-bath. (Rochleder and Kavalier, Wien. Akad. Ber. xxix. 12.)

872 GLUCOSOCITRIC—GLUCOSOTARTARIC ACID.

Xanthorhamnin is decomposed by boiling with dilute acids into rhamnetin and sugar:

GLUCOSOCITRIC ACID. $C^{42}H^{40}O^{44} = \frac{(C^6H^{12}O^6)^{17}}{2(C^6H^{12}O^6)^{17}} \cdot O^5 \cdot 4C^6H^{12}O^6 \cdot 5H^2O = C^6H^{12}O^6 + 6C^6H^{12}O^6 - 2H^2O$. (?)—The calcium-salt of this acid, prepared in a similar manner to that of glucosotartaric acid (see below) appears to contain $C^{22}H^{20}Ca^{10}O^{18} \cdot 2H^2O$. (Berthelot, Ann. Ch. Phys. [3] liv. 81.)

GLUCOSOSUCCINIC ACID. A mixture of cane-sugar and succinic acid in equivalent proportions heated to between 120° and 130° C. melts to a brown syrup, with elimination of water. The product is an acid compound of glucose with succinic acid, which decomposes at 100° C. with formation of humus, and forms with lime a salt soluble in water, insoluble in alcohol. (Van Bemmelen, Jahresb. f. Chem. 1858, p. 436.)

GLUCOSOSULPHURIC ACID. *Sulphosaccharic acid.* $C^{24}H^{40}O^{28} \cdot SO^3$. (?) (Peligot, Ann. Ch. Phys. [2] lxvii. 168.)—To prepare this acid $1\frac{1}{2}$ pt. strong sulphuric acid is added, by small portions, to 1 pt. of glucose melted at the heat of the water-bath, the mixture being continually stirred, and the vessel, if necessary, plunged into cold water. If the glucose is impure, or the heat rises too high, the product becomes somewhat brown, which, however, does not affect the purity of the lead-salt. The mixture, diffused in a large quantity of water, is saturated with carbonate of calcium; acetate of barium is added to the filtrate as long as a precipitate of sulphate of barium is thereby produced; and the liquid, again filtered, is precipitated with basic acetate of lead. If the liquid, after precipitation with acetate of barium, still remains brown, the colouring matter is removed by a small quantity of basic acetate of lead, and the pure salt is precipitated from the filtrate by a larger quantity. The precipitate, washed, and decomposed under water with sulphydric acid, yields *aqueous glucososulphuric acid*, which tastes at the same time sour and sweet, reddens litmus, decomposes when evaporated in vacuo, and more quickly over the water-bath, into glucose and sulphuric acid, and forms *salts*, almost all of which are soluble. The *lead-salt* gives by analysis 18.16 per cent. carbon, 2.4 hydrogen, 4.50 SO^3 , and 53.2 to 55.3 PbO, agreeing approximately with the formula $C^{24}H^{40}O^{28} \cdot SO^3 \cdot 4PbO$. (Peligot.)

Glucotetratartaric acid (Berthelot, Ann. Ch. Phys. [3] liv. 78).—This acid is produced by heating dextroglucose with tartaric acid:

It appears to exist in grapes at the time of ripening. When expressed grape-juice is saturated with chalk, filtered, strongly concentrated, filtered again, precipitated with 2 vol. alcohol, and the precipitate purified by washing with weak alcohol, re-resolution in water, and re-precipitation with alcohol, a calcium-salt is obtained which reduces potassio-cupric tartrate like glucosotartrate of calcium, and is resolved by acids into dextroglucose and an acid which exhibits the characters of tartaric acid.

Preparation of the calcium-salt.—An intimate mixture of equal parts of dextroglucose and tartaric acid is heated for a day or two to 120° C. in an open vessel; the cooled mass is triturated with carbonate of calcium and a small quantity of water, and the liquid is filtered. Tartrate of calcium, with the excess of carbonate, then remains on the filter, while the solution contains the salt of the new acid, together with excess of glucose. On precipitating this solution with twice its volume of alcohol, collecting the precipitate, washing it with dilute alcohol, dissolving in water, again precipitating with alcohol, and repeating the same series of operations a third time, the calcium-salt is obtained free from sugar. It is dried for a week or fortnight in vacuo, then completely by heating it to 110° C.

Aqueous glucosotartaric acid is obtained by decomposing the calcium-salt with excess of oxalic acid.

The aqueous solution of the acid and of its salts is gradually resolved by boiling into dextroglucose and tartaric acid, the decomposition being accelerated by a small quantity of sulphuric acid. The calcium and magnesium-salts reduce potassio-cupric tartrate. The acid is not fermentable.

Glucosotartaric acid is tetrabasic. The salts still retain water at 110° C. The *calcium-salt*, $C^{22}H^{22}(Ca^2)^2O^{28} + 2aq.$, is a white amorphous powder, which gives off 14.1 per cent. water at 110°. The *magnesium-salt*, $C^{22}H^{22}(Mg^2)^2O^{28} \cdot 2Mg^2O + 5aq.$, gives off, after drying in vacuo, 26.4 per cent. water at 110°. There are two *lead-salts*,

$C^{22}H^{22}(Pb^{20})^{22}$, which is insoluble, or becomes so during preparation, and $C^{22}H^{22}Pb^{20}O^{22}$, which is soluble, and after drying in vacuo, gives off 10.9 per cent. water at 110° .

GLUE. An inspissated jelly made from the parings of hides and other offal, by boiling them in water, straining through a wicker basket, suffering the impurities to subside, and then boiling it a second time. The articles should first be digested in lime-water, to cleanse them from grease and dirt; then steeped in water, stirring them well from time to time; and lastly, laid in a heap to press out the water, before they are put into the boiler. Some manufacturers recommend that the water should be kept as near as possible to a boiling heat, without suffering it to enter into ebullition. The glue is poured into flat frames or moulds, cut into square pieces when congealed, and afterwards dried in a coarse net. It is said to improve by age; and that glue is reckoned the best which swells considerably without dissolving, by three or four days' infusion in cold water, and recovers its former dimensions and properties by drying.

Shreds or parings of vellum, parchment, or white leather, make a clear and almost colourless glue. (For the details of the manufacture, see *Ure's Dictionary of Arts*, &c., ii. 376.)

GLUTEN. Wheat-flour made into a paste, and washed with a large quantity of water, separates into three distinct substances:—vegetable albumin, which is dissolved by the water, together with a little sugar and dextrin, and may be separated from it by evaporation; starch, which is suspended in the fluid, and subsides to the bottom by repose; and gluten, which remains in the hand, and is tenacious, very ductile, somewhat elastic, and of a light brown-grey colour.

The gluten, though it existed before the washing in the pulverulent form, and has acquired its tenacity and adhesive qualities from the water it has imbibed, is nevertheless totally insoluble in this liquid. It has scarcely any taste. When dry, it is semitransparent, and resembles glue in its colour and appearance. If it be drawn out thin, when first obtained, it may be dried by exposure to the air; but if exposed to warmth and moisture while wet, it putrefies like an animal substance. Dried gluten applied to the flame of a candle, crackles, swells, and burns, exactly like a feather or piece of horn. Gluten affords the same products by destructive distillation as animal matters. It is easily dissolved by caustic potash, and precipitated from the solution by acids in tumid flocks. Strong acetic acid likewise dissolves it, and leaves it on evaporation in the form of a tenacious mass. When digested in water containing $\frac{1}{1000}$ or $\frac{2}{1000}$ of hydrochloric acid, it diffuses itself through the liquid, gradually dissolves, and on filtering, yields a clear liquid which turns the plane of polarisation of a luminous ray to the left, and behaves with heat and with reagents exactly like a solution of albumin. (Bouchardat, *Compt. rend.* xiv. 962.)

In contact with water, gluten undergoes gradual decomposition, swelling up, and giving off considerable quantities of carbonic anhydride, hydrogen, and sulphydric acid. At the same time, it softens and liquefies, while the water which covers it acquires an acid reaction, and takes up leucine, together with phosphate and acetate of ammonia, the gluten all the while acquiring a darker and darker colour, and ultimately dissolving almost entirely. During these several stages of its transformation, gluten possesses the power of acting as a ferment. Thus, if a small quantity of gluten or wheat-flour be added to starch-paste diffused in water, and the mixture be exposed for several hours to a temperature of 60° or 70° C., it liquefies, becomes transparent and mobile, and ultimately acquires a sweet taste, the starch being converted first into dextrin, and then into glucose.

Gluten exhibits the same percentage composition as the albuminoids; it is not, however, a simple proximate principle, but, as first shown by Taddei (*Giornale fisica di Brugnatelli*, xii. 360), may be separated into two distinct substances, one soluble and the other insoluble in alcohol; and, according to Ritthausen (*J. pr. Chem.* lxxiv. 193, 384), the portion soluble in alcohol may be further resolved into two substances, one called mucin or vegetable casein, the other gluten, gliadin or vegetable gelatin; the portion insoluble in alcohol is called vegetable fibrin.

To separate these substances, Ritthausen proceeds as follows:—Freshly prepared gluten, divided into small fragments, is digested for several hours with alcohol of 80 or 85 per cent. The alcohol is then heated to boiling, and after half an hour the supernatant liquid is filtered, or simply decanted, and the mass of gluten is again heated several times with boiling alcohol of 75 per cent. The united alcoholic liquids become turbid on cooling, and after half the alcohol has been distilled off, they deposit on cooling considerable quantities of flocculent mucin, mixed with gluten and fat, and easily united by agitation.

To purify the mucin thus obtained, it must then be dissolved in alcohol of 50 per cent. and the hot solution filtered through calico, then left to cool, and frequently agitated while the deposit is forming. The clear liquid then retains all the gluten, together with a very small quantity of mucin. The precipitated mucin is transparent, flocculent, and

slightly coloured. After desiccation by absolute alcohol, it becomes greyish-white granular, easy to pulverise, and of earthy aspect.

Mucin is soluble in boiling alcohol, and in cold dilute acetic acid: but, under certain circumstances, it becomes changed into an insoluble modification, scarcely distinguishable from animal fibrin, this transformation taking place when mucin is precipitated by ammonia from its solution in acetic acid, when it is left for some time in contact with cold water, or with dilute alcohol, and when it is boiled for a short time with water.

The alcoholic liquid from which the mucin has been deposited contains the gluten together with a small quantity of mucin. To obtain the gluten pure, the liquid must be evaporated over the water-bath, by which the mucin is rendered insoluble, and the gluten redissolved in alcohol or in dilute acetic acid.

Gluten, or vegetable gelatin, in the hydrated state, forms a yellowish limpid liquid of the consistence of varnish, and capable of being drawn out into threads having a silky lustre. When desiccated by alcohol, treated with ether, and dried in vacuo, it forms a hard fragile mass of farinaceous aspect. By evaporating the alcoholic solution, it is obtained in a form exactly resembling that of animal gelatin.

Gluten dissolves easily in alcohol of 40 to 80 per cent., the solution remaining perfectly limpid. Absolute alcohol precipitates it gradually in the form of a white, granular, but adherent powder. It dissolves to a very slight extent in cold, and somewhat more freely in hot water, the solution yielding a white precipitate with *gallotannic acid*, and with *basic acetate of lead*, *mercuric chloride*, *sulphate of zinc*, and *nitrate of silver*. With *ferrie sulphate* mixed with ammonia, it gives the same reaction as animal gelatin, that is to say, an orange-coloured or brownish precipitate.

Gluten dissolves with blue colour in *hydrochloric acid*; in *nitric acid*, it swells up and dissolves, the solution yielding a yellow flocculent precipitate when mixed with water. It dissolves partially in *phosphoric acid*, easily and completely in *tartaric acid* and *acetic acids*. On mixing the acetic solution with a small quantity of *cupric sulphate*, slightly supersaturating with potash, and heating the liquid to boiling, a blackish precipitate of cupric oxide (?) is formed, and the liquid acquires a fine permanent bluish-violet colour. The same reaction is exhibited by mucin.

Gluten is soluble in the *fixed alkalis*, less soluble in *ammonia*. The alkaline solution forms curdy precipitates with metallic salts; carbonic acid, calcium-salts, and acetate of lead separate the gluten from it. The acetic and alcoholic solutions exhibit similar characters.

Moist gluten exhibits a fine red colour with *mercurous nitrate*. With strong *sulphuric acid* and sugar, it first produces a fugitive yellow colour, and then, after half an hour, a fine violet colour. Both gluten and mucin, when dried by heat, pass into modifications less soluble in alcohol and other solvents than the original substances. At a stronger heat, gluten melts, swells up, and leaves a carbonaceous residue.

Gluten, like mucin, appears capable of passing into an insoluble modification. Ritthausen is also of opinion that vegetable fibrin is capable of undergoing a similar change, and that the existence of the several constituents of gluten in the soluble or insoluble state may account for the differences observed between certain varieties of wheat (*blé vitreux* and *blé farineux*).

The following are analyses of crude gluten, of gluten (or rather mixtures of gluten and mucin) separated by alcohol from crude gluten, and of pure gluten, prepared by Ritthausen's process. They show that pure gluten has the same composition as crude gluten itself, and that the other constituents do not differ much in composition from it; hence it is probable that all the constituents of gluten have the same percentage composition, which indeed is that of the albuminoids (i. 70).

Mucin yielded 0.98 and vegetable fibrin 0.95 per cent. of sulphur. Vegetable fibrin dehydrated by alcohol, forms a pulverulent mass. (Ritthausen.)

The fats of gluten form a yellow oily mass, neutral, having a sweet taste, and mixed with crystals. (Ritthausen.)

Günsberg (J. pr. Chem. lxxxv. 213) has obtained results differing considerably from those of Ritthausen. According to his experiments, the substance described by Ritthausen as mucin or vegetable casein is not a distinct proximate principle, the deposit which separates from alcohol after boiling with gluten, consisting merely of small fragments of suspended fibrin. Moreover, gluten or gliadin, which remains dissolved in the alcohol after separation of this deposit, is itself not a simple proximate principle: for cold water extracts from it a brown substance containing nitrogen and sulphur; and the residue treated with boiling water yields a limpid solution, which on cooling deposits a substance free from sulphur, and containing, when dried at 130° C., 52.77 per cent. carbon, 6.79 hydrogen, 17.66 nitrogen, and 22.78 oxygen. This substance, which has nearly the same composition as animal gelatin, is regarded by Günsberg as the true gluten or vegetable gelatin. The sulphuretted and non-sulphuretted compounds just mentioned may be extracted directly from gluten by successive treatment with cold and hot water without previous solution in alcohol.

The proportions of gluten in wheat-flour vary considerably, according to the conditions of growth, such as climate, soil, manure, temperature, &c. The best wheat-flour contains from 10 to 11 per cent. of dry gluten; inferior kinds from 8 to 9 per cent. In the moist state, gluten weighs about three times as much as when dry.

The flours of barley, rye, and oats differ considerably in proximate constitution from wheat-flour, boiling alcohol extracting from them fatty and resinous matters, but only traces of gluten. Indeed these grains cannot properly be said to contain gluten, but only vegetable fibrin. Neither is gluten found in appreciable quantity in the flour of peas, beans, or lentils. It appears to exist, however, in the juice of the grape, and of many other fruits, being probably held in solution by tartaric or other vegetable acids.

GLYCERAMINE or *Glyceryl-hydramine*. $C^3H^5NO^2 = \begin{matrix} (C^3H^5)''' \\ H^2 \end{matrix} \left\{ \begin{matrix} N \\ O^2 \end{matrix} \right\} - An$
organic base produced, as a hydrobromate, by passing ammonia-gas into a solution of dibromhydrin in absolute alcohol:

By treating the hydrobromate with strong potash-ley, the base is obtained as an oily liquid easily soluble in water and in ether. *Hydrochlorate of glyceramine* becomes moist on exposure to the air, and decomposes when heated. Its alcoholic solution forms with tetrachloride of platinum, a double salt, $2(C^3H^5NO^2.HCl).PtCl^4$, which separates in orange-coloured granules. (Berthelot and De Luca, Ann. Ch. Pharm. ci. 74.)

Diglyceryl-dihydrobromamine or *Hemibromhydramide*, $C^6H^{12}BrNO^2 = \begin{matrix} H^2 \\ (C^3H^5)''' \\ (C^3H^5)''' \end{matrix} \left\{ \begin{matrix} N \\ O^2 \end{matrix} \right\}$, is an amorphous base, produced by the action of dry ammonia-gas on pure dibromhydrin (Berthelot and De Luca, i. 668); and the analogous compound, $C^9H^{12}ClNO^4$, is obtained by heating epichlorhydrin with alcoholic ammonia. (Reboul, p. 898.)

GLYCERIC ACID. $C^3H^5O^4 = \begin{matrix} (C^3H^5O)''' \\ H^3 \end{matrix} \left\{ O^4 \right\}$. (Debus, Phil. Mag. [4] xv. 196; Ann. Ch. Pharm. cix. 227; Socoloff, Ann. Ch. Pharm. cvi. 95.)—Produced by the action of nitric acid on glycerin (Debus, Socoloff); by the spontaneous decomposition of nitroglycerin (De la Rue and Müller, Ann. Ch. Pharm. cix. 122); and by heating 1 at. glycerin with 4 at. bromine and a volume of water twenty times as great in a sealed tube to 100° C. (Barth, Ann. Ch. Pharm. cxxiv. 341):

Preparation.—1 pt. of glycerin is mixed in a glass cylinder with an equal bulk of water, and 1 pt. of nitric acid of specific gravity 1.5 introduced below it by means of a long-necked funnel (100 grms. glycerin, 100 grms. water, and 100 to 150 grms. red nitric acid are good proportions). The two layers of liquid gradually mix and assume a blue colour, and the oxidation of the glycerin proceeds, accompanied by a copious evolution of gas. If the liquid becomes too hot, the action must be moderated by external cooling. When the oxidation is completed, which takes five or six days, the strongly acid liquid is divided into small portions and evaporated at 100° C. to a syrupy consistence: the united residues are diluted with water, and neutralised with chalk; and the resulting calcium-salts are precipitated by strong alcohol. The liquid (which still contains one or two substances) is carefully separated from the precipitate; the latter is treated with warm water; and the solution filtered from the oxalate of calcium is mixed with a quantity of milk of lime sufficient to produce alkaline reaction, where-

upon the calcium-salt of a peculiar acid is deposited. The liquid separated from this precipitate, freed from excess of lime by carbonic acid, and evaporated to the crystallising point, yields glycerate of calcium, which may be purified by recrystallisation, (Debus). According to Socoloff, when glycerin is mixed with a large excess of nitric acid of specific gravity 1.860, at ordinary temperatures, oxidation begins in a few hours; a large quantity of gas is evolved; crystals of oxalic acid separate in a few days; and the remaining liquid thus formed contains glyceric acid, the calcium-salt of which may be obtained as above.*

The acid is obtained by decomposing the calcium-salt with a quantity of oxalic acid exactly sufficient to precipitate the lime, and evaporating the filtrate on the water-bath (Debus). Beilstein (Ann. Ch. Pharm. cxx. 226), evaporates the product of the reaction of nitric acid upon glycerin in a large flat-bottomed basin, over the water-bath, dissolves the residue in a large quantity of water, and saturates it with oxide or carbonate of lead. The liquid boiled, filtered, and concentrated by evaporation, deposits, on cooling, crystals of glycerate of lead, which, when purified by recrystallisation, and decomposed by sulphuric acid, yield nearly colourless glyceric acid, as a thick, non-crystallising syrup. The acid, after being heated for some time to 105°C ., is converted into a soft, very tenacious, slightly brown mass, having the composition of *glyceric anhydride*, $\text{C}^3\text{H}^4\text{O}^3$, which, at 140° , changes to a brownish mass resembling gum arabic; it absorbs water with avidity, and, at a higher temperature, gives off acid vapours, turns brown, and burns with flame. (Debus.)

Glyceric acid is isomeric with pyruvic acid: it is also homologous with glyoxylic acid ($\text{C}^2\text{H}^2\text{O}^4$), and bears the same relation to glycerine, $\text{C}^3\text{H}^8\text{O}^3$, that acetic acid bears to alcohol.

Glyceric acid treated with *iodide of phosphorus* yields iodopropionic acid, $\text{C}^3\text{H}^4\text{IO}^2$ (see PROPIONIC ACID, DERIVATIVES OF). A mixture of glyceric and benzoic acids heated for a long time to 200°C ., appears to yield a benzoglyceric acid. (Beilstein, Ann. Ch. Pharm. cxx. 226.)

The aqueous solution of glyceric acid has an agreeably sour taste, dissolves iron and zinc without evolution of gas, probably forming a lactate or propionate, decomposes carbonates, and coagulates milk. Potash added to a solution of iron in glyceric acid precipitates only a part of the iron; the precipitation of copper from the sulphate by potash is likewise prevented by the presence of glyceric acid, the liquid yielding, however, a dark yellow-brown precipitate when boiled.

Glycerates.—Glyceric acid, though a triatomic acid, nevertheless appears to contain only 1 atom of hydrogen replaceable by metals. It is probable, however, that the remaining two atoms of typic hydrogen will be found to be more easily replaceable by acid radicles, just like the second atom of typic hydrogen in glycollic acid (*q. v.*)

The glycerates are soluble in water and crystallise well. They are not reddened by ferrous sulphate, and are thereby distinguished from the pyruvates.

Glycerate of Ammonium, $\text{C}^3\text{H}^5(\text{NH}^4)\text{O}^4$, forms colourless radiating crystals, which are very deliquescent, melt at a gentle heat, and at higher temperatures turn brown and give off ammonia.

Glycerate of Barium, $\text{C}^3\text{H}^4\text{Ba}^2\text{O}^6$, separates from a hot solution of carbonate of barium in the aqueous acid in large spherical aggregations of concentrically grouped laminae.

Glycerate of Calcium, $\text{C}^3\text{H}^4\text{Ca}^2\text{O}^6 + 2\text{H}^2\text{O}$, crystallises in small, white, concentrically-grouped crystals, frequently also in nodules composed of microscopic tables or prisms. By mixing a moderately strong aqueous solution with about an equal volume of hot alcohol, distinct crystals are obtained belonging to the monoclinic system: $\infty\text{P} \cdot \infty\text{P} \cdot [\infty\text{P}\infty] \cdot \infty\text{P}\infty$. They have a micaceous lustre, give off their water at about 120°C ., and begin to decompose at 160° . The salt is insoluble in alcohol. The aqueous solution precipitates lead, copper, and ferric salts. With nitrate of silver at the boiling heat it forms a black precipitate, and, on addition of ammonia, a specular deposit of silver.

Glycerate of Lead, $\text{C}^3\text{H}^4\text{Pb}^2\text{O}^6$, forms white, hard, anhydrous crystalline crusts.

Glycerate of Potassium (acid), $\text{C}^3\text{H}^4\text{KO}^4 \cdot \text{C}^3\text{H}^4\text{O}^4$, is obtained in small white crystals by exactly neutralising the acid with carbonate of potassium, adding an equal quantity of the acid, and evaporating to a syrup.

When 1 pt. of *neutral glycerate of potassium* is mixed with 1 pt. of hydrate of potassium dissolved in 2 pts. of water, and the mixture is boiled down till it gives a white precipitate with acetate of lead, after acidulation with acetic acid, the glyceric

* When the mother-liquor separated from the crystals of this calcium-salt was mixed with carbonate of potassium in quantity sufficient to precipitate the whole of the lime, and the alkaline filtrate neutralised with nitric acid and concentrated, the syrupy liquid decanted from the crystals of nitre which separated out, yielded needle-shaped crystals with a concentrated solution of acid sulphite of sodium; hence it probably contained a substance of the nature of an aldehyde. (Socoloff.)

acid is found to be resolved into oxalic and lactic acids, the former being precipitated by the acetate of lead, the latter remaining in solution. The glyceric acid is probably first resolved into lactic and malonic acids:

and the malonic acid is further resolved into oxalic and formic acids:

(Debus, Ann. Ch. Pharm. cix. 122). From an experiment made by Atkinson, it appears that glycerate of potassium, when fused with hydrate of potassium, is resolved into acetate and formate of potassium:

Glycerate of Silver is a very unstable salt.

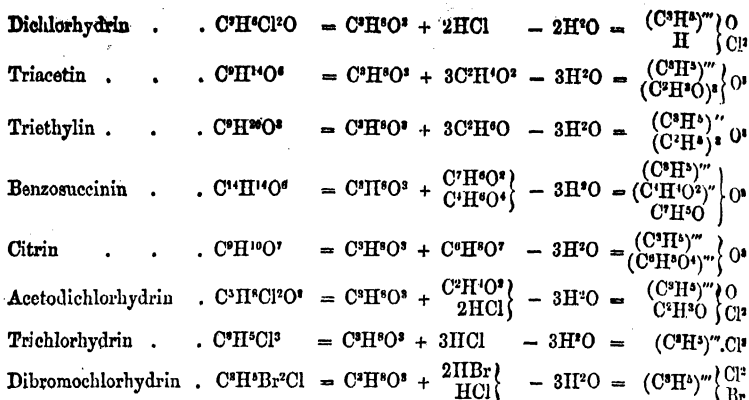

Glycerate of Zinc, $\text{C}^2\text{H}^{10}\text{Zn}^2\text{O}^8 + \text{H}^2\text{O}$, crystallises from a solution of carbonate of zinc in the warm aqueous acid in small colourless crystals, which give off their water at 140° .

GLYCERIDES. *Glycerin-ethers. Glyceryl-ethers. Saponifiable Fats.* (Chevreul, *Recherches sur les corps gras d'origine animale*. Paris, 1823.—Berthelot, *Chimie organique fondée sur la synthèse*, ii. 12—164.—Kekulé, *Lehrb. d. org. Chem.* ii. 108—135.)—These bodies are the compound ethers of the triatomic alcohol, glycerin. Some of them exist ready formed, as natural fats, in the bodies of plants and animals, and many more may be produced artificially, by the action of acids upon glycerin.

The names of the glycerides are formed, for the most part, from those of the corresponding acids, by changing the termination *ic* into *in*; thus, acetic acid forms acetins, chlorhydric acid forms chlorhydrins, &c. There are a few glycerides containing monatomic alcohol-radicles instead of acid radicles, and these are designated in like manner; thus, glycerides containing ethyl are called ethylins. The names of glycerides which possess decided acid properties are formed by prefixing the word *glycero* to the name of the acid from which they are formed, e.g. glycerotartaric, glycerophosphoric acid, &c.

The formation of glycerides takes place in the same way as that of all other compound ethers, and indeed of all salts whatever, viz. by the union of the acid and base, with elimination of the elements of water (see ACIDS, i. 43, and ETHERS, ii. 509), the number of atoms of water thus eliminated being in the majority of cases equal to the number of atoms of a monobasic acid (or alcohol) concerned in the reaction, or to twice the number of atoms of a dibasic acid, or to three times that of the number of atoms of a tribasic acid. In this manner there are formed three series of normal glycerides, having the constitution of triatomic ethers derived from glycerin, $(\text{C}^2\text{H}^3)^{\text{'''}}\text{O}^3$ or $(\text{C}^2\text{H}^3)^{\text{'''}}.(\text{HO})^3$, by the replacement of 1, 2, or 3 at. hydrogen by an equivalent quantity of an acid- or alcohol-radicle, or of 1, 2, or 3 at. HO by an equivalent quantity of the peroxide of an acid- or alcohol-radicle or of chlorine, bromine, or iodine (see ETHERS, pp. 508, 520); thus:—

There is, however, a considerable number of glycerides, whose formation is attended with the elimination of a number of atoms of water greater or less than that which would be indicated by the rule above given, *e. g.* :

For additional examples, see the table given under ETHERS (p. 520).

These abnormal glycerides differ of course in atomicity from the normal glycerides, which are all triatomic. Those whose formation (like that of the third and fourth in the preceding table) is attended with the elimination of a number of water-atoms smaller than that required by the general rule are of higher atomicity than the normal glycerides (see the table, p. 520); these are for the most part of decided acid character. Those, on the contrary, which, like the first and second in the above table, eliminate in their formation a number of water-atoms greater than would be consistent with the formation of a normal glyceride, are of lower atomicity, and for the most part diatomic. They constitute a class of ethers called glycidic ethers, which may be derived from a hypothetical diatomic alcohol, $\left(\begin{array}{c} \text{C}^2\text{H}^3 \\ \text{H}^2 \end{array} \right)^{\text{m}} \text{O}^2$ or $\left(\begin{array}{c} \text{C}^2\text{H}^3 \\ \text{H} \end{array} \right)^{\text{m}} \text{O}^2$, called glycidic. This class of compounds includes the chlor- and bromhydrins which are distinguished in Berthelot's nomenclature by the prefix *epi*, and are produced from the triatomic chlorhydrins and bromhydrins by the action of alkalis. (See GLYCIDIC ETHERS.)

Occurrence and Formation of Glycerides.—The normal glycerides containing acid radicles are artificially produced by acting upon glycerin with the corresponding acids, sometimes at ordinary temperatures, but more frequently with the aid of heat in sealed tubes, the particular compound formed depending upon the proportions of acid and glycerin present, the temperature to which the mixture is subjected, and the duration of the action. The chlorhydrins and bromhydrins are likewise produced by the action of the chlorides and bromides of phosphorus on glycerin.

The glycerides which are found in living vegetable and animal organisms all contain 3 at. of an acid radicle in place of the three replaceable hydrogen-atoms of glycerin. They are identical in all their properties with the triacid glycerides produced by artificial processes. Nearly all saponifiable fats are bodies of this nature, only a few yielding by this treatment alcohols different from glycerin, *e. g.* spermaceti, which yields ethal, or cetyl alcohol, and Chinese wax, which yields cerylic alcohol.

The glycerides which occur in plants in the form of oil or tallow are found chiefly in the seed, and most frequently in the testa, or seed-coating; rarely in the albumen (as in the poppy), or in the radicle, or in the fleshy matter surrounding the seed (as in the olive). *Cyperus esculentus* contains an oil in the root. In the animal body, fats are for the most part enclosed in the cellular tissue or in particular cavities.

Fats are separated from vegetable or animal tissue by pressure, at the temperature of the air, if they are sufficiently fluid; otherwise with the aid of heat; sometimes, however, the fat separates out spontaneously by simple fusion; or the fat may be dissolved out by boiling alcohol or ether, in which case it separates, sometimes by cooling, sometimes by evaporation, or on being mixed with water. The fat obtained by either of these processes is generally a mixture of several simple glycerides, which

may in some cases be separated, in consequence of their different fusibility, by pressing them at a temperature at which one is solid and the other liquid; thus the best kind of olive oil is obtained by filtering the crude oil at a temperature near the freezing point of water, only the most fluid portion then passing through. Another mode of separating fats is by taking advantage of their different degrees of solubility in alcohol and ether. But it is very difficult to obtain a perfectly pure simple glyceride by any of these processes.

Properties.—Glycerides in the solid state are white, transparent, or translucent. Some of them are crystalline, others have a close splintery fracture; specific gravity between 0.892 and 0.930. At a certain degree of cold they are brittle and friable, and at a less degree, more or less soft. Their melting-points range from 20 degrees or more below 0° C. to + 61° C. In the melted state they form viscid oils, generally colourless, sometimes yellowish or greenish, greasy to the touch, and making a permanent stain on paper. They are not volatile without decomposition, some only being capable of distillation in vacuo. They are neutral to vegetable colours, inodorous when pure, but often have a rancid odour, arising from incipient decomposition; they have little or no taste.

Glycerides are insoluble in water, sparingly soluble in alcohol, more soluble in ether: they dissolve also in sulphide of carbon. They mix readily with volatile oils; in the melted state they dissolve sulphur, phosphorus, and iodine (which however gradually decomposes them), also camphors, resins, and alkaloïds. They are not soluble in aqueous ammonia, but liquid fats mix with it and form a white pasty mixture, called *liniment*, which takes a long time to separate.

Many glycerides are susceptible of isomeric modifications, differing in melting-point and other physical properties. Heintz observed that stearin from mutton fat, enclosed in a capillary tube and heated in a water-bath, becomes perfectly transparent at 51° or 52° C., opalescent at a somewhat higher temperature, resumes its opacity at 58°, and melts at 62–62.5°.

These phenomena have been more minutely examined by Duffy (Chem. Soc. Qu. J. v. 197) who finds that stearin is susceptible of three isomeric modifications, each distinguished by a particular melting-point. When gradually heated, it melts at the first of these points, viz. at about 51° C., then solidifies; melts at the temperature of the second, solidifies, melts at the temperature of the third (about 69°), and then solidifies only when the temperature has fallen below all three. After solidifying at this point, it may be made to melt again at the first, second, and third melting-points respectively, solidifying as before, below all three; and these changes are producible in this succession to any extent, without the slightest loss or gain of weight. As the stearin approaches to purity (by repeated crystallisation from ether), the interval between the first and second melting-points diminishes: hence it is probable that perfectly pure stearin* (which has never yet been obtained) would exhibit only two melting points, those, namely, which are here called the first and third.

The three modifications also differ in density, the first being lighter, the second and third heavier than water; at 15°, the density of the first is 0.9867; of the second 1.0101, of the third 1.0178. These numbers apply to mutton-stearin crystallised 32 times from ether, and having its third melting point at 69.7°.

Similar modifications are exhibited by other glycerides, viz. stearin from beef-fat, a glycerin-fat from a kind of vegetable tallow (the history of which is not exactly known), palmitin and margarin. The following table exhibits the melting-points of these fats:

	Solidifying points.	Melting-points.		
		1	2	3
Mutton-stearin	51.7°	52.0°	64.2°?	69.7°
Beef-stearin	50.5	51.0	63.0	67.0
Substance from vegetable tallow .	45.0	45.0	62.0	64.5
Palmitin from palm-oil	45.0	46.0	61.7	62.8
Margarin from butter	40.0	40.5	51.0	52.6
Margarin (?) from human fat . .	43.5	44.2	54.5	56.0

The property of existing in two, if not three modifications, appears not to belong to any fatty substances excepting the glycerin-fats: at all events, the acids derived from them do not possess it; neither is it exhibited by stearic or cerotic ether, cerotin, cerotene, Chinese wax, or paraffin.

Decompositions of Glycerides.—1. *By distillation.*—Glycerides, which yield volatile acids, such as the acetins, butyrins, and valerins, may be more or less distilled without decomposition; but those which yield fixed acids, *e. g.* palmitin, olein, and stearin, are

* The purest stearin which Duffy obtained had been crystallised 32 times from ether, and amounted to only 8 grammes from 2 kilogrammes of the crude fat; it still, however, appeared to be not quite pure; for the residue of the mother-liquor differed in melting point by 2° from that which crystallised out.

almost wholly decomposed by a heat of 300° C. and upwards, yielding numerous hydrocarbons, acrolein, with its products of decomposition (acrylic acid and acetic acid), more or less of the fatty acid contained in the glyceride, and a residue of charcoal, amounting to from 1 to 4 per cent. of the fat. When a fat is made to pass in drops through an iron tube at a low red heat, it yields but a small quantity of liquid products, but is for the most part resolved into a mixture of gases called *oil-gas*, possessing great illuminating power, and consisting of carbonic oxide, hydrogen, marsh gas, olefant gas, the vapours of two empyreumatic oils (probably C^4H^8 and C^5H^{10}) and benzene, C^6H^6 .

2. *By oxidation.*—Fats, in consequence of their higher boiling-points, require a stronger heat to set them on fire than the greater number of volatile oils. They burn with a very bright white flame, which deposits no soot unless the supply of air is insufficient.

Fats likewise undergo gradual oxidation by exposure to the air at ordinary temperatures. This change takes place most rapidly with fats which are liquid at the medium temperature of the air, and the fixed oils, when they thicken, turn rancid, and sometimes undergo spontaneous combustion. Fats of the stearin class, when pure, are but little changed by exposure to the air, but when mixed with oily fats, as generally happens, they exhibit alterations similar to the latter. Some fixed oils dry up by oxidation to an elastic resinous substance; others are converted into a thick greasy mass. Hence the distinction between *drying oils*, such as linseed oil, and *non-drying oils*, like rape and olive oils.

The thickening of fixed oils is purely an effect of oxidation; but the rancidity which many oils acquire by exposure to the air appears to depend in a great measure on the presence of certain azotised substances, such as gluten or cellular tissue, which putrefy on exposure to the air, and act as ferments in inducing a peculiar kind of decomposition. (See OILS.) Accordingly, animal oils are peculiarly subject to rancidity. Oils may be kept from turning rancid by Appert's process, that is, by placing bottles completely filled with them in water, keeping the water for some hours at the boiling heat, and closing the bottles tightly while the heating is continued.

When porous substances, such as hemp or cotton, are saturated with fixed oils, so that the oil presents a very large surface to the air, the absorption of oxygen takes place more quickly; the development of heat which accompanies it accelerates the process; this again produces a more rapid evolution of heat, by which the oxidation is further accelerated; and at last, if the quantity of material is considerable, the temperature rises to the point at which rapid combustion takes place. This spontaneous combustion of fixed oils, which is a frequent cause of fires, takes place more readily with drying than with non-drying oils. It may take place in intervals varying from a few hours to several weeks, when considerable masses of lamp-black, tow, linen, paper, cotton, calico, woollen stuffs, ships' cables, wood-ashes, ochre, &c., are slightly soaked in oil and packed in such a manner that the air has moderate access to them. (See Graham's *Chemical Report on the Cause of the Fire in the Steamship "Amazon,"* Chem. Soc. Qu. J. v. 34.)

3. *Chlorine, bromine, and iodine* decompose fats, forming substitution-products, which have been but little examined.

4. Fuming *nitric acid* sets fire to drying oils. A mixture of this acid with strong sulphuric acid sets fire even to olein; but solid fats are but slowly decomposed by fuming nitric acid. When fats are heated for some time with dilute nitric acid, the products formed are the same as if a mixture of glycerin and the fatty acid had been similarly treated, the glycerin yielding oxalic, and perhaps also acetic acid, and the fatty acid being converted by progressive oxidation, first into a resinous mass, then into various other acids, such as suberic, pimelic, adipic, lipic, succinic acids, and others, differing according to the nature of the original acid. Olein yields, in addition to the acids above-mentioned, several volatile acids of the series $C^2H^2O^2$, from acetic acid, $C^3H^4O^2$, to capric acid, $C^{10}H^{20}O^2$. When weak nitric acid acts for a short time only on fats, the oxidising action is exerted almost wholly on the glyceryl, the fatty acid being set free, occasionally in a somewhat altered state.

5. Strong *sulphuric acid*, at high temperatures, browns and blackens fats, giving off sulphurous and sometimes formic acid, and forming a resinous matter, a substance like tannin, and a coaly substance, all of which appear to contain sulphuric acid. Sulphuric acid, gently heated with twice its weight of fat, separates the fatty acid, and forms *sulphoglyceric acid*, $C^3H^5O^4.SO^2$.

6. Ammonia decomposes the glycerides into glycerin and the amide of the acid contained in them (Berthelot, Bouis, Rowney), e.g.:

7. *Saponification.*—Glycerides, as already observed, are decomposed by caustic

alkalis and other hydrated oxides, yielding glycerin and a salt of the fatty acid, called a *soap*. Thus, when stearin is acted upon by caustic potash, the products are glycerin and stearate of potassium.

The stronger the base, the lower is the temperature at which the saponification may be effected. Caustic alkalis can saponify fats at ordinary temperatures, especially if the action be assisted by agitation; weaker bases, such as oxide of lead, also the alkaline carbonates, require a boiling heat, and water requires a very high temperature, such as can only be produced under increased pressure or by the use of superheated steam (p. 886).

At a temperature at which the tension of water-vapour is from five to six times that of the atmosphere, 4 pts. lime suffice to saponify completely 100 pts. fat in presence of water (Milly). One pt. lime-soap heated with an equal weight of water, and 40 times its weight of olive-oil, to 155° or 165° C., decomposes the oil completely. (Pelouze.)

Glycerides may also be saponified by *anhydrous oxides*, e.g. by lime, baryta, strontia, and oxide of lead. When tallow is heated with $\frac{1}{10}$ or rather more of its weight of quicklime to about 250° C., the whole of the fatty acids contained in it are converted into lime-soaps, and the mass treated with water yields glycerin. During the saponification, water, acetone, and glycerin are given off, amounting to 2 or 3 per cent. of the tallow. (Pelouze, *Compt. rend.* xlii. 1001.)

When a glyceride is boiled with excess of alkali, the product is always a neutral soap, and if the quantity of alkali present is less than sufficient to neutralise the whole of the fatty acid, part of the fat remains undecomposed. 100 pts. of hog's lard require for complete saponification 18 pts. of hydrate of potassium, the product then consisting of neutral stearate, oleate, &c. of potassium, without excess of either acid or alkali; but, if 100 pts. of lard are boiled for 60 hours with 9 pts. of hydrate of potassium and a small quantity of water, a homogeneous mass is obtained, consisting of neutral stearate, &c. of potassium, mixed with half the fat in its original state. The mixture thus formed is almost wholly soluble in alcohol, and does not form grease-spots, a property on which the power of soap to remove grease-spots chiefly depends. The same mixture, boiled with a large quantity of water, is decomposed into soluble soap and unaltered fat. (Chevreul.)

Some glycerides are decomposed when heated with *alcohol* in sealed tubes, yielding glycerin, and the ethyl-ether of their acid, e.g.:

but most glycerides are thus decomposed only when an acid, such as hydrochloric acid, is present, or a quantity of alkali not sufficient to neutralise the whole of the fatty acid (Berthelot); e.g.:

A simple fat, when saponified, yields glycerin and only one acid; but if the fat is a mixture of several glycerides, which is generally the case with natural fats, each of these yields a peculiar acid; so that, for every acid yielded by a fatty mixture, a corresponding glyceride may be supposed to exist therein.

To ascertain what acids have been obtained by the saponification of a fat, the first thing to be done is to decompose all the soap-salts with dilute sulphuric acid, and then separate the volatile from the fixed acids by distillation. The several volatile acids in the distillate may then be further separated by fractional distillation; acetic, butyric, and valeric acids, better by Liebig's method of partial saturation with potash, and subsequent distillation (i. 250).

To separate the fixed acids, Heintz (Pogg. Ann. lxxxiv. 221) dissolves the mixture in such a quantity of alcohol, that nothing separates out from the solution at 0° C., and adds to the boiling alcoholic solution a quantity of acetate of lead sufficient to convert about half the acids into lead-salts, the quantity of the crystallised acetate required for this purpose being generally about one-third of the weight of the acid. Any precipitate which forms at the boiling heat is to be redissolved by a mixture. A few drops of acetic acid, and the solution left to cool. The liquid is then filtered from the salts, which separate in the solid state, by filtration and pressure, and the fatty acids are separated from both the dissolved and the solid lead-salts by sulphuric acid. The fractional precipitation is then to be repeated in the same manner in both portions of acid, till the products no longer exhibit any alternation of melting-point or other physical properties. [For Chevreul's method of separation, see his "Recherches sur les corps gras;" also *Gm. ch.* 233.] The separation of the fatty

acids is on the whole a less difficult problem than that of the fats themselves; indeed, the only way of obtaining an absolutely pure glyceride is to produce it artificially by the action of the corresponding acid upon glycerin.

The following is a list of the fatty acids which have been obtained from natural glycerides:

1. Volatile acids.		2. Fixed acids.	
Butyric $C^4H^8O^2$	Laurostearic $C^{12}H^{24}O^2$
Valeric $C^5H^{10}O^2$	Cocinic $C^{18}H^{36}O^2$
Caproic $C^6H^{12}O^2$	Myristic $C^{14}H^{28}O^2$
Caprylic $C^8H^{16}O^2$	Benic? $C^{15}H^{30}O^2$
Capric $C^{10}H^{20}O^2$	Moringic $C^{15}H^{30}O^2$
Hercic ?	Linoleic $C^{18}H^{34}O^2$
Sabadillie ?	Palmitic $C^{16}H^{32}O^2$
Crotonic $C^8H^{16}O^2$	Hypogæic $C^{16}H^{32}O^2$
Ricinic ?	Margaric $C^{17}H^{34}O^2$
		Oleic, Elaidic, and Ricinoleic	$C^{18}H^{34}O^2$
		Stearic $C^{18}H^{36}O^2$
		Arachidic $C^{20}H^{40}O^2$

According to Heintz, margaric acid is merely a mixture of stearic and palmitic acids; and benic acid is identical with palmitic acid.

The neutral fats corresponding to several of these acids have not been obtained in the separate state, their existence being merely inferred from the formation of corresponding acids in the saponification of mixed fats.

The normal glycerides containing acid radicles are specially described after the several acids (see ACTINS, BUTYRINS, CHLORHYDRINS, &c.). The acid glycerides (glycerophosphoric acid, &c.) and the glycidic ethers (p. 895) will be described in separate articles. We shall here describe the normal glycerides containing monatomic alcohol-radicles, of which the following have been prepared and analysed by Reboul (Ann. Ch. Phys. [3] lx. 5; Jahresb. f. Chem. 1860, p. 462), and by Reboul and Lourenço. (Compt. rend. lii. 466; Jahresb. 1861, p. 674.)

Glycerides containing Monatomic Alcohol-radicles.

Ethylin $C^2H^4O^2$	=	$C^2H^4(C^2H^3)O^2$.
Amylin $C^5H^{10}O^2$	=	$C^5H^{10}(C^2H^3)O^2$.
Ethylchlorhydrin $C^2H^{11}ClO^2$	=	$C^2H^4(C^2H^3)ClO^2$.
Amylchlorhydrin $C^5H^{11}ClO^2$	=	$C^5H^9(C^2H^3)ClO^2$.
Diethylin $C^4H^8O^2$	=	$C^4H^8(C^2H^3)^2O^2$.
Ethylamylin $C^{10}H^{20}O^2$	=	$C^5H^9(C^2H^3)(C^2H^3)O^2$.
Diamylin $C^{10}H^{20}O^2$	=	$C^5H^9(C^2H^3)^2O^2$.
Diethylchlorhydrin $C^4H^{13}ClO^2$	=	$C^4H^8(C^2H^3)^2ClO^2$.
Ethyl-chlorobromhydrin $C^2H^{10}BrClO^2$	=	$C^2H^4(C^2H^3)BrClO^2$.
Triethylin $C^6H^{12}O^2$	=	$C^6H^{12}(C^2H^3)^3O^2$.

The glycerin-ethers containing 1 at. of a monatomic alcohol-radicle are produced: 1. By the combination of a glycidic ether containing a monatomic alcohol-radicle (p. 895) with H^2O , HCl , HBr , &c.; thus,

2. By the action of a sodium-alcohol on monochlorhydrin:

Glycerin-ethers containing 2 at. of a monatomic alcohol-radicle are produced by the action of ethyl- or amyl-chlorhydrin on a sodium-alcohol: thus,

Diethylin and diamylin are however more conveniently prepared by the action of the sodium-alcohols on dichlorhydrin, *e. g.* :

or on epichlorhydrin, in which case it is probable that a glycidic ether is first formed, *e. g.* :

and this, uniting with the free alcohol usually present in the sodium-alcohol, forms the glycerin-ether :

Diethylchlorhydrin is produced by the action of pentachloride of phosphorus on diethylin :

and this compound, treated with ethylate of sodium, forms triethylin :

Triethylin may also be obtained, though less pure, by the action of iodide of ethyl on the sodium-salt of diethylin :

The methods above described for the preparation of the ethyl- and amyl-derivatives of glycerin are evidently of general application. Another general method of preparing the glycerides in which all three atoms of the typic hydrogen are replaced by alcohol-radicles, is to treat a sodium-alcohol with the compound resulting from the union of a glycidic ether with an ordinary monatomic ether : thus epichlorhydrin, $\text{C}^2\text{H}^5\text{ClO}$, heated in a sealed tube with bromide of ethyl, $\text{C}^2\text{H}^5\text{Br}$, forms ethylchlorobromhydrin, $\begin{array}{c} \text{(C}^2\text{H}^5\text{)}^m \\ \text{C}^2\text{H}^5 \end{array} \left\{ \begin{array}{c} \text{Cl} \\ \text{O} \\ \text{Br} \end{array} \right\}$; and this compound treated with 2 at. of a sodium-alcohol yields a glycerin-ether containing 3 at. of a monatomic alcohol-radicle, *e. g.* :

Ethylin, $\text{C}^2\text{H}^{12}\text{O}^3$.—Obtained by adding chlorhydrin to ethylate of sodium, heating the resulting mass to 200°C . to expel the excess of alcohol, treating the residue with water, and then with carbonate of potassium, agitating with ether, evaporating the ethereal solution over the water-bath, and submitting the residue to repeated fractional distillation. It is an oily liquid, boiling between 225° and 230°C ., soluble in water, and precipitated therefrom by carbonate of potassium. (Reboul.)

Ethyl-chlorhydrin, $\text{C}^2\text{H}^{11}\text{ClO}^2$, obtained by agitating ethyl-glycidic ether with fuming hydrochloric acid, is a combustible liquid, having a pungent peppery odour, boiling at 180°C ., insoluble in water, somewhat soluble in hydrochloric acid. (Reboul.)

Diethylin, $\text{C}^4\text{H}^{16}\text{O}^3$, obtained by the action of ethylate of sodium on dichlorhydrin, is a liquid whose vapour-density is by observation = 5.22; by calculation (2 vol.) = 5.14. (Reboul.)

Diethylchlorhydrin, $\text{C}^4\text{H}^{15}\text{ClO}^2$, is a liquid of specific gravity 1.005 at 17°C .; insoluble in water, miscible with alcohol and ether.

Ethylchlorobromhydrin, $\text{C}^4\text{H}^{15}\text{BrClO}$, is a heavy oily liquid boiling between 186° and 188° , insoluble in water, but soluble in all proportions in alcohol and ether. Obtained by heating epichlorhydrin with bromide of ethyl.

Triethylin, $C^3H^9O^3$, obtained by heating diethylchlorhydrin with ethylate of sodium to $120^\circ C.$, evaporating the excess of alcohol over the water-bath, and treating the residue with water, is a colourless oil, boiling between 180° and $190^\circ C.$, insoluble in water, soluble in alcohol and ether.

Amylin, $C^8H^{11}O^3$.—Reboul obtained this compound by heating amyl-glycidic ether with water to $200^\circ C.$ in a sealed tube for several hours; $(C^5H^9)^3O^3 + H^2O = C^8H^{11}O^3$. Two layers then form, the upper of which, when agitated with aqueous carbonate of potassium, to remove water, then distilled and repeatedly rectified, yields amylin as a colourless, thickish liquid, of specific gravity 0.98 at $20^\circ C.$ It burns with a bright flame; boils between 260 and $262^\circ C.$; is soluble in water, 1 volume of it mixing with 2 vol. water, but not with more; and mixes in all proportions with ether.

Amyl-chlorhydrin, $C^5H^{11}ClO^2 = C^5H^9(C^2H^5)ClO^2$, obtained by agitating amyl-glycidic ether with fuming hydrochloric acid, is an oily liquid of specific gravity 1.0 at $20^\circ C.$, boiling at 235° , insoluble in water. (Reboul.)

Amyl-bromhydrin and **Amyl-iodhydrin** are obtained in like manner. The latter, which is produced with violent action, is a heavy liquid having a repulsive odour, and not volatile without decomposition. (Reboul.)

Diamylin $C^{11}H^{20}O^3 = C^5H^9(C^3H^7)^2O^3$, obtained by treating dichlorhydrin with amylate of sodium, dissolving out the resulting chloride of sodium with water, distilling the liquid which rises to the surface, and rectifying the portion which goes over between 275° and $290^\circ C.$, is a strong-smelling liquid, of specific gravity 0.907 at $9^\circ C.$, boiling between 272° and 274° , insoluble in water, not attacked by potash. Heated with hydrochloric acid to $100^\circ C.$ in closed vessels, it yields chloride of amyl. (Reboul.)

Ethylamylin, $C^8H^{13}O^3 = C^5H^9(C^2H^5)(C^3H^7)O^3$, prepared in like manner by the action of amylchlorhydrin on ethylate of sodium, is a liquid of specific gravity 0.92, boiling between 238° and $240^\circ C.$; burning with a bright flame, insoluble in water.

Polyglycerides. These are glycerides derived from 2 or more molecules of glycerin, either by simple dehydration in various degrees, or by dehydration and the replacement of the whole or part of the remaining typic hydrogen by acid or alcohol-radicles, *e. g.*:

For the special description of these compounds see GLYCERYL, HYDRATES OF (p. 893).

GLYCERIN. $C^3H^8O^3 = \left\{ \begin{matrix} C^2H^5 \\ H \end{matrix} \right\}^3 O^3 = (C^2H^5)^3(HO)^3$. *Principe doux des huiles, Oelsüss, Oelzucker*. (Gm. ix. 486.—xiii. 566; Gerh. i. 763; iv. 912.)—This substance is produced from most of the fixed oils and solid fats existing in the bodies of plants and animals by the process of saponification, that is to say, by treating these fatty bodies with an alkali, or other metallic oxide, in presence of water, or with water itself at a high temperature. It does not, for the most part, exist ready formed in natural fats, but is formed from them, together with a fatty acid, by addition of the elements of water, just as alcohol may be produced from acetate of ethyl. In short, glycerin is an alcohol, and bears to the fats, stearin, olein, &c., the same relation that alcohol bears to the compound ethers. (See ALCOHOLS, ETHERS, and GLYCERINES.) It was discovered in 1779 by Scheele, who obtained it in the preparation of lead-plaster by saponifying lard with oxide of lead. Chevreul (*Recherches sur les corps gras d'origine animale*, 1823) afterwards showed that it is a constant product of the saponification of the ordinary fats, and pointed out the relations just mentioned; and the recent researches of Berthelot (Ann. Ch. Phys. [3] xli. 216) on the synthesis of fats by the

direct action of acids upon glycerin, have shown that this body is a triatomic alcohol, in which 1, 2 or 3 at. of hydrogen may be replaced by acid radicles, producing fatty or oily compounds, some of which are identical in composition and properties with the natural fats, stearin, palmitin, &c.

Glycerin exists ready formed in a few vegetable oils, in palm-oil for example, from which it may be obtained by simple treatment with boiling water. Pasteur has shown that it is always produced in the alcoholic fermentation of sugar, to the amount of about 3 per cent. of the sugar decomposed, and that it occurs in all fermented liquors, especially in wine. (*Compt. rend.* xvi. 567; xlvii. 224.)

Artificial Formation.—Tribromide of allyl heated with acetate of silver yields triacetin, and triacetin treated with caustic alkalis, baryta-water for example, yields glycerin (Wurtz, *Ann. Ch. Phys.* [3] li. 97):

and

This reaction does not, however, afford the means of synthetically forming glycerin from inorganic constituents: for tribromide of allyl has hitherto been obtained only from iodide of allyl (iodotritylene), which in its turn is obtained from glycerin itself. The process is therefore more strictly analogous to the formation of glycerin by ordinary saponification than to a true synthesis.

Preparation.—1. *By saponification with oxide of lead.*—Five pts. of finely pounded litharge are heated with nine pts. of olive oil or any other glyceride and a small quantity of water, the mixture being stirred, and the water renewed till the oxide of lead is converted into a plaster; the watery liquid is then separated from this plaster, and freed from lead by a stream of sulphydric acid gas, and the filtrate is evaporated to a syrup over the water-bath.

For many years all the glycerin of commerce was obtained by this method; but it was very apt to retain small quantities of lead, the presence of which is very objectionable in any therapeutic application of glycerin.

2. *From the alkaline mother-liquor of the soap-works* (from which the soap has been separated by means of common salt), by neutralising with sulphuric acid; removing the excess of that acid by carbonate of barium; evaporating the filtrate to a syrup; digesting it for several days with alcohol; separating the alcoholic liquid from the sulphate of sodium which crystallises out; decolorising with animal charcoal; again evaporating to a syrup; exhausting the residue with strong alcohol; and finally evaporating the filtered solution over the water-bath (Riegel). This process is, however, too troublesome and expensive for use on the large scale.

The separation of glycerin from spent soap-lyes may be more economically effected by means of superheated steam, a method of doing which has been patented by H. Reynolds (10th of June, 1858). The liquid may be first reduced by evaporation, and raised nearly to the boiling point, by being passed through a heated still-like vessel, or heated in any other convenient vessel. It is then passed into a second vessel, where it is met by a jet or jets of superheated steam, at a temperature of 350° to 400° Fahr., which raises it to the boiling point and evaporates the glycerin, carrying the vapour upwards with it, and leaving the salts to deposit in the vessel. If greater purity is required, it may be obtained by repeating the process, and the little colour that remains can easily be removed by animal charcoal or chlorine.

3. *From the residue of the manufacture of stearic acid for candles.*—In this process the tallow is saponified by lime, and the glycerin separates from the calcium-salts of a fatty acids in the form of a brown liquid, which may be purified by evaporating to a syrup, treating the residue with alcohol as above, expelling the alcohol from the filtered liquid by distillation, digesting the solution with oxide of lead, till a portion of the oxide is dissolved, then filtering and removing the lead by sulphydric acid. The object of this treatment is to free the glycerin from a peculiar acid which is produced during the saponification, and forms with lead an insoluble basic salt. The liquid, after being treated with sulphydric acid, has merely a slight yellowish tint, which may be completely removed by animal charcoal. It is then concentrated by evaporation.

A process better adapted for preparation on the large scale is that of M. Cap. The liquid containing the glycerin from lime-saponification is concentrated, and afterwards treated with sulphuric acid to remove the remaining lime. It is then boiled and agitated in a close vessel to expel volatile fatty acids, left to cool when it has attained the density of 1.07 (14° of Twaddell's hydrometer), then rendered neutral, if necessary, by the

addition of carbonate of lime. After this the boiling is renewed, and continued till the liquid marks 37.5° Tw. (specific gravity 1.187), when it is again cooled, and any further deposit of sulphate of lime removed by filtration. Finally, the liquid is concentrated by evaporation to 49° Tw. (specific gravity 1.245), and passed through washed animal charcoal to remove the colour. This reduces the density to 45° Tw. (specific gravity 1.225), but by careful concentration, a fourth part of the water may be removed, and the density raised to 51.2° (specific gravity 1.256).

This method, when properly carried out, yields a very pure product, but it is somewhat complicated, and unless great attention is paid to every part of it, small quantities of lime are apt to remain in the glycerin, rendering it unfit for many purposes, especially for use in medicine and pharmacy.

3. *By heating neutral fats with water or with steam.*—This is the only unobjectionable method of obtaining glycerin, inasmuch as it alone ensures the entire absence of mineral impurities. It was first carried out by Mr. Tilghman in the following manner. The fat or oil having been thoroughly mixed to an emulsion with about half its bulk of warm water, is forced by a pump through a long coil of strong iron tubing heated to about the temperature of melted lead, the pump being worked at such a rate that the liquid may occupy about ten minutes in travelling through the coil. On issuing from the coil, the liquid separates into two layers, the upper of which consists of the fatty acid, and the lower of an aqueous solution of glycerin, which requires only to be concentrated by evaporation.

This process is very simple, and is capable of yielding very pure products. It has not, however, been carried out on a very large scale in the form just described, but it appears to have led to the invention of the method by which nearly all the pure glycerin of commerce is now obtained, viz. the decomposition of the fats by distillation in an atmosphere of superheated steam.

The distillation of fatty bodies and the introduction of steam into the apparatus was first suggested by Chevreul and Gay-Lussac, in 1825, and the process was afterwards carried out, with various improvements and modifications, by several chemists and manufacturers, both in this country and in France. But all these processes had for their special object the preparation and purification of the fat acids, not of the glycerin; indeed, the temperature employed was generally so high that the glycerin was completely decomposed, giving off intensely acrid fumes of acrolein, and leaving a charred residue. The distillation of fats in an atmosphere of steam in such a manner as to obtain the glycerin as well as the fatty acids, was first effected by the process above-mentioned, patented by G. F. Wilson and G. Payne on the 24th of July, 1854. The process is as follows:

An ordinary still and condensing or refrigerating apparatus is employed, preference being given to one with an ample refrigerating surface. The bottom of the still is heated by a fire provided with a damper to the flue or chimney, that the contents may not be heated above the desired temperature. In charging a still, a quantity of neutral or partially neutral fats is introduced into the heated still, and heated steam is introduced below the fats or oils, so as to rise up through them in numerous streams, care being taken that the temperature of the matters in the still shall not rise to the temperature which will decompose the glycerin. A thermometer is inserted into the still to indicate the temperature of the contents, and it is desirable in all cases with neutral fats and oils, to keep the heat below 600° and above 550° Fahr.; the glycerin is then not decomposed, but comes over very pure. When the fats or oils are only partially neutral, which is very commonly the case with palm-oil, the draught of the fires may be quickened, and the process hastened so long as there are fat acids in the still; but as soon as the fat acids have passed over, if the temperature is much above 600° Fahr., acrolein will probably be formed, particularly if steam be not freely supplied, its production being quickly indicated by its pungent smell, and its action on the eyes of persons near the condenser. Charges have nevertheless been worked off at higher temperatures, keeping up a very plentiful supply of steam, and the glycerin has not been decomposed; still, there is no superior result obtained, whilst there is greater hazard of decomposing the glycerin.

It is, however, most convenient to retain the contents of the still rather under than above 600° Fahr. (keeping up a free supply of steam) during the whole process, whether the fats or oils be neutral or partially neutral. The external heat immediately under the still should be very moderate, the heated steam admitted into the still being chiefly depended on for maintaining the higher temperature. Different neutral fatty and oily substances appear to vary in some degree, but not to a great extent, in regard to the temperature at which they may be distilled most quickly in an atmosphere of steam without decomposing the glycerin.

When a still with a refrigerator or condenser in successive compartments is used, each provided with a cock to draw off the distilled and condensed products, which is the

most convenient arrangement, it is found that the products which flow from the hottest of the condensers are for the most part free from water and glycerin, the greater part of the glycerin passing off with the products which condense in the compartments of the condenser more distant from the still, where the temperature is lower; and in all the receivers, the fat acids quickly separate from the glycerin and water, when allowed to stand and cool for a short time. The compartment of the condenser most distant from the still is open to the atmosphere, no pressure being necessary within the still and condenser.

When the glycerin is required in a more concentrated state than it is when it comes over and is condensed, the water contained in it may be more or less separated by evaporation.

The process of distillation just described may also be employed to purify glycerin prepared by either of the old processes, such as saponification by lime or oxide of lead.

For the description of various forms of apparatus for distilling fats with superheated steam, see *Richardson and Watts's Chemical Technology*, i. part 3, p. 754.

4. Lastly, glycerin may be separated from fats by the action of *hydrochloric acid*. When castor-oil is dissolved in absolute alcohol, and hydrochloric acid gas is passed through the heated solution for some time, and the liquid is agitated with water, an aqueous solution of glycerin is obtained, surmounted by an oily liquid. On decanting the watery liquid with a siphon, evaporating to a syrup, and treating the residue with ether, that liquid dissolves out the fatty acids of the castor-oil, and leaves the glycerin. (Rochleder, *Ann. Ch. Pharm.* lix. 260.)

Properties.—Glycerin, concentrated as much as possible by evaporation, is an uncrystallisable syrupy liquid, colourless, inodorous, sweet to the taste, neutral to test-paper. Its specific gravity is 1.260 at 15.5° C. (60° F.) When it is distilled *per se*, only a small portion passes off undecomposed, but in an atmosphere of steam it distils without decomposition.

Glycerin dissolves in *water* in all proportions. The following table exhibits the specific gravities and freezing points of aqueous solutions containing different percentages by weight of glycerin.

Glycerin per cent.	Specific gravity.	Freezing point.	Glycerin per cent.	Specific gravity.	Freezing point.
10	1.024	-1° C.	60	1.159	} below -35° C.
20	1.051	-2.5°	70	1.179	
30	1.075	-6°	80	1.120	
40	1.105	-17.5°	90	1.232	
50	1.127	-31.34°	94	1.241	

When an aqueous solution of glycerin freezes, only a portion of the water passes into the solid state, while a more concentrated solution of glycerin still remains liquid. (Fabian, *Dingl. pol. J.* clv. 345.)

Glycerin dissolves also in all proportions in *alcohol* and in *chloroform*, but is insoluble in *ether*.

Glycerin dissolves *iodine* in large quantity, forming an orange-yellow solution, without decomposition. Aqueous glycerin dissolves *arsenious acid* more abundantly than pure water, the solution depositing part of the acid on standing, and more quickly when boiled. (Schiff, *Ann. Ch. Pharm.* cxviii. 86.)

With *baryta*, *strontia*, and *lime*, glycerin forms compounds soluble in water and not precipitated by carbonic acid. Even in the anhydrous state, it dissolves considerable quantities of *potash* and *soda*. It dissolves all *deliquescent salts*, and many others, e.g. the *sulphates of potassium, sodium, and copper*, the *chlorides of potassium and sodium*, &c. Aqueous and even anhydrous glycerin dissolves *oxide of lead*, and consequently does not precipitate a solution of basic acetate of lead. Other bodies, insoluble in water, are not dissolved by anhydrous glycerin (Pelouze). *Sesquichloride of iron* mixed with a large quantity of glycerin is not precipitated by alkalis or alkaline sulphides (H. Rose). *Sulphate of copper* mixed with glycerin forms, with a small quantity of potash, a precipitate which dissolves in excess of potash; but the resulting blue solution decomposes below 100° C., depositing bluish flakes.

Glycerin dissolves the *vegetable acids*, and dissolves or suspends the *vegetable alkalis* in the same manner as aqueous liquids, the resulting products being available for the same purposes as though mixed with oil. Thus the salts of *morphine* dissolve in it completely, even cold, in all proportions. *Sulphate of quinine*, in the proportion of one-tenth, dissolves in it when hot, but when cold, separates in clots, which, when

trituated with the supernatant liquid, give it the consistence of a cerate, very useful for frictions and embrocations. It is the same with the salts of *brucine*, *strychnine*, *veratrine*, and most preparations of the same order.

Uses.—The solvent powers of glycerin, its unctuous character, and its property of remaining liquid even at low temperatures, together with its perfect harmlessness, render it a valuable agent in pharmacy, as an excipient for various substances, and for many other purposes, as in the preparation of cosmetics. It is used also for mixing with soap, forming the “glycerin-soap” recommended for softening the skin. It has been found very useful as an outward application in skin-diseases and inflammations of the mucous membranes of the nose, mouth, &c., and has been used in diseases of the eye and ear, and as a substitute for cod-liver oil in the treatment of phthisis; but its efficacy in these latter cases is not yet satisfactorily proved.

Glycerin may also be used for preserving articles of food, especially those which require to be kept moist, as sugar, fruits, chocolate, &c., enclosed in tin cases. Meat keeps well in it, retaining its flavour and softness. A very useful application of it is to mix with tobacco for the purpose of keeping it moist.

Barreswil recommends the use of glycerin for keeping modelling clay moist. It is also useful as a solvent for gum-arabic and white of egg, the solutions remaining unaltered for a long time, and for *aniline-violet* (*aniline* or *indisine*); the solubility of this colouring matter in glycerin has not been exactly ascertained, but it appears to dissolve more freely in that liquid than in alcohol or acetic acid. (C. Gros-Renaud, *Rép. Chim. app.*, 1859, p. 427.)

Amadon (*Technologiste*, January 1858, p. 191), describes a process of madder-dyeing with the aid of glycerin. Alizarin and alcoholic madder-extract dissolve in glycerin even in the cold; at higher temperatures more quickly and in larger quantity, so that the liquid acquires a deep scarlet colour. The alcoholic extract of madder does not yield any deposit on cooling, or on addition of water, but the solution of alizarin in glycerin deposits red flocks on being mixed with water.

Messrs. Vasseurs and Houbigant have patented (May 21, 1858), the application of glycerin for the preparation of ink, paper, and other materials. Glycerin diluted with four or five times its weight of water, imparts to paper the peculiarity of retaining a permanently damp condition, so that, in taking copies of letters, &c., written on paper so prepared, pressure and damping of the copying paper will not be required. The writing paper may be prepared either by introducing glycerin into the pulp of which it is to be manufactured, or by damping it therewith after it has been made up into books or otherwise. Or, ink may be prepared or combined with glycerin, and writings effected with the ink so treated will remain for a long period in a sufficiently damp state to allow of copies or impressions being taken without pressure or damping of the copying paper.

Glycerin may also be employed, instead of common salt, for preserving untanned skins and hides, especially when intended for exportation, and therefore requiring rapid means of applying a preserving agent. Paste, cement, mortar, mastic, and other inatters, especially when intended for daily use, may be treated with glycerin, in order to keep them in a suitably damp condition; this treatment will also have the effect of preserving them from frost. Vesicatory or blister paper, lint, and textile fabrics, particularly cloths, rags, and bandages, intended for medical or surgical purposes, may be treated with glycerin to render them absorbent.

As glycerin never freezes, and is not altered by exposure to the air, it may be advantageously applied as a lubricator for delicate machinery, such as clockwork. For this purpose it is superior to the purest olein or oleic acid, the lubricants commonly used, as the former thickens by oxidation, and the latter solidifies at a few degrees below the freezing point of water. It may also be added to the water of gas-meters to prevent freezing and evaporation. The introduction of a few drops of it into the tube of a mercurial pressure-gauge is said to prevent the mercury from sticking to the surface of the glass, and thus enable it to record the pressure more exactly. (Friedheim, *Dingl. pol. J.* clxvi. 237.)

Lastly, it is well adapted for filling the *floating compasses* used on board screw-steamers, being preferable for that purpose to water, alcohol, or fluid tar, the liquids hitherto employed, because it neither solidifies in cold, nor evaporates in hot climates. (Santi, *Compt. rend.* li. 1093.)

Impurities and Adulterations.—Glycerin prepared by the older methods (1 and p. 876) is apt to be contaminated with small quantities of lead or lime. The former may be detected by sulphydric acid; the latter by dissolving the glycerin in its own volume of alcohol containing 1 per cent. of sulphuric acid, in which case, if lime is present, a precipitate will be formed. (Cap, *J. Pharm.* [3] xxv. 81.)

Glycerin prepared by distillation is free from these and all other mineral impurities; but the great extension which has of late years been given to the industrial application

of this compound has led to the practice of adulterating it with various kinds of sugar. This adulteration, even if it amounts to three-fourths of the entire liquid, is not easily detected by ordinary observation, since the sugar does not alter either the taste or the syrupy character of the glycerin; but it may always be discovered, whatever the kind of sugar employed for adulteration, by examining the liquid with polarised light, inasmuch as all kinds of sugar (excepting mannite, which is too costly for the purpose) turn the plane of polarisation either to the right or to the left, whereas glycerin is totally destitute of optical rotatory power. The only kinds of sugar likely to be used for adulterating glycerin are cane-sugar, starch-sugar, and syrups containing uncrystallisable sugar (p. 864). The two former of these sugars turn the plane of polarisation to the right, though in different degrees; the third turns it to the left; moreover cane-sugar when boiled for about ten minutes with one-tenth of its volume of strong hydrochloric acid, is *invert. d.*, that is, converted into *laevo-rotatory*, uncrystallisable sugar (p. 864), whereas starch-sugar (dextroglucose) remains unaltered when thus treated. The direction of the rotatory power possessed by the solution before and after treatment with hydrochloric acid, serves therefore to distinguish between these two kinds of sugar. The optical method serves also to determine the quantity of either kind of sugar used to adulterate the glycerin; but for the mode of applying it for this purpose, we must refer to the article SACCCHARIMETRY.

Another method of detecting and estimating either kind of sugar in glycerin is by means of *chloroform*, in which glycerin dissolves with ease, whereas cane-sugar and glucose are quite insoluble. The liquid is first heated to expel the water contained in it, then mixed with chloroform; the whole is then poured upon a tared filter, and repeatedly washed with chloroform, after which the filter with its contents is dried at 100° C. and weighed. (Palm, Zeitschr. anal. Chem. 1862, p. 486.)

The presence of glucose may also be detected by boiling the liquid with caustic *potash* or *soda*: if glucose is present, a brown colour will be produced, whereas glycerin, either pure or adulterated only with cane-sugar, will not produce this colour (Cap; Palm). According to Palm, the presence of cane-sugar may be detected by adding a drop or two of *dilute sulphuric acid*, and heating the liquid in the water-bath till all the water is expelled; if cane-sugar is present, the liquid ultimately blackens, an effect which is not produced by glycerin, either pure or containing only glucose.

Decompositions.—1. Glycerin distilled *per se* passes over partly unaltered; but the greater portion suffers decomposition, yielding acrolein, acetic acid, empyreumatic oil, combustible gas, and carbonic anhydride, together with polyglyceric compounds (p. 894).—2. Distilled with *phosphoric anhydride*, it yields a distillate of pure acrolein ($C^3H^4O = C^2H^3O^2 - 2H^2O$).—3. Distilled with *acid sulphate of potassium*, it also yields acrolein, but mixed with acrylic acid and other secondary products, likewise giving off sulphurous anhydride, and leaving a carbonaceous residue.—4. With free access of air, glycerin *burns* with a clear flame like an oil.—5. Anhydrous or nearly anhydrous glycerin in contact with *platinum-black*, becomes heated, gives off a slightly acid vapour, and, according to Dübner, is converted into a non-volatile, uncrystallisable acid, which, with aid of heat, reduces mercurous nitrate and nitrate of silver. If the experiment be made in oxygen gas over mercury, complete absorption takes place in a few hours, the same acid is formed, but is ultimately converted into water and carbonic anhydride.—6. When the aqueous solution of glycerin is evaporated in contact with the *air*, a brown substance is formed which is precipitated by basic acetate of lead.—7. Glycerin is rapidly decomposed by *peroxide of manganese* and *hydrochloric* or *sulphuric acid*, yielding carbonic anhydride and a large quantity of formic acid.—8. Glycerin is oxidised by *nitric acid*, the nature of the products varying according to the manner in which the action takes place. If it be moderated by external cooling, and by carefully pouring the nitric acid to the bottom of the aqueous glycerin, so that the liquids may mix gradually, the chief products are oxalic acid and glyceric acid, $C^3H^4O^4$ (p. 876). When syrupy glycerin is added by drops to a mixture of equal volumes of strong nitric and sulphuric acids, cooled by a freezing mixture, a substitution-product, *nitroglycerin*, $C^3H_5(NO^2)_3PO^2$, is formed.—9. Glycerin dissolved in a large quantity of water, and exposed to the air for several months in contact with well-washed *yeast*, gives off a few gas-bubbles, and is converted into propionic acid (Redtenbacher).—10. A moderately concentrated aqueous solution of glycerin (1 pt. glycerin to 10 pts. water) exposed to diffused daylight in an open flask in contact with certain *animal membranes* (the membrane of the testicle answers best), is converted, in an interval varying from one to twelve weeks, into glucose (Berthelot, p. 857). Glycerin gently heated with *hydrate of potassium* is converted into acetate and formate of potassium, with evolution of hydrogen:

11. With *cupric acetate* or *sulphate*, glycerin forms a deep blue liquid, which deposits

a small quantity of cuprous oxide when boiled. Potash added to the mixture throws down a precipitate which dissolves in excess of potash, and the liquid thus formed deposits bluish flakes at 100° C.—12. From solution of *trichloride of gold* glycerin throws down a dark purple powder.—13. Glycerin enclosed for several months in a bottle filled with *chlorine*, is converted, with formation of hydrochloric acid, into a syrupy liquid, from which water separates flakes of a white fusible substance, having an unpleasant ethereal odour and a harsh bitter taste.—14. Glycerin heated in sealed tubes with *bromine* and water, yields hydrobromic and glyceric acids, together with bromoform and carbonic anhydride (Barth).—15. When bromine is dropped into heated anhydrous glycerin, acrolein is formed, together with an oil containing a small quantity of dibromhydrin, but probably consisting chiefly of bromacetic acid, as, when treated with boiling water, it yields a considerable quantity of glycollic acid (Barth, Ann. Ch. Pharm. cxxiv. 341).—16. Glycerin dissolves *iodine* without decomposition.—17. With *di-iodide of phosphorus*, it yields trityleno-gas, a distillate of water and iodotriethylene (iodide of allyl), and a residue containing oxygen-acids of phosphorus, together with free iodine, undecomposed glycerin, and a trace of red phosphorus. The principal part of the action appears to take place as represented by the equation :

18. With *tribromide* and *pentabromide of phosphorus* glycerin yields the bromhydrins (i. 667); several liquids which volatilise in vacuo at 200° C. or above, and appear also to be bromhydrins; a brominated compound, volatile between 65° and 67° C.; acrolein; and dibromallylphosphine = P.H.(C³H⁴Br)² (Berthelot and De Luca, Ann. Ch. Phys. [3] xlviii. 304).—19. Similarly with *trichloride* and *pentachloride of phosphorus*, glycerin yields the chlorhydrins (i. 893) though in small quantity only; most of these compounds are more readily produced by the direct action of hydrochloric acid upon glycerin (Berthelot).—20. With *chloride of sulphur*, glycerin yields dichlorhydrin and another compound, which appears to be a glyceryl-sulphurous ether; if, however, the glycerin is heated for a considerable time with a larger excess of chloride of sulphur, trichlorhydrin is produced (Carius, Ann. Ch. Pharm. cxxii. 222, footnote).

21. Glycerin heated with *acids* is, for the most part, transformed into glycerides or glycerylic ethers (p. 877), the proportions of the acid and glycerin which enter into the combination varying according to the proportions in which they are mixed, the temperature and pressure to which the mixture is subjected, and the time for which the action is continued: in most cases two or more compounds are formed at the same time. Thus, with *acetic acid* it forms the acetins (i. 25), with *citric acid* the citrins (i. 1001), with *phosphoric anhydride* or *glacial phosphoric acid*, it yields glycerophosphoric acid, C³H⁵PO⁶ (p. 891); with strong *sulphuric acid*, glycerosulphuric acid, C³H⁵SO⁴ (p. 892). With *cyanic acid* it forms allophanate of glyceryl, C³H⁵O³.(CHNO)³ (i. 134). With *hydrobromic* and *hydrochloric acids* glycerin forms the bromhydrins and chlorhydrins. When saturated with *hydriodic acid* and heated to 100° C. for forty hours, it yields the so-called iodhydrin, C³H¹¹O³ (Berthelot), which is a derivative of pyroglycide (p. 894): (C³H⁵)²H²O⁴ + HI - H²O = C³H¹¹O³; but when heated with a saturated solution of the same acid to 145° C. for five hours, it forms a solid black substance, and a liquid which yields, by distillation, iodide of allyl, C³H³I. This compound is also formed abundantly when glycerin is distilled with hydriodic acid; if, however, the proportion of the latter is increased, the iodide of allyl gradually disappears, and is replaced by iodide of trityl, C⁶H³I. The brown or black residue of the distillation yields, when distilled with water, white needle-shaped crystals insoluble in water. If the same residue be exhausted with alcohol, the solution evaporated over the water-bath to a syrup, and then mixed with potash, a brown solution is formed which deposits white aromatic iodated crystals, not yet examined. (Erlenmeyer, Zeitsch. Ch. Pharm. 1861, pp. 362, 673.)

Nitroglycerin. C³H⁵N³O⁹ = C³H³(NO³)³O³. *Glonoïn*.—Discovered by Sobrero (Compt. rend. xxiv. 247); further investigated by Railton (Chem. Soc. Qu. J. vii. 222), and De Vrij (J. Pharm. [3] xxviii. 38). A compound produced by the action of a mixture of strong nitric and sulphuric acids on glycerin at low temperatures.

Preparation.—1. A hundred grammes of syrupy glycerin of specific gravity 1.262 are gradually added to 200 c. c. of nitric acid of specific gravity 1.52, immersed in a freezing mixture, the liquid being continually stirred, the temperature allowed to fall to -10° C. before each fresh addition, and never to rise above 0°. A homogeneous mixture having been thus obtained, 200 c. c. of strong sulphuric acid are gradually added, the mixture being still kept below 0°. The oily nitroglycerin (200 grms.) which then floats on the surface is separated by a tap-funnel from the acid liquid (which yields 20 grms. more of nitroglycerin on being diluted with water), and dissolved

in the smallest possible quantity of ether: the solution is repeatedly shaken with water till the water no longer reddens litmus; the ether evaporated; and the remaining nitroglycerin heated over the water-bath till its weight remains constant. The product amounts to 184 grms. of pure nitroglycerin (De Vrij). According to Railton, nitroglycerin is decomposed by evaporation, even in vacuo over sulphuric acid, at ordinary temperatures.

2. Half an ounce of dehydrated glycerin is poured, with constant stirring, into a mixture of 2 oz. of oil of vitriol and 1 oz. fuming nitric acid of specific gravity 1.52, the temperature of the mixture being kept below 25° C. by external cooling with ice; and, as soon as oily drops begin to form on the surface, the mixture is poured, with constant stirring, into 50 ounces of cold water. Nitroglycerin then separates, and may be purified by washing and drying, in small portions, in a vapour-bath. (Liebe, Arch. Pharm. ciii. 168; civ. 282—See also Sobrero, Rép. Chim. app. ii. 400.)

Properties.—Nitroglycerin is a light yellow oily liquid, of specific gravity 1.595 to 1.600, at 15° C. (De Vrij); inodorous, but has a sweet pungent aromatic taste, and when placed upon the tongue, even in small quantity, produces headache, which lasts for several hours (Sobrero). Slightly soluble in water, more soluble in alcohol and in ether.

Nitroglycerin, when left to itself, frequently undergoes spontaneous decomposition, but, when well purified, it may be kept for a long time without alteration. De la Rue and Müller (Ann. Ch. Pharm. cix. 122) found glyceric acid among the products of decomposition of nitroglycerin, which had been left to itself in an apartment the temperature of which rose sometimes to about 30° C. Oxalic acid was likewise formed, together with an acid the barium-salt of which was not crystallisable. At 160° C. it decomposes, with evolution of red vapours, and at higher temperatures sometimes explodes with sufficient violence to shatter the containing vessel; sometimes takes fire without explosion. It detonates when struck. Mixed with fuming *hydriodic acid*, it decomposes below 100° C., yielding glycerin and pure nitric oxide (Mills). Its ethereal solution is decomposed by *sulphydic acid*, with copious precipitation of sulphur (De Vrij). Nitroglycerin, heated with aqueous *potash*, is decomposed, with formation of glycerin and nitrate of potassium (Railton):

According to Gladstone, nitroglycerin exhibits different properties according to the manner in which it is prepared. Ordinary hydrated glycerin added to a mixture of 3 pts. sulphuric and 1 pt. fuming nitric acid, is converted into a liquid which detonates violently under the hammer; but anhydrous glycerin treated in like manner yields a non-explosive body which burns without noise. Both kinds of nitroglycerin, when exposed to a mixture of solid carbonic acid and alcohol, become gummy, and assume the appearance of fatty acids; and both decompose spontaneously, with evolution of red vapours. A sample of nitroglycerin which decomposed in this manner on exposure to summer sunshine, yielded crystals of oxalic acid, together with two liquids, the upper of which contained nitric acid, ammonia, oxalic acid, hydrocyanic acid, and other compounds not examined (Reports of the British Association, 1856; Jahresb. f. Chem. 1857, 479.) Mills found that nitroglycerin kept for a fortnight no longer exploded when struck, but showed no signs of decomposition or chemical alteration. (Communication from G. C. Foster.)

GLYCEROCITRIC ACID. *Citroglyceric acid*.—Obtained by heating a mixture of glycerin and citric acid not strongly enough to produce the citric ethers of glycerin described at p. 1001, vol. i. (Van Bemmelen, Scheik. Onderzoek. ii. 1; Jahresb. 1859, p. 434.) Lourenço has obtained a glycerocitric acid containing $\text{C}^3\text{H}^4\text{O}^6$ (p. 894).

GLYCERO-OXALIC ACID. *Oxaloglyceric acid*.—This acid is produced when oxalic acid is heated with glycerin, before the temperature has risen high enough to induce the resolution of the oxalic acid into formic acid and carbonic oxide (p. 686). Its calcium-salt is soluble in water, and the solution is not precipitated by alcohol, but deposits oxalate of calcium when heated after addition of ammonia. (Van Bemmelen, loc. cit.)

GLYCEROPHOSPHORIC ACID. *Phosphoglyceric acid*. $^+\text{C}^3\text{H}^5\text{PO}^4 = (\text{PO})^3\text{H}^5\text{O}^3$. (Pelouze, Compt. rend. xii. 718.—Gobley, J. Pharm. [3], ix. 161; xi. 409; xii. 5.—Gm. ix. 492; Gerh. i. 770.)—This acid exists in the yolk of eggs and in the brain (Gobley), and is produced by the action of phosphoric acid or phosphoric anhydride on glycerin (Pelouze). To obtain it in this way, glycerin is mixed with excess of phosphoric anhydride, or glacial phosphoric acid; the mixture is dissolved in water, and neutralised, first with carbonate of barium, then with baryta-water; the solution is filtered from phosphate of barium, and treated with a quantity of sulphuric acid just sufficient to precipitate the baryta; and the filtrate is evaporated in vacuo.

To obtain it from the yolk of eggs, that substance is freed from the greater part of its water by heat, then exhausted with boiling alcohol or ether; the filtrate evaporated; the residue, consisting of egg-oil and a viscid substance, collected on a filter and left to drain in the hot air chamber till the greater part of the oil has run off; and the residual viscid matter is pressed between folds of paper, renewed as often as any oil is thereby extracted. The soft, orange-yellow, translucent mass, smelling of yolk of egg, is then heated with dilute potash in the water-bath for 24 hours; the solution slightly supersaturated with acetic acid, and filtered from oleic, margaric acid, &c.; the filtrate precipitated with neutral acetate of lead; the precipitated glycerophosphate of lead washed, suspended in water, and decomposed by sulphydric acid; the filtrate concentrated by gentle evaporation, and freed from a small quantity of hydrochloric acid by agitation with a small quantity of oxide of silver and filtration; the silver precipitated by sulphydric acid; the filtered liquid freed from a small quantity of acid phosphate of calcium by saturation with lime-water; the liquid separated by filtration from the phosphate of calcium, and the solution of glycerophosphate of calcium evaporated to the crystallising point. The crystals are purified by again dissolving them in water, filtering, and recrystallising; the lime precipitated from their aqueous solution by an equivalent quantity of oxalic acid; and the filtrate evaporated in vacuo. (Gobley.)

Glycerophosphoric acid is also produced by the action of baryta-water on *lecithin*, a phosphoretted fat contained in the brain. (Strecker, Compt. rend. lii. 1270.)

Glycerophosphoric acid is an uncrystallisable liquid. It may be concentrated by evaporation to a certain point, but beyond that it decomposes into phosphoric acid and glycerin. When concentrated in vacuo, it thickens and becomes viscous. It has a very acid taste, is very soluble in water and in alcohol, and yields, when carbonised, a strongly acid cinder.

The glycerophosphates are for the most part soluble in water, but insoluble or sparingly soluble in alcohol.

The *barium-salt*, $\text{C}^3\text{H}^7\text{Ba}^1\text{PO}^6$ (at 150°C .), is very soluble in water, and is precipitated from the solution by alcohol.

The *calcium-salt*, $\text{C}^3\text{H}^7\text{Ca}^1\text{PO}^6$ (at 120°C .), forms snow-white, pearly laminae, inodorous, but having a rather sharp taste. It sustains a heat of 170° without decomposition, but blackens at a somewhat stronger heat. When boiled down with lime and water, it is resolved into phosphate of calcium and glycerin. It dissolves much more abundantly in cold than in boiling water, so that it separates almost completely from the cold solution on boiling. From the aqueous solution it is precipitated by alcohol.

The *lead-salt*, $\text{C}^3\text{H}^7\text{Pb}^1\text{PO}^6$, is insoluble in water.

GLYCEROSULPHURIC ACID. *Sulphoglyceric Acid.* $\text{C}^3\text{H}^5\text{SO}^4 = \left. \begin{matrix} (\text{C}^3\text{H}^5)^{''''} \\ (\text{SO}^2)^{''} \\ \text{H}^8 \end{matrix} \right\} \text{O}^1$.

—(Pelouze, Ann. Ch. Phys. lxxiii. 21; Gm. ix. 494; Gerh. i. 770.)—Produced by the action of strong sulphuric acid upon glycerin. 1 pt. of glycerin is mixed with 2 pts. sulphuric acid; the mass, when cold, is dissolved in water; the solution saturated with lime, filtered, and evaporated to a syrup; the crystals of the calcium-salt which separate on cooling are collected and dissolved in water; the lime is precipitated from the solution by the proper quantity of oxalic acid; and the liquid is filtered.

By this process, *aqueous glycerosulphuric acid* is obtained in the form of a colourless, inodorous, strongly acid liquid, which is so unstable that it decomposes into sulphuric acid and glycerin when evaporated in vacuo at a few degrees below 0°C , even if it still retains a considerable quantity of water.

The aqueous acid decomposes carbonates. The glycerosulphates decompose with great facility, and are very soluble in water. The potassium and calcium-salts yield, by dry distillation, sulphurous anhydride, acrylic acid, acrolein, and secondary products of decomposition. (Redtenbacher, Ann. Ch. Pharm. xlvii. 118.)

The *barium-salt* is decomposed, when its aqueous solution is heated with baryta, even below 100°Q , into sulphate of barium, which is precipitated, and an aqueous solution of glycerin.

The *calcium-salt*, $\text{C}^3\text{H}^5\text{Ca}^1\text{S}^2\text{O}^{12}$, forms colourless needles which have a bitter taste. It begins to decompose between 140° and 150°C ., emitting an intolerable odour of distilled tallow, and leaves, first a carbonaceous residuum, then a white residue of sulphate of calcium. The aqueous solution is not decomposed by lime-water at ordinary temperature, but on boiling for a short time with lime-water, it contains sulphate of calcium. The salt dissolves in less than 1 pt. of water, but not in alcohol.

Other salts are soluble in water.

Sulphurous acid (*schwefelichte Säure*), which Dulk obtained by treating sulphuric acid, and the sulphadipic acid obtained in like manner by Chevreul, were perhaps identical with glycerosulphuric acid.

GLYCEROTARTARIC ACIDS. By heating tartaric acid and glycerin in various proportions and to various temperatures, four acids are obtained, the formation of which is attended with elimination of quantities of water less than would be required for the formation of normal glycerides (p. 877). They are composed as follows:

The first of these acids was discovered by Berzelius (*Traité de Chimie*); the other three by Des Plats. (Compt. rend. xlix. 216.)

Glycerotartaric acid, $\text{C}^7\text{H}^{13}\text{O}^8 = \left\{ \begin{array}{l} \text{C}^3\text{H}^5 \\ \text{H}^3 \end{array} \right\} \text{O}^6$.—Produced by heating equi-

valent quantities of glycerin and coarsely pounded tartaric acid (or effloresced paratartaric acid), to about 150°C . (Berzelius); by heating equal weights of glycerin and tartaric acid to 100°C . for forty hours (Des Plats). The mixture on cooling is transparent, and solidifies to a soft ropy mass. It is inodorous, has a faint but purely acid taste, absorbs moisture from the air, and changes to a thick syrup. It is insoluble in pure ether, but dissolves easily in ether-alcohol. In the syrupy state, it may be preserved unaltered. Neither carbonate nor acetate of potassium, added to it in small quantity, produces any precipitate of acid tartrate of potassium.

The syrupy acid, mixed with a large quantity of water, is partly resolved into glycerin and tartaric acid; the decomposition is accelerated by warming the liquid, but on evaporating the mixture and again heating it to 150°C ., the glycerotartaric acid is reproduced.

Glycerotartaric acid expels carbonic acid from alkaline and earthy carbonates, forming soluble salts which have a gummy aspect. The glycerotartrates are insoluble in alcohol, which precipitates them from aqueous solution. They are tasteless. The neutral salts, dissolved in a large quantity of water and evaporated, decompose, yielding glycerin and tartaric acid (Berzelius). The decomposition is accelerated by addition of baryta- or lime-water. (Des Plats.)

The barium-salt contains $\text{C}^4\text{H}^{12}\text{Ba}^1\text{O}^{10}$.

Glycerotartrate of calcium, $\text{C}^{14}\text{H}^{22}\text{Ca}^1\text{O}^{16} + 3\text{aq.}$, is prepared by saturating aqueous glycerotartaric acid with carbonate of calcium, evaporating, filtering to remove a quantity of tartrate of calcium which separates in confused crystals, and adding alcohol to the concentrated solution. It then separates in the form of a thick pulp, which sticks to the sides of the vessel when the liquid is agitated; the portion which remains suspended in the alcohol takes several days to settle down. On dissolving the precipitated salt in a small quantity of water, and filtering to separate any small portion of tartrate that may be present, a colourless solution is obtained, which may be evaporated without decomposition at a gentle heat. The residue forms a colourless mass, having the lustre and aspect of glass, and splitting when dried. The salt is not deliquescent; it cannot be deprived of its crystallisation-water without decomposition. (Berzelius.)

Glyceroditartaric acid, $\text{C}^{11}\text{H}^{16}\text{O}^{13} = 2 \left\{ \begin{array}{l} \text{C}^3\text{H}^5 \\ \text{H}^7 \end{array} \right\} \text{O}^8$.—Obtained by heating

equal weights of glycerin and tartaric acid with a certain quantity of water to 100°C . for fifty hours. It is dibasic, its barium- and calcium-salts having the composition $\text{C}^{11}\text{H}^{14}\text{M}^2\text{O}^{12}$. (Des Plats.)

Epiglyceroditartaric acid, $\text{C}^{11}\text{H}^{14}\text{O}^{12} = 2 \left\{ \begin{array}{l} \text{C}^3\text{H}^5 \\ \text{H}^3 \end{array} \right\} \text{O}^8$.—This acid, which

is related to the preceding in the same manner as epidichlorhydrin to dichlorhydrin, is obtained by heating equal weights of glycerin and tartaric acid to 140°C . It is monobasic, the barium- and calcium-salts containing $\text{C}^{11}\text{H}^{12}\text{MO}^{12}$. (Des Plats.)

Glycerotritartaric acid, $\text{C}^{13}\text{H}^{22}\text{O}^{19} = 3 \left\{ \begin{array}{l} \text{C}^3\text{H}^5 \\ \text{H}^{11} \end{array} \right\} \text{O}^{12}$.—Obtained by heating

1 pt. glycerin with 20 pts. tartaric acid to 140°C ., or 1 pt. glyceroditartaric acid with 15 pts. tartaric acid for 30 hours. It is tetrabasic, the barium and calcium-salts containing $\text{C}^{13}\text{H}^{14}(\text{M}')^4\text{O}^{18}$. (Des Plats.)

GLYCERYL. C^3H^5 . The triatomic radicle of glycerin and the

GLYCERYL, BROMHYDRATES and BROMIDE OF

HYDRINS (i. 667).

GLYCERYL, CHLORHYDRATES and CHLORIDE OF. See **CHLORHYDRINS**, (i. 893.)

GLYCERYL, HYDRATES OF. Besides glycerin, which is the normal hydrate of glyceryl, three others are known, which are analogous in constitution to the polyethylenic alcohols (p. 576), and may be derived from glycerin by dehydration, in the same manner as the polyethylenic alcohols are derived from glycol; thus:—

In addition to these compounds, which have been actually obtained, the hypothetical body glycide, $\text{C}^3\text{H}^5\text{O}^2$, must also be mentioned, which is the alcohol of the glycide ethers, and is related to glycerin in the same manner as pyroglycide to pyroglycerin, differing from it, that is to say, by 1 at. H^2O .

The polyglyceric compounds are obtained by distilling glyceric chlorhydrin with excess of glycerin, in the same manner as the polyethylenic alcohols are obtained from glycolic bromhydrin and excess of glycol (p. 576). When glycerin, diluted with one-third its bulk of water, is saturated at 100°C . with hydrochloric acid gas, an equal quantity of glycerin then added, the whole heated to 120°C . in a flask with ascending passing tube, for 12—15 hours, and then distilled, water and hydrochloric acid pass off till the temperature rises to 150° ,—then between 150° and 275° , a distillate (A), consisting of dichlorhydrin, together with the chlorhydric ethers of the polyglyceric alcohols. (Lourenço, Compt. rend. lii. 359.)

Diglycerin or Pyroglycerin, $\text{C}^6\text{H}^{11}\text{O}^5$.—The brown residue, distilled between 220° and 230° in rarefied air, yields pyroglycerin, as a thick liquid insoluble in ether, sparingly soluble in cold, easily in hot water, miscible in all proportions with alcohol.

Its formation is represented by the equation—

Chlorhydrodiethyl-pyroglycerin, $\text{C}^{10}\text{H}^{21}\text{ClO}^4 = \left\{ \begin{array}{c} \text{C}^6\text{H}^3 \\ \text{C}^2\text{H}^3 \end{array} \right\} \text{O}^4 \text{Cl}$.—Produced by heating diethylin (p. 884) with epichlorhydrin to 200°C .

also, together with ethyl- and diethyl-chlorhydrin, by heating epichlorhydrin with alcohol to 200°C . It is a yellowish oily liquid, of sp. gr. 1.11 at 17°C ., boiling at 285° , sparingly soluble in water, miscible in all proportions with alcohol and ether. (Reboul and Lourenço, Compt. rend. lii. 401.)

Triethyl-pyroglycerin, $\text{C}^{12}\text{H}^{26}\text{O}^5 = \left\{ \begin{array}{c} \text{C}^6\text{H}^3 \\ \text{H} \end{array} \right\} \text{O}^5$.—Produced, together with diethylin

and tetrethyl-triglycerin, by the action of epichlorhydrin on ethylate of sodium [? containing alcohol]. After all the diethylin has passed over, the portion which distills between 280° and 300°C . is collected apart and rectified.

Triethylpyroglycerin is a colourless oily liquid, of sp. gr. 1.00 at 14°C ., boiling at about 290° , soluble in water, alcohol, and ether, and precipitated from the aqueous solution by carbonate of potassium. (Reboul and Lourenço, *loc cit*.)

Triglycerin, $\text{C}^9\text{H}^{20}\text{O}^7$, passes over after the pyroglycerin, between 275° and 285°C ., as a liquid similar to the latter, but more viscid and consistent.

As the temperature rises to 320°C ., products of continually greater complexity pass over, as in the preparation of the polyethylenic alcohols.

Tetraethyl-triglycerin, $\text{C}^{15}\text{H}^{34}\text{O}^7 = \left\{ \begin{array}{c} \text{C}^6\text{H}^3 \\ \text{C}^2\text{H}^3 \end{array} \right\} \text{O}^7$.—If the oily residue boiling above 300°C . obtained in the preparation of triethyl-pyroglycerin be distilled in air rarefied to 20 mm., this compound passes over at about 290° , as a yellowish liquid, of specific gravity 1.023 at 14° , soluble in water, alcohol and ether. (Reboul and Lourenço.)

Diglycide, Pyroglycide, or Metaglycerin, $C^3H^{10}O^4$, which has the composition of pyroglycerin minus H^2O , is obtained from that portion of the distillate A (p. 894) which passes over under the ordinary atmospheric pressure between 170° and $270^\circ C$. (and consists of dichlorhydrin, together with the chlorhydric ethers of the polyglycerin alcohols) by cautiously decomposing the portion boiling between 230° and 270° with ignited potash, distilling the liquid decanted from the chloride of potassium which separates, and collecting the portion which goes over between 245° and 255° . It is a colourless oil, soluble in water and in alcohol, insoluble in ether.

Polyglyceric compounds may also be obtained by distilling glycerin under the ordinary atmospheric pressure, and treating the portion which goes over between 130° and $260^\circ C$. with ether. The undissolved portion boils at a temperature above 300° under a pressure of 10 mm., and yields polyglyceric compounds. The glycerin is, perhaps, first converted into glycide, by loss of water ($C^3H^5O^2 - H^2O = C^3H^3O^2$), and the glycide then unites with 1, 2, or 3 at. glycerin, forming the polyglyceric compounds. (Lourenço.)

GLYCERYL, IODEHYDRATES OF. See IODHYDRINS.

GLYCERYL, OXIDE OF. $C^3H^5O^2 = \frac{C^3H^5}{C^3H^3} \{ O^2 \}$.—Obtained by the action of potash on iodhydrin. It is a liquid soluble in ether and volatile without decomposition. (Berthelot.)

GLYCERYL, OXYGEN-SALTS OF. See ACETINS, BENZOINS, BUTYRINS, &c.

GLYCERYL, SULPHYDRATES OF. *Thioglycerins*. (Carius, Ann. Ch. Pharm. cxxii. 72; cxxiv. 222.)—The oxygen of glycerin may be wholly or partly replaced by sulphur, yielding the three compounds:

These compounds are produced by the action of alcoholic sulphhydrate of potassium on mono-, di- and trichlorhydrin. They are syrupy liquids of unpleasant ethereal odour, soluble in alcohol, very sparingly soluble in water, insoluble in ether. They react with metallic oxides and salts like sulphhydrate of ethyl (mercaptan), forming compounds in which the typic hydrogen is more or less replaced by a metal, in proportion to the number of sulphur-atoms in the thioglycerin. The general formulæ of the metallic derivatives of the three thioglycerins are therefore:

The thioglycerins are decomposed by heat, trithioglycerin giving off sulphydric acid, and leaving dithioglycide, while the other two compounds give both sulphydric acid and water, and yield sulphuretted compounds analogous to pyroglycide; thus:

The thioglycerins are oxidised by nitric acid, forming glycerosulphurous ethers, monothioglycerin yielding *glycerin-monosulphurous acid*, which is monobasic, and dithioglycerin yielding *pyroglyci-trisulphurous acid*, a dibasic acid related in composition to trithiopyroglycide. The salts of these acids are represented by the formulæ:

GLYCID. $C^3H^5O^2 = \frac{C^3H^5}{H} \{ O^2 \}$.—The hypothetical alcohol corresponding to the glycidic ethers. It differs from glycerin, in the same manner as oxide of ethylene, C^2H^4O , differs from glycol, $C^2H^6O^2$, viz. by 1 at. water.

glycerides by the action of water or of alcohols, or generally speaking of acids, although Reboul states that epichlorhydrin is very slowly converted into trichlorhydrin by boiling with hydrochloric acid. It is, however, most convenient to describe them in connection with the glycidic ethers of the first series, to which they are certainly related by their mode of formation.

The polyglyceric compounds and the glycidic ethers of the first series are related to glycerin in the same manner as metaphosphoric acid and some of its modifications to orthophosphoric acid; this will be seen from the following table:

Types . .	2H ² O.	3H ² O.	4H ² O.	5H ² O.	6H ² O.	7H ² O.	9H ² O.
Glycidic Series .	$\left(\begin{smallmatrix} \text{C}^2\text{H}^3 \\ \text{H} \end{smallmatrix} \right)^{\text{'''}} \text{O}^2$	$\left(\begin{smallmatrix} \text{C}^2\text{H}^3 \\ \text{H}^2 \end{smallmatrix} \right)^{\text{'''}} \text{O}^2$	$\begin{smallmatrix} \text{C}^2\text{H}^3 \\ \text{C}^2\text{H}^3 \\ \text{H}^2 \end{smallmatrix} \text{O}^2$	$\begin{smallmatrix} \text{C}^2\text{H}^3 \\ \text{C}^2\text{H}^3 \\ \text{H}^1 \end{smallmatrix} \text{O}^2$	$\begin{smallmatrix} \text{C}^2\text{H}^3 \\ \text{C}^2\text{H}^3 \\ \text{C}^2\text{H}^3 \\ \text{H}^2 \end{smallmatrix} \text{O}^2$	$\begin{smallmatrix} \text{C}^2\text{H}^3 \\ \text{C}^2\text{H}^3 \\ \text{C}^2\text{H}^3 \\ \text{H}^2 \end{smallmatrix} \text{O}^2$	$\begin{smallmatrix} \text{C}^2\text{H}^3 \\ \text{C}^2\text{H}^3 \\ \text{C}^2\text{H}^3 \end{smallmatrix} \text{O}^2$

	Metaphosphoric acid.	Orthophosphoric acid.	Maddrell's metaphosphate of sodium.	Pyrophosphoric acid.	Fleitmann and Hennenberg's metaphosphate of sodium.		Phosphoric anhydride.

The polyglycerides constitute the intermediate links between glycide and the true glyceric ether or glyceride anhydride. (*Kekulé's Lehrbuch*, ii. 117.)

The greater number of the following compounds have been prepared and partially described by Berthelot (See BROMHYDRINS and CHLORHYDRINS); but the experiments of Reboul have rendered our knowledge of them much more exact.

A. Glycidic ethers containing 1 at. Acid- or Alcohol-radicle.

Amylglycide. $\text{C}^2\text{H}^1\text{O}^2 = \left(\begin{smallmatrix} \text{C}^2\text{H}^3 \\ \text{C}^2\text{H}^1 \end{smallmatrix} \right)^{\text{'''}} \text{O}^2$.—Produced by the action of potash on amylechlorhydrin (p. 884). When a mixture of equal volumes of epichlorhydrin and amylic alcohol is heated to 220° C. for ten or twelve hours in a sealed tube; the resulting yellowish oily liquid distilled; the portion which goes over between 225° and 260°, and contains amylechlorhydrin, shaken up with excess of strong boiling potash-ley; the oil which separates from the resulting solution of chloride of potassium on addition of water distilled; and the portion which passes over between 180° and 220° C. several times rectified,—amyglycide is obtained as a mobile liquid of specific gravity 0.90 at 20° C., and having an odour of ripe quinces. It is insoluble in water, boils at 188°, is inflammable, and burns with a bright flame. By agitation with fuming hydrochloric acid, it is converted into amylechlorhydrin, $\text{C}^2\text{H}^4(\text{C}^2\text{H}^1)\text{ClO}^2$, and by hydrotromic and hydriodic acids, into the corresponding brom- and iod-hydrins. Heated with water in sealed tubes, it takes up H²O, and is converted into amylin, $\text{C}^2\text{H}^7(\text{C}^2\text{H}^1)\text{O}^2$.

Ethylglycide. $\text{C}^2\text{H}^1\text{O}^2 = \left(\begin{smallmatrix} \text{C}^2\text{H}^3 \\ \text{C}^2\text{H}^1 \end{smallmatrix} \right)^{\text{'''}} \text{O}^2$.—Produced by the action of potash on ethylchlorhydrin. The formation of this latter compound, by heating epichlorhydrin with ethylic alcohol in sealed tubes to 180° C., is attended with the production of considerable quantities of dichlorhydrin and diethylin, according to the equation:

The greater part of the resulting liquid distils between 188° and 189° C.; and the distillate, treated with potash, yields an ethereal oil which distils for the most part between 126° and 130°, and consists of ethylglycide mixed with a considerable quantity of epichlorhydrin (produced by the action of the alkali on the dichlorhydrin). The ethylglycide may be freed from the greater part of the epichlorhydrin by treatment with alcoholic potash. It is a mobile liquid, having a faint but agreeable ethereal odour, boiling between 128° and 129° C., and of nearly the same density as water. It dissolves in 4 or 5 times its volume of cold water, somewhat more freely in

hot water, and is separated from the solution by chloride of calcium. Its reactions are similar to those of amylglycide.

Monobromhydroglycide. *Epibromhydrin.* $(C^3H^5)^m \begin{Bmatrix} Br \\ O \end{Bmatrix}$. — Produced by the action of alkalis on dibromhydrin; also, together with other products, by the action of pentachloride of phosphorus on glycerin (p. 890). It boils at 138° — 140° C., unites with fuming hydrochloric acid, forming bromochlorhydrin, C^3H^5BrClO , and with hydriodic acid, forming iodobromhydrin. (See IODHYDRINS.)

Monochlorhydroglycide. *Epichlorhydrin.* $(C^3H^5)^m \begin{Bmatrix} Cl \\ O \end{Bmatrix}$. — Produced by the action of alkalis on dichlorhydrin. To prepare the latter, a mixture of 5 vols. glycerin (the commercial product dehydrated by heating it to about 170° C. may be used) and 4 vols. glacial acetic acid is saturated at 100° C. with hydrochloric acid gas, and then distilled; whereby a distillate is obtained between 180° and 220° consisting of dichlorhydrin, mixed with a large quantity of acetodichlorhydrin and a small quantity of acetochlorhydrin. This distillate may be used immediately for the preparation of epichlorhydrin (the acetodichlorhydrin being converted by the potash into dichlorhydrin, with formation of acetate of potassium). For this purpose a lukewarm solution of 350 grms. caustic potash in the smallest possible quantity of water, is added by small portions to 500 grms. of the distillate just mentioned, the liquid being well shaken and left to cool after each addition; the whole is then left to itself for an hour or two; the oily layer which floats on the surface is removed and distilled; the portion which goes over below 165° C. is collected apart; and this by repeated fractional rectification, yields pure epichlorhydrin.

Epichlorhydrin is a mobile liquid, of specific gravity 1.194 at 11° C.; it boils at 118° or 119° ; smells like chloroform; has a sweet taste, with burning aftertaste; burns with a bright, smoky, green-edged flame. It is nearly insoluble in water, but takes up a small quantity of it, and retains it obstinately; soluble in all proportions in alcohol and ether. Its vapour-density is by experiment = 3.21; by calculation (2 vols.) = 3.19.

Strong sulphuric acid acts violently on epichlorhydrin; if it is added by drops, and the liquid kept cool, no hydrochloric acid is evolved, but the liquid becomes viscid, and a so-called conjugated sulphuric acid appears to be formed.

Chloride of zinc likewise acts violently on epichlorhydrin, hydrochloric acid being evolved and the mass blackening if not sufficiently cooled, whereas if the temperature is prevented from rising, the two substances simply unite. Epichlorhydrin is converted by pentachloride of phosphorus into trichlorhydrin:

and by pentabromide of phosphorus into chlorodibromhydrin, $C^3H^5Br^2Cl$ (i. 894), a liquid of specific gravity 2.085 at 9° C., and boiling at 202° — 203° .

Epichlorhydrin heated with alcoholic ammonia to 100° C. in a closed vessel forms chloride of ammonium, and a white gummy mass, consisting of diglyceryl- $\begin{matrix} C^3H^5 & N \\ & | \\ & O^2 \end{matrix}$ dihydrochloramine, or hemichlorhydramide, $C^6H^{12}ClNO^2 = \begin{matrix} C^3H^5 & \\ & | \\ & H \end{matrix} \begin{matrix} O^2 \\ Cl \end{matrix}$, ana-

logous to Berthelot's hemibromhydramide (i. 668; ii. 875):

With cold aqueous ammonia, epichlorhydrin thickens and gradually dissolves; and the liquid, after neutralisation with hydrochloric acid, contains chloride of ammonium, and an encrystallisable salt, from whose highly concentrated solution caustic potash throws down a reddish gummy base, which redissolves on the addition of a small quantity of water.

Epichlorhydrin unites directly with hydrochloric acid, forming dichlorhydrin, $C^3H^5Cl^2O$ (boiling at 180° C.); with hydrobromic acid, forming bromochlorhydrin, C^3H^5BrClO (a colourless oily liquid of specific gravity 1.740 at 12° C., boiling at 197° , having a faint odour like that of dichlorhydrin, sparingly soluble in water); and with hydriodic acid, forming iodochlorhydrin, C^3H^5IClO (see IODHYDRINS). The combination is in all cases attended with evolution of heat, which is considerable when epichlorhydrin is agitated with fuming hydrochloric acid; stronger with fuming hydrobromic acid; and especially violent with fuming hydriodic acid, each drop of the acid producing a hissing noise.

Epichlorhydrin heated with amyl alcohol in sealed tubes, unites with it, forming amyl-chlorhydrin; but at the same a secondary reaction takes place, resulting in the formation of dichlorhydrin and diamylin:

With *ethyl alcohol* a similar reaction takes place, but the secondary products bear a larger proportion to the ethylchlorhydrin produced by direct combination (p. 897).

Mono-iodhydroglycide. *Epi-iodhydrin*, C^H^2IO .—This compound cannot be prepared in the same manner as the two preceding, inasmuch as di-iodhydrin has not been obtained, not being produced from glycerin by the action either of hydriodic acid or of iodide of phosphorus. *Epi-iodhydrin* may, however, be prepared by heating epichlorhydrin with iodide of potassium to 100° in a sealed tube, care being taken to purify the materials from water as much as possible, since its presence would give rise to the formation of iodhydrin, $C^H^2HIO^2$. On treating the product of the reaction with a small quantity of water, to dissolve chloride of potassium and the excess of iodide, there remains a heavier liquid, from which, by distillation and repeated rectification of the portion which distils between 160° and $180^\circ C$, pure *epi-iodhydrin* is obtained.

Epi-iodohydrin is a mobile ethereal liquid, having a somewhat alliaceous odour; specific gravity 2.03 at 13°C; insoluble in water; soluble in all proportions in alcohol and ether. With *hydrochloric acid* it forms iodochlorhydrin, C^3H^5IOClO , identical with the compound formed by the combination of HI and C^3H^5ClO ; with *hydriodic acid*, it yields a viscid heavy liquid, strongly coloured by iodine, and probably containing di-iodhydrin, $C^3H^5I^2O$.

B. Glycidic ethers containing 2 at. Bromine, Chlorine, &c.

These compounds are produced by the action of alkalis on the triatomic glycerides containing 3 at. Br, Cl, &c.

Dibromhydroglycide. *Epidibromhydrin*. (C^2H^4) Br^2 or ($\text{C}^2\text{H}^4\text{Br}$) Br .—Obtained by treating tribromhydrin, $\text{C}^2\text{H}^3\text{Br}^3$, with solid hydrate of potassium (a small quantity of acrolein being formed at the same time); distilling the heavy oil which passes over; and rectifying the portion which distils below 156°C . It is a liquid, insoluble in water, of specific gravity 2.06 at 11°C ., having a distinctly alliaceous odour, and boiling at 151° — 152°C . It is decomposed by *alcoholic ammonia*, slowly in the cold, completely by heating for several hours to 100°C ., yielding bromide of ammonium and dibromallylamine (i. 146):

The formation of this base tends to support the supposition that the compound $C^3H^4Br^2$ contains the monatomic radicle C^3H^4Br (p. 896).

Epidibromhydrin unites directly with 2 at. bromine, forming the compound $C_2H_4Br^+ = (C_2H_4Br)^+Br^-$, a liquid of specific gravity 2.64, and boiling, with slight evolution of hydrobromic acid, at $250^\circ - 252^\circ C$.

Dichlorohydroglycide. *Epichlorohydrin*. $(C^2H^4)^nCl^2$ or $(C^2H^4Cl)^nCl$.—Metamerie with dichlorotriptylene. When trichlorohydrin is gently heated with lumps of solid potash, chloride of potassium is formed, with rise of temperature and violent action, and a distillate is obtained, consisting of water, with a lower layer of liquid, which, when freed from a small quantity of epichlorohydrin by agitation with sulphuric acid diluted with half its bulk of water, and distilled, yields epidichlorohydrin, as a liquid boiling with partial decomposition between 101° and $102^\circ C.$, of specific gravity 1.21 at 20° , having a pungent, ethereal, somewhat allineous odour, insoluble in water, soluble in all proportions in alcohol and ether. It unites slowly at $100^\circ C.$ with *hydrochloric, hydrobromic, and hydriodic acids*, forming triatomic glycerides; with water, and alcohols it does not unite, even at 100° . It unites directly with 2 at. *bromine*, forming the compound $C^2H^4Cl^2Br^2 = (C^2H^4Cl)^2Br^2Cl$, a liquid insoluble in water, of specific gravity 2.10 at $13^\circ C.$, boiling at $220^\circ - 221^\circ$.

Chlorobromhydroglycide. *Epichlorobromhydrin*. $(\text{C}^3\text{H}^3)\text{ClBr}$, or $(\text{C}^3\text{H}^3\text{Cl})\text{Br}$, or $(\text{C}^3\text{H}^3\text{Br})\text{Cl}$.—Produced by heating chlorodibromhydrin (i. 874; ii. 898) with solid potash, and purified like the preceding compound. Colourless liquid, turning yellow when exposed to light; smells like epichlorohydrin; boils at $126^\circ\text{—}127^\circ\text{C}$. Specific gravity 1.69 at 14°C . It is not perceptibly decomposed by heating with water, to 100°C . for two days. Not attacked by sodium in the cold, but slowly when heated, with formation of bromide of sodium. It unites directly with 2 at. *bromine*, forming the compound $\text{C}^3\text{H}^3\text{ClBr}_2 = (\text{C}^3\text{H}^3\text{Cl})\text{Br}_2$, a liquid of specific gravity 2.39 at 14°C , and boiling, with slight evolution of hydrobromic acid, at 238° .

GLYCIDYL. C^3H^4 .—The diatomic radicle which may be supposed to exist in the glycidic ethers (p. 896).

GLYCOCOLIC ACID. $C^2H^3NO_3$.—This acid, discovered by L. Gmelin (*Handbuch*, 3^{re} Aufl. ii. 833), constitutes, in the form of a sodium-salt, the essential part of ox-bile, in which it is mixed with small quantities of taurocholic acid, mucus, cholesterin, cholechroom, &c. (i. 585). Its composition and metamorphoses have been chiefly studied by Strecker. (*Ann. Ch. Pharm.* lxx. 9; lxxii. 1; lxx. 161 and 166.)

Preparation.—1. The precipitate formed in fresh ox-bile by neutral acetate of lead is treated with boiling alcohol of 85 per cent., and the liquid is filtered hot, so as to obtain a solution of a lead-salt sufficiently concentrated to become turbid on cooling. The residue is exhausted on the filter with alcohol, and this alcohol is used for the treatment of new precipitates. Sulphydic acid gas is then passed into the hot concentrated solution; the sulphide of lead is separated by filtration and washed with a large quantity of water; and the liquid is left at rest as soon as it begins to become turbid. After twelve hours, it is found to be converted into a white crystalline mass, which is to be washed with cold water.

2. Fresh ox-bile is evaporated to dryness over the water- or sand-bath; the residue is coarsely pulverised and treated with cold absolute alcohol; and the filtered solution, after addition of a small quantity of ether, is left to itself; after some hours, the bottom of the vessel is found to be covered with a tenacious, strongly coloured mass. On decanting the liquid, treating it with fresh quantities of ether, and leaving it at rest, it deposits a considerable quantity of plumose crystals (Plattner's crystallised bile), which go on gradually increasing. The remaining liquid is decanted, and the residue after washing with a small quantity of ether, is dissolved in water, while still saturated with ether. The solution is then mixed with dilute sulphuric acid, till it becomes milky, after which it is left at rest. Twelve or twenty-four hours afterwards, it becomes filled with crystals, usually mixed with drops of an oily liquid; these crystals are thrown on a filter and washed with cold water. This process yields a larger product than the former.

Glycocholic acid prepared by either of these methods is mixed with a certain quantity of an isomeric body called *paraglycocholic acid* (p. 901). To free it from this admixture, the crystals are washed with cold water and then treated with boiling water: the paraglycocholic acid then remains in the form of insoluble scales, whilst the glycocholic acid dissolves and crystallises out as the solution cools.

Properties and Reactions.—Glycocholic acid crystallises in bulky groups of white slender needles, which contract considerably in drying, and cover the paper with a thin silky film; 1000 pts. of cold water dissolve 3·3 pts. of it; 1000 pts. of boiling water dissolve 8·3 pts.; the cold aqueous solution has a saccharine and slightly bitter taste, reddens litmus, and is not precipitated by acids, neutral acetate of lead, mercuric chloride, or nitrate of silver; but forms a slight precipitate with basic acetate of lead.

Glycocholic acid is easily soluble in *alcohol*, and the solution evaporated over the water-bath leaves a residue which is syrupy at first, but afterwards becomes resinous. On mixing the alcoholic solution with water till it becomes milky, it deposits after 24 hours, a quantity of needle-shaped crystals, the liquid becoming clear at the same time. The acid is very soluble in *ether*.

The solutions of glycocholic acid turn the plane of polarisation to the right. The specific rotatory power is +27·2° for red, and +29·9° for yellow light; it is not diminished by combination with alkalis. (F. Hoppe, Chem. Centr. 1859, 65.)

Glycocholic acid dissolves readily in aqueous *ammonia*, in dilute *potash*- and *soda*-ley, and in *baryta-water*. The addition of acids, even of acetic acid, to these solutions throws down a resinous substance, which changes after a while into crystals resembling those of wavelite. This transformation of the acid into crystals is produced with greater rapidity by ether.

Glycocholic acid boiled with *potash* is resolved into cholic acid and glycochine (p. 902):

The same decomposition is produced by *baryta-water* at the boiling heat.

Acetic acid dissolves glycocholic acid, and deposits it in crystals when left to evaporate.

Glycocholic acid dissolves easily at common temperatures in strong *hydrochloric* or *sulphuric acids*, and is precipitated therefrom by water; but if the acid solution be boiled, it becomes turbid and deposits oily drops of cholonic acid, which solidify after a while:

Glycocholic acid dissolved in water and boiled with *hydrochloric acid*, yields first choloidic acid and afterwards dyslysin (p. 380), together with glycochine. As dyslysin and choloidic acid differ from cholic acid only by the elements of water, this transformation is similar to that produced by boiling potash.

On adding to a solution of glycocholic acid, or an alkaline glycocholate, a few drops of solution of *sugar*, then strong *sulphuric acid* by small quantities at a time, and applying a gentle heat, a violet or purple colour is produced, which disappears on addi-

tion of water. This is Pettenkofer's test (see *BILL*, i. 586). For the application of this test to the detection of biliary acids in the urine, see *URINE*; also *Neukomm* (*Ann. Ch. Pharm.* cxvi. 30).

Glycocholates.—The general formula of these salts is $C^{\alpha}H^{\alpha}MNO^{\alpha}$, the acid being monobasic. All the glycocholates are soluble in alcohol; those of the alkali- and earth-metals are easily soluble in water; the rest are sparingly soluble, and may be obtained by precipitation. The solutions of the glycocholates have a sweet and slightly bitter taste.

Ammonium-salt.—When dry ammonia-gas is passed into a solution of glycocholic acid in absolute alcohol, in such quantity that no precipitate is formed, needle-shaped crystals separate from the liquid after a while, increasing in number when it is left at rest in closed bottles. The addition of ether accelerates their formation. They lose a considerable quantity of ammonia when kept under an exhausted receiver.

Barium-salt. $Ba''(C^{\alpha}H^{\alpha}NO^{\alpha})_2$.—Glycocholic acid dissolves easily in baryta-water, and on removing the excess of baryta by carbonic acid, then boiling, filtering, and evaporating, glycocholate of barium separates in the form of a white amorphous mass.

The calcium-salt is soluble in water.

The cupric salt is a bluish white precipitate.

The ferric salt forms yellowish flocks, very soluble in alcohol.

The lead-salt is a flocculent precipitate obtained on mixing neutral acetate of lead with an alkaline glycocholate; the precipitation is not however complete, a certain quantity of lead always remaining in solution; it may be completely prevented by adding acetic acid to the solution of the alkaline glycocholate before pouring in the acetate of lead. Basic acetate of lead precipitates sodic glycocholate completely; the precipitate is soluble in alcohol and in excess of acetate of lead.

The magnesium-salt is soluble in water. The potassium-salt closely resembles the sodium-salt.

The silver-salt is obtained as a white gelatinous precipitate on adding nitrate of silver to the solution of an alkaline glycocholate. The precipitate dissolves partially on boiling (completely if the solutions are dilute), and separates again on cooling; in needles if the liquid cools slowly, in the gelatinous form on rapid cooling; but it then becomes crystalline on addition of ether. The salt becomes coloured on exposure to light.

The sodium-salt, $C^{\alpha}H^{\alpha}NaNO^{\alpha}$, constitutes a considerable proportion of ox-bile. It is obtained in the pure state by dissolving glycocholic acid in aqueous carbonate of sodium and evaporating to dryness; or by agitating an alcoholic solution of the acid with effloresced carbonate of sodium, and evaporating off the alcohol. On dissolving the residue in absolute alcohol, and adding ether to the solution, glycocholate of sodium separates in stellate groups of colourless needles, exactly like crystallised bile. It is very soluble in water, less soluble in absolute alcohol, 1000 pts. of alcohol dissolving 15.39 parts of it. When the aqueous solution is evaporated, the salt separates on the edge of the capsule in undulated amorphous crusts; the alcoholic solution behaves in the same manner if evaporated over the water-bath, but yields crystals when very slowly evaporated in a flask. According to *Städeler* (*J. pr. Chem.* lxxii. 267) glycocholate of sodium is precipitated in the amorphous state by ether, even from the alcoholic solution of the pure crystallised salt, and more completely in proportion as the alcohol and the ether have been thoroughly freed from water; whence it appears that a certain quantity of water is essential to the crystallisation of the salt. In fact, it separates in a few minutes in very fine stellate groups of needles, without any admixture of the amorphous salt, on adding to the alcoholic solution a sufficient quantity of ether to produce a strong milky turbidity, then dropping in water and stirring till the turbidity just disappears.

Glycocholate of sodium melts when heated, and then burns with a smoky flame, leaving a very fusible cinder, which has an alkaline reaction and contains a large quantity of cyanate.

Glycocholate of strontium is soluble in water; consequently the solutions of alkaline glycocholates do not precipitate the solutions of strontium-salts.

Paraglycocholic acid. This acid, isomeric with glycocholic acid, constitutes that portion of the precipitate formed by sulphuric acid in crystallised bile, which is insoluble in boiling water; it is composed of nacreous scales, which exhibit under the microscope the form of hexagonal tablets. Similar crystals are found amongst the needles of glycocholic acid crystallised from boiling water; and by dissolving the latter in a fresh portion of boiling water, a certain quantity of the insoluble acid may be separated. It agrees with glycocholic acid in composition (67.10 per cent. C, 9.25 H, and 3.01 N, and 20.64 O), and in all its properties, excepting its crystalline form and insolubility in water; it likewise yields salts which are undistinguishable from the glycocholates. It is therefore merely a physical modification of glycocholic acid.

GLYCOCINE, or **GLYCOCOL**. $C^2H^3NO^2 = \left(\begin{smallmatrix} H^2 \\ C^2H^2O \end{smallmatrix} \right) \left\{ \begin{smallmatrix} N \\ O \end{smallmatrix} \right\}$. *Sugar of Gelatin.*

Leimzucker. Leimsüss. Glycollamic acid. (Gm. ix. 247; Gerh. i. 214.)—An organic base homologous with alanine ($C^2H^3NO^2$) and leucine ($C^2H^5NO^2$). It was discovered by Braconnot (Ann. Ch. Phys. [2] xiii. 114), who obtained it by the action of sulphuric acid on gelatin. It is also produced by the action of caustic alkalis on gelatin, or on meat (Mulder, J. pr. Chem. xvi. 290); by boiling hippuric acid with hydrochloric acid. (Dessaignes, Ann. Ch. Phys. [3] xvii. 50):

in the metamorphosis of glycocholic and hyoglycocholic acid, under the influence of alkalis (Strecker, Ann. Ch. Pharm. lxxvii. 25; lxx. 188):

and by the action of ammonia on bromacetic acid (Perkin and Duppa, i. 664), or chloracetic acid (Cahours):

Preparation.—1. By the action of potash on gelatin. Glue is boiled with potash-ley, which gives rise to a copious evolution of ammonia; the liquid is neutralised with sulphuric acid, evaporated, separated from sulphate of potassium, which crystallises out, and again evaporated; and the residue is exhausted with alcohol, which takes up the glycocine, together with a small quantity of leucine, from which the glycocine may be easily separated by crystallisation, as it is much less soluble in alcohol than leucine (Mulder). Milk of lime may be used instead of potash. (Boussingault.)

The preparation of glycocine by the action of sulphuric acid upon gelatin is less advantageous, because a considerable quantity of leucine is formed at the same time.

2. Hippuric acid is boiled for half an hour with strong hydrochloric acid, and the liquid is diluted with water and left to cool; the greater part of the benzoic acid then separates, while the glycocine remains in solution. The decanted liquid is evaporated over the water-bath to expel the excess of hydrochloric acid; the dried residue is treated, first with ammonia, then with absolute alcohol; and the glycocine, which remains in the form of a crystalline powder, is washed on a filter with absolute alcohol.

3. Glycocholic acid is boiled for some time with hydrate of barium; the liquid is filtered to separate the crystalline cholate of barium which forms, then treated with carbonic acid to remove the excess of baryta, and with hydrochloric acid to precipitate a small quantity of cholic acid which remains in solution.

The whole of the baryta is next precipitated by sulphuric acid; the liquid boiled with hydrate of lead to remove sulphuric and hydrochloric acid; and the excess of lead precipitated by sulphydric acid. The colourless solution thus obtained deposits crystals of glycocine by evaporation.

Properties.—Glycocine crystallises much more readily than cane-sugar, a pellicle soon forming on the surface of its solution during evaporation. The crystals are granular, very hard, and crackle between the teeth. They are flattened prisms or aggregated plates, belonging to the monoclinic system, with the faces ∞P , ∞P_2 , ∞P_{∞} , (∞P_{∞}) , (P_{∞}) , $2P_2$. Ratio of the principal axis, clinodiagonal and orthodiagonal, = 1 : 1.8667 : 2.2036. Inclination of clinodiagonal to principal axis = $68^{\circ} 20'$. $\infty P : \infty P$ in the clinodiagonal principal section = $103^{\circ} 52'$; $(P_{\infty}) . (P_{\infty}) = 134^{\circ} 16'$; $(\infty P_{\infty}) : \infty P_2 = 111^{\circ} 23'$. Cleavage very distinct, parallel to (∞P_{∞}) (Schabus, *Bestimmung der Krystallgestalten in chemischen Laboratorien erzeugter Producte*, Wien. 1855, S. 16; see also Keferstein, Pogg. Ann. xcix. 276). The crystals melt more easily than common sugar, and have a sweet taste about equal in strength to that of grape-sugar.

Glycocine is sparingly soluble in water, insoluble in ether, and in absolute alcohol, even at the boiling heat, but dissolves with moderate facility in hydrated alcohol. According to Mulder and Horsford, it has no acid reaction with vegetable colours, but according to Dessaignes it reddens litmus sensibly. It decomposes acetate of copper at the boiling heat, expelling the acetic acid, and dissolves lime when boiled for some time with chalk (Dessaignes). According to Horsford (Ann. Ch. Pharm. lx. 1), glycocine prevents the precipitation of copper from the sulphate by potash, and its aqueous solution dissolves oxide of copper, forming a blue solution which deposits needles on cooling.

Decompositions.—1. The crystals of glycocine begin to turn brown at $170^{\circ} C$, the lower part giving off gas, while the upper part melts and crystallises again on cooling. At 190° , partial carbonisation takes place (Horsford).—2. The crystals of glycocine, boiled with strong potash-solution, assume a fiery-red colour, and give off ammonia;

but if the heat be continued, the colour disappears. On adding hydrochloric acid to the residue, hydrocyanic acid is disengaged, and the liquid is found to contain oxalic acid (Horsford). The same fiery-red colour is also produced by heating glycocine with hydrate of barium or oxide of lead. Dilute potash and baryta-water do not eliminate ammonia from glycocine.—3. Glycocine heated with *anhydrous baryta* gives off methylamine (mixed with ammonia), and leaves carbonate of barium.—4. With *hydrate of potassium*, the same products appear to be formed in the first instance, but the methylamine is immediately decomposed into ammonia and free hydrogen, and the residue contains oxalate of potassium as well as carbonate:

and

(Cahours, Ann. Ch. Phys. [3] liii. 322; Ann. Ch. Pharm. cix. 29).—5. *Strong sulphuric acid* blackens glycocine when heated with it.—6. When glycocine is heated with a mixture of *dilute sulphuric acid* and *peroxide of lead* or *manganese*, carbonic anhydride is evolved, and the liquid yields by distillation pure hydrocyanic acid:

—7. On boiling glycocine with water and peroxide of lead alone, a strong ammoniacal distillate is obtained, and the residue contains carbonate of lead, but no cyanide or formate.—8. It is oxidised by *mercurous nitrate*, the mercury being reduced to the metallic state.—9. *Nitrous acid* converts glycocine into glycollic acid, which may be separated from the liquid by agitating with other and evaporating:

(Socoloff and Strecker, Ann. Ch. Pharm. lxxx. 18; Dessaignes, Compt. rend. xxxviii. 44).—10. Glycocine boiled for some time with *nitric acid*, or treated with a mixture of *chlorate of potassium* and *hydrochloric acid*, is converted into an acid, which, when saturated with ammonia, yields with chloride of barium a crystalline precipitate, containing, according to Horsford, $\text{C}^2\text{H}^4\text{BaO}^2$. The same acid is produced from glycocine by the action of *chlorine-water*, *nitrous acid* (?) or *permanganate of potassium* (Horsford).—11. *Chlorine gas* immediately attacks the crystals of glycocine, separating water and hydrochloric acid, and producing a hard brown substance partly soluble in water. The acid solution when concentrated deposits large prisms. *Bromine* and *iodine* act like chlorine.—12. Glycocine heated in sealed tubes with *benzoic acid* is converted into hippuric acid (Dessaignes, J. Pharm. [3] xxxii. 44):

Hippuric acid is likewise produced by treating the zinc-salt of glycocine with *chloride of benzoyl* (Dessaignes, Compt. rend. xxxvii. 251):

and by treating the silver-salt of glycocine with *chloride of anisyl*, $\text{C}^9\text{H}^7\text{O}^2\text{Cl}$, and *chloride of cumyl*, $\text{C}^{10}\text{H}^{11}\text{OCl}$, acids analogous to hippuric acid are obtained, viz. anisuric acid, $\text{C}^{10}\text{H}^{11}\text{NO}^3$, and eumauric acid, $\text{C}^{12}\text{H}^{13}\text{NO}^3$.

13. Glycocine mixed in solution with *cyanamide*, CN^2H^2 , unites with it, forming glycoeyamine, $\text{C}^2\text{H}^7\text{N}^3\text{O}^2$, a compound homologous with creatine (p. 96). (Strecker, Compt. rend. lii. 1212.)

14. According to Braconnot, the aqueous solution of glycocine is not thrown into fermentation by yeast, but according to Buchner (Ann. Ch. Pharm. lxxvii. 203), it is decomposed under the influence of a ferment, and in presence of an alkali, giving off carbonate of ammonium and yielding a number of other products.

Metallic Compounds of Glycocine. *Glycollamates* or *Oxyacetamates*.—The

general formula of these compounds is $\text{C}^2\text{H}^4\text{MNO}^2 = \left. \begin{matrix} \text{H}^2 \\ \text{C}^2\text{H}^4\text{O}^2 \\ \text{M} \end{matrix} \right\} \text{N}^1 \text{O}^1$.

The *potassium-salt*, obtained by evaporating a solution of glycocine in dilute potash to a syrup over the water-bath, forms alkaline, very deliquescent needles, which must be quickly washed with alcohol. The *barium-salt* is obtained in the crystalline state, by triturating glycocine with hydrate of barium, mixing the semifluid mass with water, and leaving the liquid to evaporate. The remaining salts are obtained by heating the respective oxides with an aqueous solution of glycocine. The *cadmium-salt*, $\text{C}^2\text{H}^4\text{Cd}^2\text{N}^2\text{O}^4$, forms foliated crystals having a silky lustre. The *copper-salt*, $\text{C}^2\text{H}^4\text{Cu}^2\text{N}^2\text{O}^4$, is obtained as above; also by treating a mixture of glycocine and sulphate of copper, first with potash and then with alcohol, which precipitates the compound at a certain degree of concentration of the liquid: It forms blue crystals, very soluble in water, not decomposed by carbonic acid. At 100°C , the crystals give off their water

of crystallisation, amounting to 8 per cent., and turn green. The *lead-salt*, $C^4H^4Pb^1N^2O^4$, obtained by boiling protoxide of lead in aqueous glycocine, and evaporating the filtrate out of contact of air, forms colourless needles, which are decomposed by carbonic acid. On adding alcohol to the filtrate obtained after boiling glycocine with oxide of lead, colourless needles are formed, resembling cyanide of mercury. The *mercury-salt*, $C^4H^4Hg^1N^2O^4.H^2O$, forms small crystals, the aqueous solution of which is decomposed by boiling, metallic mercury being separated, and formate of ammonium being produced. The *silver-salt*, $C^4H^4Ag^1NO^2$, is difficult to obtain of constant composition. Oxide of silver dissolves readily in aqueous glycocine, but to obtain a saturated solution, the mixture must be digested for some time at 80° to 100° C., then boiled for a few seconds, and filtered at the boiling heat.

Compounds of Glycocine with Acids and Salts. These compounds are produced by direct combination.

Acetate of Glycocine, $2C^2H^4NO^2.C^2H^4O^2.3H^2O$, is precipitated in crystals on adding alcohol to a solution of glycocine in acetic acid. It crystallises from solution in water.

Chromate of Glycocine. *Chromosaccharic acid*.—Chromosaccharate of potassium is deposited in crystals on adding alcohol to an aqueous mixture of glycocine and acid chromate of potassium. It decomposes in a few days, with separation of carbonaceous matter, even while immersed in the liquid.

Hydrochlorate of Glycocine.—A *monobasic salt*, $C^2H^4NO^2.HCl$, is produced by boiling hippuric acid with hydrochloric acid. It has an acid, slightly astringent taste, dissolves very easily in water and in common alcohol, sparingly in absolute alcohol. By dissolving glycocine in hydrochloric acid, and leaving the solution to cool, a *dibasic hydrochlorate*, $2C^2H^4NO^2.HCl$, is obtained in crystals belonging to the trimetric system. Dominant faces ∞P , ∞P_2 , ∞P_∞ , \bar{P}_∞ , $\frac{1}{2}\bar{P}_\infty$, P . Ratio of principal axis, macrodiagonal and brachydiagonal, = 1 : 1.1108 : 0.3091. $\infty P : \infty P$ in the brachydiagonal principal section = $148^\circ 54'$; $\infty P_2 : \infty P_2 = 121^\circ 48'$; $P_\infty : P_\infty = 96^\circ$; $\frac{1}{2}P_\infty : \frac{1}{2}P_\infty = 131^\circ 32'$. Cleavage very distinct, parallel to $\frac{1}{2}\bar{P}_\infty$ (Schabus, *loc. cit.* p. 902). On adding a concentrated solution of tetrachloride of platinum and excess of hydrochloric acid to an aqueous solution of glycocine, and then adding absolute alcohol drop by drop, cherry-coloured crystals are obtained of a platinum-salt containing $2(C^2H^4NO^2.HCl).PtCl^4$.

Glycocine combines with the *chlorides of potassium, sodium and barium*; also with *stannous chloride*. The barium-compound forms crystals apparently belonging to the rhombic system, with the dominant faces ∞P , P_∞ , ∞P_∞ .

Nitrate of Glycocine, or *Nitrosaccharic acid*, $C^2H^4NO^2.NO^2H$, is obtained by carefully evaporating a solution of glycocine in dilute nitric acid, in crystals which may be purified by recrystallisation. They belong to the trimetric system. Dominant faces, ∞P , ∞P_∞ , P_∞ , ∞P_∞ . Ratio of the principal and secondary axes = 1 : 3.4122 : 2.9687. Inclination of the faces, $\infty P : \infty P_\infty = 126^\circ 15'$; $P_\infty : \infty P_\infty = 106^\circ 20'$; $P_\infty : P_\infty = 142^\circ 30'$; $\infty P_\infty : \infty P_\infty = 90^\circ$; $\infty P_\infty : \infty P = 146^\circ 15'$. (Nicklès, *Compt. chim.* 1849, p. 256). The crystals have an acid, slightly saccharine taste, somewhat like that of tartaric acid. Nitrate of glycocine when heated swells up considerably, melts, though not completely, and gives off a pungent odour. It does not affect the solutions of the salts of the earth-metals or heavy metals. It dissolves iron and zinc with evolution of hydrogen. By slowly evaporating a solution of 2 at. glycocine in 1 at. nitric acid, Dessaignes obtained a basic nitrate, $2C^2H^4NO^2.NO^2H$, in crystals resembling nitrate of urea.

Nitrosaccharates.—These salts are obtained by saturating the solution of nitrosaccharic acid with various bases. The *potassium-salt*, $C^2H^4NO^2.NO^2K$, and the *calcium-salt* crystallise in needles sparingly soluble in alcohol. The *magnesium-salt* is uncrystallisable and deliquescent; the *lead-salt* uncrystallisable and gummy. The *sino-salt* is crystallisable, and may be obtained by dissolving metallic zinc in nitrosaccharic acid. The *copper-salt*, $C^2H^4Cu^1N^2O^4.Cu^1N^2O^4 + 2H^2O$, obtained by dissolving the copper-compound of glycocine in nitric acid, crystallises in blue needles, which give off their water of crystallisation and turn green at 150° C., and decompose with explosion at 180° or 182° . The *silver-salt*, $C^2H^4NO^2.NO^2Ag$, crystallises in needles, which absorb moisture from the air and alter quickly on exposure to light.

Oxalate of Glycocine is obtained by boiling hippuric acid with a concentrated solution of oxalic acid. The liquid first deposits benzoic acid, and afterwards oxalate of glycocine. The salt forms crystals belonging to the trimetric system, with dominant faces ∞P , ∞P_∞ , ∞P_2 , P_∞ . Ratio of principal and secondary axes = 1 : 3.0715 : 2.792. Inclination of $\infty P : \infty P_\infty = 132^\circ$; $\infty P : \infty P_2 = 162^\circ$; $\infty P_\infty : \infty P_2 = 113^\circ 48'$; $P_\infty : \infty P = 101^\circ 56'$; $P_\infty : P_\infty = 152^\circ 10'$. (Nicklès, *loc. cit.*)

Sulphate of Glycocine, or *Sulphosaccharic Acid*. $C^2H^4NO^2.SO^2H^2$ (?).—

Obtained by dissolving glycocine in sulphuric acid, in large colourless prisms, which are permanent in the air. They have a sour taste, do not give off anything at 100°, are soluble in water and in warm aqueous alcohol, insoluble in absolute alcohol, and in ether. According to Nicklès (*loc. cit.*), the crystals belong to the trimetric system, with the dominant faces ∞P , $\infty P\infty$, $\infty P\infty$, $P\infty$. Ratio of principal and secondary axes = 1 : 0.4244 : 0.3207. Inclination of faces, $\infty P : \infty P\infty = 126^\circ 10'$; $\infty P : \infty P\infty = 146^\circ$; $\infty P\infty : \infty P\infty = 90^\circ$; $\infty P : P\infty = 119^\circ 4'$; $P\infty : \infty P\infty = 113^\circ$; $P\infty : P\infty = 138^\circ 20'$. The composition of this compound has not been satisfactorily determined. Horsford obtained two kinds of crystals, to which he assigned the formulæ $C^4H^4NO^2.SO^2$ and $C^4H^4NO^4.SO^2$. The formula above given was suggested by Gerhard. Horsford likewise obtained two basic sulphates, the composition of which is doubtful. Sulphosaccharate of potassium is precipitated in transparent prisms on adding alcohol to an aqueous mixture of glycocine and acid sulphate of potassium.

Ethylglycocine, $C^4H^5NO^2 = C^2H^4(C^2H^3)NO^2$.—The hydriodate of this base is obtained by heating glycocine with iodide of ethyl and absolute alcohol in sealed tubes. It forms rhombic crystals, which when decomposed by oxide of silver yield the base in small crystals having an alkaline reaction. It forms a crystalline platinum-salt. (Schilling, *Ann. Ch. Pharm.* cxxvii. 97.)

Dimethyl-glycocine, $C^4H^6NO^2 = C^2H^3(CH^3)^2NO^2$.—The hydriodate of this base, $C^4H^6NO^2.HI$, (isomeric with the preceding) is obtained in like manner, together with another hydriodate (probably of methyl-glycocine) the latter crystallising out first. The hydriodate of dimethyl-glycocine crystallises in transparent rhombic prisms. (Schilling, *loc. cit.*)

Diglycollamic acid, $C^4H^7NO^4$, and **Triglycollamic acid**, $C^6H^9NO^6$. (Heintz, *Ann. Ch. Pharm.* cxxii. 267; cxxiv. 297.)—These acids are produced, simultaneously with glycocine (monoglycollamic acid) by the action of ammonia on chloracetic acid, the reactions taking place as shown by the equations:

To separate them, the solution obtained by boiling chloracetic acid with ammonia, after being freed from sal-ammoniac by precipitation with alcohol, is boiled with hydrate of lead. A precipitate is then formed consisting of oxychloride and triglycollamate of lead (from which the acid may be separated by sulphuretted hydrogen), and a solution of mono- and di-glycollamate of lead. This solution, after being freed from lead by sulphuretted hydrogen, is boiled with recently precipitated carbonate of zinc, whereby both the acids are converted into zinc-salts, which may be easily separated, the monoglycollamate (zinc-salt of glycocine) being easily soluble in water, while the diglycollamate is very sparingly soluble even at the boiling heat.

Both di- and triglycollamic acids in the free state are crystalline solids, less soluble in water than glycocine, insoluble in alcohol and ether. Their composition and mode of formation show that they are related to glycocine in the same manner as di- and triethylamine are related to ethylamine. The three compounds may be formulated as follows:

these formulæ being derived from the water-ammonia types,

by substitution of the diatomic radical, C^2H^3O , for the several pairs of bracketed hydrogen-atoms.

Each of these formulæ contains three atoms of hydrogen not included in the radicle C^2H^3O ; but in the first only one of these hydrogen-atoms belongs to the water-molecule, and is therefore easily replaceable by metals, whereas the second formula contains two, and the third three, hydrogen-atoms thus replaceable: hence glycocine is monobasic, diglycollamic acid is dibasic, and triglycollamic is tribasic.

Diglycollamic acid forms both neutral and acid salts, the *ammonium-salt* being $\text{O}^{\text{H}}(\text{NH})\text{NO}^{\text{A}}$, and the *copper-salt* $\text{C}^{\text{H}}\text{Cu}^{\text{N}}\text{NO}^{\text{A}}$. Triglycollamic acid forms di- and tri-metallic salts, its *barium-salt* being $\text{C}^{\text{H}}\text{Ba}^{\text{N}}\text{NO}^{\text{A}}$, and its *silver-salt* $\text{C}^{\text{H}}\text{Ag}^{\text{N}}\text{NO}^{\text{A}}$.

GLYCOCYAMIDINE. $\text{C}^{\text{H}}\text{N}^{\text{O}}$.—An organic base homologous with creatinine, and related to glycoeyamine in the same manner as creatinine to creatine. The *hydrochlorate*, $\text{C}^{\text{H}}\text{N}^{\text{O}}\text{O}^{\text{H}}\text{Cl}$, is obtained by heating hydrochlorate of glycoeyamine to 160°C . It is easily soluble in water, and forms, with *tetrachloride of platinum*, the double salt, $2(\text{C}^{\text{H}}\text{N}^{\text{O}}\text{O}^{\text{H}}\text{Cl})\cdot\text{PtCl}^{\text{A}} + 2\text{H}^{\text{O}}$.

The base itself is obtained by boiling the hydrochlorate with hydrate of lead. It is easily soluble in water, has an alkaline reaction, crystallises in laminæ, and forms with *chloride of zinc* a sparingly soluble needle-shaped salt, resembling the zinc-chloride of creatinine. (Strecker, Compt. rend. lii. 1212.)

GLYCOCYAMINE. $\text{C}^{\text{H}}\text{N}^{\text{O}}\text{O}^{\text{H}}$.—A compound homologous with creatine (p. 98), produced by the union of cyanamide, $\text{CN}^{\text{H}}\text{H}^{\text{N}}$, with glycocine, $\text{C}^{\text{H}}\text{N}^{\text{O}}\text{O}^{\text{H}}$. When a solution containing these two bodies, together with a little ammonia, is left to itself for a few days, colourless crystals of glycoeyamine are deposited, soluble in 126 parts of cold water, more soluble in hot water and in acids, insoluble in alcohol. The *hydrochlorate*, $\text{C}^{\text{H}}\text{N}^{\text{O}}\text{O}^{\text{H}}\text{Cl}$, obtained by saturating the base with hydrochloric acid gas, crystallises easily in rhomboidal prisms, and forms with *tetrachloride of platinum* the double salt, $2(\text{C}^{\text{H}}\text{N}^{\text{O}}\text{O}^{\text{H}}\text{Cl})\cdot\text{PtCl}^{\text{A}}\cdot 3\text{H}^{\text{O}}$, which becomes anhydrous at 100°C .

By boiling the solution of glycoeyamine with various metallic salts, precipitates are formed consisting of glycoeyamine in which 1 at. H is replaced by a metal. Thus, with acetate of copper, a light blue precipitate is formed, containing $\text{C}^{\text{H}}\text{Cu}^{\text{N}}\text{O}^{\text{A}}$.

GLYCOGEN. $\text{C}^{\text{H}}\text{O}^{\text{O}}$. *Animal starch. Animal dextrin. Hepatin.* (Cl. Bernard, Compt. rend. xli. 461; xlv. 578 and 1325; xlviii. 77, 763, and 884.—Hensen, Wurz. medic. Verhandl. vii. 219; Archiv. für pathol. Anatomie, ix. 214.—Sanson, Compt. rend. xlv. 1159 and 1323; xlv. 140 and 343.—Schiff, Compt. rend. xlviii. 880.—E. Pelouze, Compt. rend. xlv. 1321.—Bonnet, Compt. rend. xlv. 139 and 573.—Kekulé, Heidelb. naturw. Verhandl. 1858, Jan.; Chem. Centr. 1858, p. 300.—Poggiale, J. Pharm. [3] xxxiv. 99.—G. Harley, Proc. Roy. Soc. x. 289.—F. W. Pavy, Phil. Mag. [4] xvii. 142; Proc. Roy. Soc. x. 523; xi. 90.—Gorup-Besanez, Ann. Ch. Pharm. cxviii. 227.—R. M'Donnell, Proc. Roy. Soc. xii. 476.—Gm. xv. 183.—Jahresb. f. Chem. 1855, p. 734; 1856, p. 705; 1857, p. 553; 1858, p. 579; 1859, p. 583; 1860, p. 583; 1861, p. 799.)

A substance isomeric with starch, occurring in the liver and in the placenta (Bernard), and entering largely into the constitution of most of the tissues of the embryo. The liver of rabbits contains as much as 2 per cent. of it (Kekulé); the muscular tissues of the fœtus are full of it, the muscles of foetal calves of 3 to 7 months yielding from 20 to 50 per cent.

Preparation.—1. The liver of a quite recently killed animal is cut into small pieces, immersed in boiling water, pounded, and boiled for about an hour with a small quantity of water; the liquid is then strained off, the residue squeezed out, and the filtrate precipitated with four or five measures of alcohol of 38 to 40 per cent. The yellowish white flocks are freed from sugar and soluble biliary matter by washing with a large quantity of alcohol, and from adhering nitrogenous substances by boiling for half an hour to an hour with concentrated potash-ley, whereby they are decomposed, with evolution of ammonia; the solution is then mixed with a small quantity of water, filtered, and precipitated with four or five measures of alcohol of 38 or 40 per cent. The precipitate is freed from potash by washing with a large quantity of alcohol; it is then dissolved in a small quantity of water, the solution neutralised with acetic acid, and again precipitated with alcohol. Purer glycogen is thus precipitated, while acetate of potassium remains in solution (Bernard). So prepared, it is apt still to contain calcium-salts, which may be removed for the most part by repeated solution in strong acetic or cold dilute nitric acid and precipitation with alcohol. (Kekulé.)

2. The fresh-filtered and cooled decoction of the liver is precipitated with glacial acetic acid, whereupon nearly pure glycogen is thrown down, the albuminous substances remaining in solution. (Bernard.)

3. If the liver is washed out with cold water by inserting the nozzle of a caoutchouc syringe into the portal vein, and driving a stream of cold water through the capillaries by careful pressure, a blood-red liquid is first obtained, then a bright rose-coloured liquid, then a milky liquid, and at last water. The rose-coloured and milky liquids are heated to boiling, and the filtrate precipitated with two measures of alcohol of 90 per cent.; and the flocks which separate are collected after some hours, washed with alcohol, dissolved in water containing acetic acid, and again heated to boiling. The filtrate, precipitated a second time with alcohol, yields flocks of glycogen in abundance, which must be freed from fat by washing with ether, and dried in vacuo. (Gorup-Besanez.)

Properties.—Glycogen is a white mealy powder, exhibiting no particular form, even under the microscope. It is neutral, inodorous, and tastes like starch. Dried at 100° C. it contains 44.49 per cent. carbon, 6.49 hydrogen, and 49.02 oxygen (Kekulé), agreeing nearly with the formula $C^6H^{10}O_5$, which requires 44.44 C, 6.17 H, and 49.39 O.

Glycogen forms with water an opalescent solution, which, in the absence of ferments, does not undergo spontaneous alteration (Bernard). On evaporating the solution the glycogen separates in films (Hensen). Glycogen is precipitated from its aqueous solution by animal charcoal (Bernard), and according to Bernard and Lehmann, by acetic acid; but according to Gorup-Besanez, this precipitation does not take place, the solution being on the contrary rendered clearer by addition of acetic acid. According to Bernard, it is precipitated from aqueous solution by basic acetate of lead; according to Hensen it is not.

Glycogen is quite insoluble in alcohol (Bernard); slightly soluble. (Hensen.)

Iodine colours it violet or bright brown-red, seldom pure blue (Bernard); violet or most frequently red-brown. (Kekulé.)

Decompositions.—1. All reagents which transform starch into sugar, similarly change glycogen, first into a substance corresponding to dextrin, then into sugar (Bernard). The sugar so produced is identical with grape-sugar (Bertholot and de Luca, *Compt. rend.* xlix. 213). This transformation is occasioned by dilute mineral acids, diastase, and the ferments contained in the blood, saliva, liver, and pancreas (Bernard). Boiling dilute sulphuric acid first clarifies the aqueous solution, and only produces sugar after continued boiling (Kekulé).—Neutral aqueous glycogen is immediately converted into sugar by saliva; the transformation takes place very slowly, or not at all, in presence of free acid, caustic alkalis, or alkaline carbonates (Pavy). If the glycogen contained in a concentrated decoction of liver or muscular flesh is warmed with saliva, it ferments on the subsequent addition of yeast (Poggiale). Glycogen which has not undergone this preliminary treatment does not ferment on addition of yeast. (Bernard.)

2. By roasting, glycogen is converted into a substance similar to dextrin (Bernard). The dextrin formed thus, or according to 1, rotates the plane of polarisation towards the right, does not reduce an alkaline cupric solution, is not coloured blue by iodine, and does not ferment with yeast. It gives a clear solution with water, not with strong alcohol. (Bernard.)

3. Glycogen yields xylöidin when treated with concentrated nitric acid; and oxalic acid when boiled with dilute nitric acid (Pelouze). If concentrated nitric acid is poured over glycogen dried at 100° C., solution takes place after a few moments, and, if water is immediately added, a quantity of xylöidin is obtained amounting to 130 per cent. of the glycogen employed. If the nitric acid solution is allowed to stand for some time, water precipitates a smaller quantity of xylöidin, and after several days none at all (Pelouze).—4. Glycogen does not reduce an alkaline solution of a cupric salt. (Bernard.)

Physiological relations.—The function of glycogen in the animal economy is a subject on which the opinions of physiologists are much divided. Bernard, who discovered it, maintains, that it is converted into sugar in the liver, by the action of a ferment contained in that organ, and that this conversion of glycogen into sugar is a constant and normal function of the liver. This view is founded on the observation, made by Bernard himself and others, that in carnivorous animals the blood of the portal vein is quite free from sugar, whereas that of the hepatic veins contains a considerable quantity of it; and that in herbivorous and omnivorous animals the amount of sugar in the hepatic veins is always much greater than in the portal vein. Lehmann (*Compt. rend.* xl. 228) found that the portal blood of dogs which had been kept fasting or fed entirely on meat was free from sugar, whereas that of the hepatic vein contained a quantity amounting to between 0.6 and 0.9 per cent. of the dried residue of the blood. When the dogs were fed on potatoes, the portal blood contained only traces of sugar, the blood of the hepatic vein from 0.8 to 1 per cent. (of the dry residue). The portal blood of horses fed on bran, hay, and straw, contained 0.05 per cent. sugar, that of the hepatic vein from 0.6 to 0.9 per cent. (of the dry residue). Lehmann also found that in the passage of the blood through the liver, the fibrin disappears altogether and the albumin in great part; and he supposed that the sugar in the liver was formed from the fibrin of the blood. Harley (*Proc. Roy. Soc.* x. 297) obtained results similar to those of Bernard and Lehmann, with regard to the presence or absence of sugar in the portal blood according to the nature of the diet; he also finds that sugar is a normal constituent of the blood of the general circulation; that the livers of dogs contain sugar whether the diet is animal or vegetable, and that, under favourable circumstances, sugar may be found in the liver of an animal after three entire days of rigid fasting; and he concludes that the sugar found in the bodies of animals fed on a

mixed diet is partly derived from the food, partly formed in the liver; that the livers of animals restricted to flesh diet possess the power of forming glycogen, which glycogen is at least partly transformed into sugar; and that, as sugar is found in the liver at the moment of death, its presence cannot properly be ascribed to a *post mortem* change, but is to be regarded as the result of a natural condition.

On the other hand, Figuier, Pavy, and others find that the blood, after leaving the liver does not, under normal conditions, contain a larger amount of sugar than before entering that organ. According to Pavy, blood collected from the right side of the heart during life (by catheterism) contains but a trace of sugar, although when collected from the same part after death, it gives abundant indication of the presence of that substance. The heart excised instantaneously after sudden killing, contains blood as free from sugar as during life. Pavy also concludes from his own experiments, that the saccharine state of the liver, which has hitherto been looked upon as belonging to life, is the result of a *post mortem* change which takes place with astonishing rapidity. The glycogen (or heparin) in the liver is in contact with a ferment capable under certain circumstances of transforming it into sugar, but this transformation does not take place during life, and moreover may be checked by the influence of acids, alkalis, extreme cold, and a heat sufficient to destroy and coagulate the ferment; and by means of these agencies it may be shown that if the liver contains any sugar at the moment of death, it is only to the extent of the merest trace. Carbonate of sodium injected into the portal system during life causes a rapid disappearance of glycogen from the liver without any sign of the production of sugar. The livers of animals naturally of low temperature, such as the frog, oyster, and mussel, are free from sugar during life and at the time of death.

The ingestion of starchy and saccharine substances leads to a great accumulation of glycogen in the liver, that organ at the same time increasing greatly in size. The average weight of the liver of eleven dogs fed on animal diet was $\frac{1}{30}$ of that of the animal, and an analysis of seven of the livers gave an average percentage of glycogen amounting to 7.19. Five dogs fed upon a vegetable diet gave an average weight of liver equal to $\frac{1}{15}$ of that of the animal. An analysis of three of the livers gave an average percentage of glycogen amounting to 17.23. Four dogs fed upon a diet of animal food with a large admixture of sugar, gave an average weight of liver equal to $\frac{1}{16.5}$ of that of the animal, with a percentage of glycogen amounting to 14.5. Similar results were obtained by experiments upon rabbits, showing that saccharine and amylaceous matters received as food are converted in the liver into glycogen. Pavy regards this fact as affording a strong argument against the supposition that sugar is formed in the liver during life, as it appears highly improbable that sugar should be first transformed by the liver into glycogen, in order to be reconverted into sugar in the same organ.

M'Donnel regards glycogen as the basis of an azotised protoplasm forming a constituent of blood. For if it be true—as appears from the observations of Lehmann, Brown-Séquard, and also of M'Donnell—that the fibrin and much of the albumin of the portal blood vanishes in the liver, and that the liver, at the same time that it destroys these azotised compounds, forms its own non-azotised amyloid substance, and excretes bile containing so little nitrogen that it need hardly be taken into account, the conclusion seems obvious that “the nitrogen, which leaves the liver by no other outlet, may go forth in the hepatic blood in union with the amyloid substance, thus changed into a new azotised principle; that thus the liver is a great blood-making organ, in which there is constantly going on a reconstruction of certain ingredients of the blood; that in it, the fibrin, &c., which has done its work, is disintegrated, the hydrocarbons of the bile abstracted, and the nitrogen combined with the amyloid substance, which instead of being normally changed into sugar, emerges from the liver, as a constituent principle of the protoplasm, from which (to use the words of Bernard with reference to the fetal tissues) organic evolution is accomplished.”

GLYCO-HYPOCHOLIC ACID. See HYPO-GLYCOCHOLIC ACID.

GLYCOL, AMYLENIC. See AMYLENE, HYDRATE OF (i. 208).

GLYCOL. See ETHYLENE, HYDRATES OF (p. 574).

GLYCOLALDEHYDE. The name given by Heintz (Pogg. Ann. cxi. 166, 291) to a diatomic radicle, C^2H^2 , which he supposes to exist in oxalic and saccharic acids.

GLYCOLIC ETHERS. The ethers of the diatomic alcohols or glycols (p. 517); not to be confounded with glycollic ethers, the ethers of glycollic acid.

GLYCOLLAMIDE. $C^2H^2NO = \left(\begin{array}{c} H \\ C^2H^2O \\ H \end{array} \right) \begin{array}{c} O \\ N \end{array}$ —This compound, isomeric with glycocine, is produced:—1. By dissolving glycollide in aqueous ammonia.—2. By the action of ammonia on glycollate of ethyl (*H. intz*).—3. By the action of heat on

tartrate of ammonium: $C^2H^3(NH^4)O^3 = C^2H^3NO^3 + CO^2 + H^2O$. This salt melts at $150^\circ C$. with violent evolution of carbonic anhydride; on continuing the heat, carbonate of ammonium escapes, and at length there remains a residue which solidifies on cooling, and when recrystallised from water yields beautiful crystals of glycollamide. (Dessaignes, *Compt. rend.* xxxviii. 47.)

This substance dissolves readily in water, and sparingly in alcohol, and may be recrystallised from boiling alcohol, differing in this respect from glycocine, which is nearly insoluble in alcohol. It has a faint, somewhat sweetish taste, and slight acid reaction (Dessaignes). According to Heintz, it is neutral, melts at $120^\circ C$., without decomposition, and does not unite with bases (glycocine melts with partial decomposition at 170° and forms salts with bases). It is not decomposed by potash in the cold; but when boiled with potash, it yields ammonia and glycollate of potassium, in which respect also it differs from glycocine (p. 903). It is decomposed in a similar manner by aqueous acids. Heated to $100^\circ C$. in a current of dry hydrochloric acid gas, it unites directly with the acid, forming a thick liquid, which crystallises on cooling, provided the action has not been too long continued; but at a higher temperature it is decomposed, yielding sal-ammoniac and glycollide. (Heintz, *Ann. Ch. Pharm.* cxxiii. 212.)

GLYCOLLIC ACID. $C^2H^3O^3 = \left(\begin{smallmatrix} H \\ C^2H^2O^2 \end{smallmatrix} \right)^n \left\{ \begin{smallmatrix} H \\ O \end{smallmatrix} \right\}_0$. *Oxalactic acid.* (Socoloff and

Strecker, *Ann. Ch. Pharm.* lxxx. 18.—Dessaignes, *Compt. rend.* xxxviii. 44.—Kekulé, *Ann. Ch. Pharm.* cv. 286.—Gm. xii. 508; xiii. 435.—Gerh. i. 222; ii. 930.—Schulze, *Zeitschr. Ch. Pharm.* 1862, pp. 606, 682.—Drechsel, *Ann. Ch. Pharm.* cxxvii. 150.)

Formation and Preparation.—1. Benzoglycollic acid, $C^2H^3(C^6H^5O)O^3$, is resolved by boiling with water to which a little sulphuric acid is added, into glycollic and benzoic acids: the greater part is decomposed in the course of a few hours, but to render the decomposition quite complete, several days' boiling is required. The liquid is evaporated as long as benzoic acid continues to separate on cooling, then neutralised with carbonate of barium, filtered from the resulting sulphate of barium, and evaporated to a syrup. The barium-salt, which crystallises out on cooling, is dissolved in a small quantity of water, and decomposed by dilute sulphuric acid; the filtered solution evaporated to a syrup; this residue dissolved in ether; and the ethereal solution left to evaporate. (Socoloff and Strecker.)

2. An aqueous solution of glycocine is decomposed by nitrous acid with evolution of nitrogen gas (p. 903); and the liquid mixed with ether and evaporated leaves glycollic acid. If the liquid is evaporated immediately after the action of the nitrous acid, the glycollic acid thus produced is converted into oxalic acid. (Socoloff and Strecker.) Dessaignes, by the same process, obtained glycollic acid in the crystalline form.

3. Tartaric acid, $C^4H^4O^6$, is heated to $180^\circ C$., till no more gas is evolved; the residue, consisting of nearly pure glycollide, is washed with cold water and dissolved in potash; the resulting glycollate of potassium is precipitated by nitrate of silver, and the glycollic acid is separated from the silver-salt by hydrochloric acid. (Dessaignes.)

4. By the action of alkalis on glyoxal or glyoxylic acid (Debus):

5. By boiling bromacetate of silver with water (Perkin and Duppa, i. 665):

By boiling iodoacetic acid with oxide of silver, or iodoacetate of lead with water, or by decomposing the solution of that salt with sulphuric acid (Perkin and Duppa, *Phil. Mag.* [4] xviii. 54). In like manner, by boiling chloracetic acid with caustic alkalis, or heating crystallised chloracetate of potassium or sodium, *e. g.*:

Chloracetate of potassium, heated to 100° – $120^\circ C$. becomes moist, and acquires an acid reaction; and if the heat be continued till the mass becomes dry, and the residue digested with ether-alcohol, glycollic acid dissolves and may be obtained by evaporation as a yellowish syrup. It may be obtained colourless by prolonged boiling of the concentrated solution of the chloracetate of potassium, or by heating the crystallised salt in a closed tube for several hours to 120° – $140^\circ C$. The acid thus prepared does not crystallise: but by decomposing chloracetate of silver with sulphuric acid, and

evaporating the filtrate to a syrup, glycollic acid is obtained in radiate groups of large, very deliquescent crystals. (Kekulé, Ann. Ch. Pharm. cv. 286.)

6. When glycol ($C^2H^4O^2$) is dissolved in four times its bulk of nitric acid of specific gravity 1.33, and the solution, after standing for several days, is concentrated in vacuo over quick-lime, an acid syrupy residue is left, which, when dissolved in water, neutralised with chalk, and mixed with alcohol, yields a precipitate of glycolate of calcium; and on precipitating the calcium by the exact quantity of oxalic acid required, and evaporating the filtrate in vacuo, glycollic acid is obtained in crystals (Wurtz, Compt. rend. xlv. 1306; Ann. Ch. Pharm. cii. 366). Glycollic acid is also formed, together with other products, when tritylene-glycol, $C^6H^6O^2$, is oxidised by nitric acid, and in small quantity—lactic acid being the chief product—when air is slowly passed over a mixture of platinum-sponge and platinum-black moistened with tritylene-glycol (Wurtz, Compt. rend. xlv. 306).

7. Glycollic acid is produced, together with glyoxal, glyoxylic acid and other products, by the action of nitric acid upon alcohol (Debus, see page 922). A quicker mode of preparation is given by Lautemann (*Kolbe's Org. Chem.* i. 678). A few grammes of strong alcohol are gently heated in a capacious vessel, with a small quantity of nitric acid, till the vessel becomes filled with red fumes of nitrous acid; and when the action has been thus set up, about 500 grms. alcohol of 20 per cent., and 440 grms. nitric acid of specific gravity 1.34 are poured in. The reaction, which must be moderated by immersing the vessel in water at $20^\circ C$, is complete in about 12 hours. The glycollic acid may then be separated from the other products in the form of a calcium-salt by Debus's method (see GLYOXYLIC ACID, p. 922).—Drechsel dissolves the mixture of glycolate of calcium, glyoxal and glyoxylate of calcium in boiling water, and boils it for several hours with milk of lime, whereby both the glyoxal and the glyoxylic acid are converted into glycollic acid. The hot filtrate freed from excess of lime by carbonic acid yields tolerably pure glycolate of calcium; and by decomposing this salt with oxalic acid, neutralising the filtrate with carbonate of lead, and evaporating, the neutral glycolate of lead is obtained in well developed crystals. The hot aqueous solution of this salt, decomposed by an equivalent quantity of dilute sulphuric acid, yields a solution of glycollic acid, which may be crystallised by evaporation to a syrup at 60° or $70^\circ C$, afterwards in vacuo over oil of vitriol, and purified by recrystallisation from anhydrous ether.

In the mother-liquor obtained in the preparation of fulminating mercury (p. 732), Cloez (Compt. rend. xxxiv. 864) found an uncrystallisable acid (which he called *Homolactic acid*) having the composition of glycollic acid.

8. By the action of nascent hydrogen upon oxalic acid, $C^2H^2O^4 + H^+ = C^2H^4O^4 + H^2O$ (Schulze). An aqueous solution of oxalic acid is boiled with sulphuric acid, and excess of zinc powder gradually added as long as hydrogen continues to escape; the filtrate is neutralised with lime, &c. as above; the calcium-salt is converted into a basic lead-salt by precipitation with neutral acetate of lead; and from this salt the free acid is prepared. According to Church, glyoxylic acid is produced in this reaction, as well as glycollic acid, and afterwards converted into glycollic acid by boiling with lime (see No. 4). A larger quantity of glycollic acid may be at once produced by conducting the process so as to increase the energy of the reducing action as much as possible. With this view, Church adds oxalic acid in successive small portions to a large quantity of zinc and sulphuric acid heated over a lamp; keeps up a brisk evolution of hydrogen for some hours; boils the liquid with excess of zinc till all the acids present are saturated; then adds excess of lime, saturates the whole with carbonic acid, boils, and filters. The filtrate on concentration deposits abundance of glycolate of calcium in concentric tufts of fine needles. The mother-liquor contains a peculiar acid, isomeric with acetic acid.

9. By the action of nitric acid upon acrolein (Claus, Ann. Ch. Pharm. Suppl. ii. 119).—10. By the action of boiling water on the brominated oil obtained by treating anhydrous glycerin with bromine. (Barth, p. 890.)

Properties.—Glycollic acid appears to exist in two, if not in a greater number of isomeric modifications. The acid which Socoloff and Strecker obtained from hippuric acid, and that found by Cloez in the mother-liquor of the preparation of fulminate of silver, were syrupy and uncrystallisable. All the other processes above given yield crystallisable acids; but those obtained by Dessaignes from glycocine and from tartronic acid, and that which Kekulé prepared from chloracetic acid, were extremely deliquescent, whereas Drechsel's acid, prepared by the action of nitric acid on alcohol, deliquesced only in very damp air. This acid exhibits the following properties. It crystallises from anhydrous ether by slow evaporation in beautiful regular crystals; has a very sour taste; dissolves easily in water, alcohol and ether; is permanent in dry or in moderately damp air, but deliquesces in very damp air, the deliquesced mass crystallising again in regular crystals on being removed to a dry atmosphere. It melts at 78° or $79^\circ C$, and after cooling remains liquid for some time, but solidifies in the

crystalline ~~form~~ on being touched with a pointed body. When heated in a retort, the fused acid begins to boil at 100°C ., aqueous glycollic acid passing over as the temperature continually rises. Above 150° it gives off extremely pungent vapours, and yields an oily distillate, which on exposure to the air gradually solidifies to a deliquescent crystalline magma. The acid obtained by reduction of oxalic acid behaves in a similar manner, but does not begin to decompose till heated above 180°C . (Schulze.)

The acid prepared from alcohol, when kept for some time in the fused state at the temperature of the water-bath, gradually loses its property of recrystallising, and is ultimately converted into an uncrystallisable syrup containing a higher percentage of carbon than pure glycollic acid, and consisting probably of a mixture of that acid with glycollide. The syrupy acid thus produced can only be partially brought back to the crystallisable state by boiling with water, and forms with bases, salts which differ in some respects from those of the crystalline acid. (See below.)

GLYCOLLATES.—Glycollic acid is diatomic but monobasic (like lactic acid) only one of its hydrogen-atoms being *saline*, that is, replaceable by metals. The other is *alcoholic*, that is to say, more easily replaced by acid-radicles, as in benzoglycollic acid (see GLYCOLLIC ETHERS, p. 915). This difference between the hydrogen-atoms may be conveniently represented in the rational formula, by writing the alcoholic H above, and the saline H below. The general formula of the metallic glycollates will

then be $\begin{matrix} \text{H} \\ \text{C}^{\text{H}}\text{H}^{\text{O}} \end{matrix} \begin{matrix} \text{O} \\ \text{O} \end{matrix}$; that of benzoglycollic acid, $\begin{matrix} \text{C}^{\text{H}}\text{H}^{\text{O}} \\ \text{C}^{\text{H}}\text{H}^{\text{O}} \end{matrix} \begin{matrix} \text{O} \\ \text{O} \end{matrix}$.

Glycollate of Ammonium (with excess of acid), $\text{C}^{\text{H}}\text{H}^{\text{O}}(\text{NH})\text{O}^{\text{C}}\text{H}^{\text{O}}\text{O}^{\text{H}}$.—This salt is obtained by repeatedly evaporating a solution of glycollic acid in ammonia; also by evaporating the mother-liquor which remains in the preparation of glycolamide (p. 908), by the action of ammonia on acid glycollate of ethyl. It crystallises in concentric groups of slender needles, which are easily soluble in water and in boiling alcohol, have a strong acid reaction, and cannot be dried at 100° — 110°C without decomposition. (Heintz.)

Glycollate of Barium, $\text{C}^{\text{H}}\text{H}^{\text{O}}\text{Ba}^{\text{O}}\text{O}^{\text{C}}\text{H}^{\text{O}}\text{O}^{\text{H}}$, separated from a moderately concentrated solution forms large transparent crystals; if the solution be evaporated to a syrup the salt separates in crystalline crusts (Kekulé). It melts when heated, forming a clear liquid, which crystallises on cooling. At a stronger heat it is decomposed, leaving carbonate of barium. Dissolves in 7.91 pts. water at 17°C . (Schulze.)

Glycollate of Calcium, $\text{C}^{\text{H}}\text{H}^{\text{O}}\text{Ca}^{\text{O}}\text{O}^{\text{C}}\text{H}^{\text{O}}\text{O}^{\text{H}}$, obtained by boiling the dry acid with lime-water, removing the excess of lime by carbonic acid, and concentrating, separates on cooling in stellate groups of asbestos-like needles. It dissolves sparingly in cold water, but sufficiently to give a precipitate with alcohol. The crystals contain water, $\frac{2}{3}$ at. according to Schulze, which they give off at 100°C . At a higher temperature the salt burns away, leaving carbonate of calcium (Kekulé). Debus, by neutralising glycollic acid with chalk, precipitating with alcohol, and recrystallising from water, obtained crystals containing 3 at. water, $\text{C}^{\text{H}}\text{H}^{\text{O}}\text{Ca}^{\text{O}}\text{O}^{\text{C}}\text{H}^{\text{O}}\text{O}^{\text{H}} \cdot 3\text{H}_2\text{O}$, which they gave off at 100° , or a little above. A double salt of *glycollate and glyoxylic acid of calcium*, $\text{C}^{\text{H}}\text{H}^{\text{O}}\text{Ca}^{\text{O}}\text{O}^{\text{C}}\text{H}^{\text{O}}\text{O}^{\text{C}}\text{H}^{\text{O}}\text{O}^{\text{H}} + 2\text{H}_2\text{O}$, crystallises from the mother-liquors obtained in the preparation of glyoxylic acid (p. 922).

Glycollates of Lead.—The *neutral salt* crystallises from a solution of the basic salt in free glycollic acid, in beautiful shining monoclinic crystals resembling those of gypsum. It dissolves in about 31 pts. water at 17°C ., but is decomposed at the same time into the basic salt, which is precipitated, and free glycollic acid (Schulze).—The *neutral lead-salt* prepared from crystalline glycollic acid (by neutralising it with carbonate of lead) crystallises in monoclinic prisms, exhibiting the faces αP , $\alpha\text{P}\infty$, αP . Inclination of clinodiagonal to principal axis = $82^{\circ} 36'$; $\alpha\text{P}' : \alpha\text{P} = 78^{\circ} 6'$; $\alpha\text{P}\infty : \alpha\text{P} = 129^{\circ} 10'$; $\alpha\text{P} : \alpha\text{P}\infty = 94^{\circ} 40'$; $\alpha\text{P}' : \alpha\text{P}\infty = 97^{\circ} 94'$; they are sometimes short prisms, sometimes tabular from predominance of $\alpha\text{P}\infty$. Dissolves in 33.1 pts. water at 15°C . The lead-salt prepared from the syrupy acid has the same composition, but forms pointed crystals which appear as if they belonged to the trimetric system, but the faces were too much striated and curved to admit of exact angular measurement. Soluble in 35.9 pts. water at 15°C . (Drechsel.)

A *basic lead-salt*, $\text{PbO} \cdot \text{C}^{\text{H}}\text{H}^{\text{O}}\text{Pb}^{\text{O}}\text{O}^{\text{C}}\text{H}^{\text{O}}\text{O}^{\text{H}}$, is obtained by precipitating a solution of the calcium-salt in not more than 100 pts. water with neutral acetate of lead, the neutral salt being probably formed in the first instance, and then decomposed by the water as is above mentioned; with basic acetate of lead it is produced more quickly and in greater quantity. It is crystalline, requires more than 10,000 pts. cold, and nearly as much hot water to dissolve it; but is easily soluble in free acetic acid, and in acetate of lead, whether neutral or basic. (Schulze.)

Glycollate of Magnesium separates from aqueous solution by slow evaporation

in nodular groups of hydrated needles and laminae. It does not swell up when heated. (Schulze.)

Glycollate of Silver, $C^2H^3AgO^3$, separates on mixing a hot aqueous solution of the calcium-salt with nitrate of silver, and leaving the liquid to cool—in spangles if the solution is rather strong, in laminae from weaker solutions. It dissolves sparingly in cold water, is decomposed by boiling with water, and is insoluble in alcohol (Kekulé). Dessaignes, by mixing a solution of glycollide in potash with nitrate of silver, obtained a precipitate which soon became crystalline, dissolved readily in hot water, and separated therefrom in large crystals having the composition of glycollate of silver containing water: $C^2H^3Ag^+O^3 + H^2O$.

The silver-salt prepared from crystalline glycollic acid crystallises easily, and with great beauty; that from the syrupy acid decomposes very quickly. (Drechsel.)

Glycollate of Zinc, $C^2H^3Zn^+O^3 \cdot 2H^2O$, crystallises in tufts of needles or prisms, which give off their water at $100^\circ C$. When the salt in excess is shaken up with water at $17^\circ C$, a solution is formed, containing 1 pt. of the anhydrous salt in 31.6 pts. water; but in hot water supersaturated solutions are formed, which after cooling to 17° may contain as much as 1 pt. of the salt in 26.14 pts. water. (Schulze.)

The crystalline acid yields a zinc-salt which crystallises in well developed needles; the syrupy acid, a salt which forms microscopic four- or six-sided tablets. Both require 34 pts. water at $15^\circ C$. to dissolve them. (Drechsel.)

Derivatives of Glycollic acid.

Acetoglycollic acid, $C^2H^3O^4$. See ACETOGLYCOLLATE OF ETHYL (p. 917).

Bromoglycollic acid, $C^2H^3O^4$. (See vol. i. p. 548.)

Bromoglycollic acid, $C^2H^3BrO^3 = \left\{ \begin{smallmatrix} C^2HBrO^3 \\ H^2 \end{smallmatrix} \right\} O^3$. (Perkin and Duppa, Chem. Soc. Q. J. xii. 5.)—Produced by boiling dibromacetate of silver with water:

It forms a silver-salt which, when heated with water, yields bromide of silver and glyoxylic acid, $C^2H^3O^4$ (p. 922): $C^2H^3AgBrO^3 + H^2O = AgBr + C^2H^3O^4$.

Diglycollic acid, $C^2H^3O^4 = \left\{ \begin{smallmatrix} C^2H^2O^3 \\ H^2 \end{smallmatrix} \right\} O^3$. *Paramalic acid*.—This acid, which is isomeric with malic acid, and stands to glycollic acid in the same relation as diethylenic to monoethylenic alcohol, is produced by the dehydration of glycollic acid; $2C^2H^3O^3 - H^2O = C^2H^3O^4$, and by the oxidation of diethylenic and triethylenic alcohols. It was discovered by Heintz (Pogg. Ann. cix. 470; Jahresb. 1859, p. 362), who obtained it in preparing glycollic acid by heating chloracetate of sodium with caustic soda, and gave it the name of *paramalic acid*. Wurtz soon afterwards obtained an acid of the same composition, which he called *diglycollic acid*, by oxidising diethylenic alcohol with nitric acid or with platinum-black (Compt. rend. li. 162; Jahresb. 1860, p. 444); and Heintz subsequently showed (Pogg. Ann. cxv. 280, 452; Jahresb. 1861, p. 440) that the acids obtained by these two methods are identical. It is also produced by heating glycollic acid to 200° — $240^\circ C$, but the greater part of it then suffers further decomposition, yielding glycollide, $C^2H^2O^2$, and a small quantity of dioxymethylene. Its formation from chloracetic acid probably takes place thus:

Preparation.—1. *From Chloracetic acid*. The acid, mixed with a large quantity of water is [slightly] supersaturated with slaked lime and the solution is boiled till it again exhibits an acid reaction; more lime is then added, and this treatment is repeated till the alkaline reaction no longer disappears, even after prolonged boiling. The excess of lime is then precipitated from the boiling liquid by carbonic acid, and the solution is filtered; it then on cooling deposits a considerable quantity of diglycollate of calcium in colourless crystals. The liquid filtered from this deposit yields by evaporation, after the chloride of calcium contained in it has been extracted by absolute alcohol, a residue which still contains diglycollate of calcium, together with a small quantity of glycollate, from which it may be freed by recrystallisation, the diglycollate being much the less soluble of the two. The diglycollate of calcium, boiled with a mixture of ammonia and carbonate of ammonium, yields the acid ammonium-salt, and the solution of this salt saturated with ammonia and mixed with

acetate of lead, yields a precipitate of diglycollate of lead, from which the acid may be obtained by decomposition with sulphuretted hydrogen. (Heintz.)

2. *By oxidation of Diethylenic alcohol.*—Diethylenic alcohol is violently attacked by nitric acid, with copious evolution of red fumes. The acid liquid when evaporated solidifies to a crystalline mass; and by dissolving this residue in water, saturating with milk of lime, heating to the boiling point, filtering to separate oxalate of calcium, filtering again and leaving the filtrate to cool, diglycollate of calcium is obtained in long shining needles. The boiling aqueous solution of this salt mixed with nitrate of silver yields a precipitate of diglycollate of silver; and this, decomposed by sulphuretted hydrogen, yields diglycollic acid. (Wurtz.)

A liquid containing nitrate of silver and milk-sugar used in photography for dipping papers impregnated with succinic acid, citric acid, &c. has been found, after long usage, to deposit a silver-salt isomeric with malate and diglycollate of silver (Kämmerer, J. pr. Chem. lxxxviii. 321; Rép. Chim. pure, 1863. p. 370). The acid obtained from this salt, called by its discoverer isomalic acid, is perhaps identical with diglycollic acid; but the identity is not quite established. (See ISOMALIC ACID.)

Properties.—Diglycollic acid crystallises in thick rhombic prisms containing $C^4H^2O^5.H^2O$ (Wurtz); in monoclinic prisms (Heintz). It has a very sour taste, is inodorous, and has no action on polarised light (Heintz). The crystals give off their water slowly in the air at ordinary temperatures, quickly in *vacuo* or at $100^\circ C.$; they dissolve easily in water and in alcohol, sparingly in ether. The dry acid melts at $148^\circ C.$, and solidifies in the crystalline form on cooling. Between 250° and $270^\circ C.$ it decomposes, giving off a gaseous mixture containing but little carbonic anhydride, burning with a blue flame, and leaving a residue which, when distilled over the open fire, yields a thick strongly acid liquid, which after a while solidifies to a crystalline mass.

DIGLYCOLLATES.—Diglycollic acid is dibasic, forming neutral salts, $C^4H^2M^2O^5$, and acid salts, $C^4H^2MO^5$. The neutral diglycollates of the alkali-metals are easily soluble in water; the rest are sparingly soluble, and may be obtained by precipitation. The solution of the free acid is not precipitated by lime-water, but gives precipitates after a while with baryta- and strontia-water. Nitrate of silver precipitates it only on addition of ammonia; the precipitate is soluble in excess of ammonia, but separates out unaltered on boiling the solution. The solution of the ammonium-salt immediately forms white precipitates with nitrate of silver and mercurous nitrate; white crystalline precipitates after a while with acetate of lead and sulphate of zinc; blue crystalline with sulphate of copper; and reddish crystalline with nitrate of cobalt.

Diglycollate of Ammonium (acid), $C^4H^2(NH^4)^2O^5$, obtained by boiling the calcium-salt with ammonia or carbonate of ammonium, then filtering and evaporating, forms long monoclinic prismatic crystals, insoluble in common alcohol, very sparingly soluble in boiling absolute alcohol (Heintz). The neutral ammonium-salt has not been obtained pure.

Diglycollate of Barium, $C^4H^2Ba^2O^5.H^2O$.—Obtained by precipitating the solution of a neutral alkaline diglycollate with chloride of barium, as a white crystalline precipitate, sparingly soluble in cold water, insoluble in alcohol. It must be recrystallised to free it from chloride of ammonium and excess of chloride of barium, which adhere to it somewhat obstinately, and cannot be removed by washing. (Heintz.)

Diglycollate of Calcium, $C^4H^2Ca^2O^5.6H^2O$, prepared as above described, crystallises in long shining needles, nearly insoluble in cold, sparingly soluble in boiling water. It gives off its water at $160^\circ C.$ (Wurtz), at $180^\circ C.$ (Heintz.)

Diglycollate of Copper, $C^4H^2Cu^2O^5$.—Blue, sandy, slightly crystalline precipitate, which dissolves slowly in water, taking up at the same time a certain quantity, which may be expelled to the amount of 3 per cent. at $180^\circ C.$ The undried salt probably contains $2C^4H^2Cu^2O^5.H^2O$. (Heintz.)

Diglycollate of Lead, $C^4H^2Pb^2O^5$, obtained by precipitation, as above described, forms white microscopical crystals, which dissolve sparingly in water, easily in nitric and in hydrochloric acid, and begin to decompose with slight coloration at $200^\circ C.$ (Heintz.)

Diglycollate of Magnesium, $C^4H^2Mg^2O^5.3H^2O$, obtained by saturating the aqueous acid with magnesia, forms small prismatic crystals, which do not give off their water till heated above $200^\circ C.$; the anhydrous salt is not decomposed at 240° . (Heintz.)

Diglycollates of Potassium.—The acid salt, $C^4H^2KO^5$, is sparingly soluble in water, and separates in crystals when one-half of a strong solution of the acid is neutralised with potash, and then mixed with the other half (Wurtz). The crystals are trimetric combinations, $\infty P \infty . \infty P . P \infty$. Inclination of $\infty P : \infty P = 112^\circ 54'$;

$P_{\infty} : P_{\infty}$ over the principal axis = $118^{\circ} 30'$ (Heintz). The solution left to stand in an open vessel becomes covered with mould. The salt blackens when heated, giving off the odour of burnt sugar (Wurtz). The *neutral salt*, $C^4H^4K^2O^4$, obtained by neutralising the free acid or the preceding salt with potash, crystallises in long deliquescent needles. (Heintz.)

Diglycollate of Silver, $C^4H^4Ag^2O^4$, is obtained as a white granular precipitate on adding nitrate of silver to a boiling saturated solution of the calcium-salt. (Wurtz.)

Diglycollates of Sodium.—The *acid salt*, $C^4H^4NaO^4$, forms small tabular crystals, sparingly soluble in water, but more soluble than the acid potassium-salt. The *neutral salt* is not deliquescent; it is insoluble in alcohol even at the boiling heat. (Heintz.)

Diglycollate of Sodium and Potassium, $C^4H^4KNaO^4 \cdot 2H^2O$, obtained by exactly saturating the acid potassium-salt with soda, forms small tabular prismatic crystals, which have a nacreous lustre, are insoluble in alcohol, and melt in their water of crystallisation at $100^{\circ} C$. An *ammonio-sodic* salt has been obtained, but not in the pure state. (Heintz.)

Diglycollate of Strontium, $C^4H^4Sr^2O^4 \cdot H^2O$, resembles the barium-salt, and is prepared in a similar manner, but is more easily obtained in a state of purity. (Heintz.)

Diglycol-ethylenic acid. $C^6H^{10}O^6 = 2 \left(\frac{C^3H^5O^3}{H^2} \right) O^4$, (Wurtz, Compt. rend.

li. 162; Jahresb. 1859, p. 446.)—This acid is produced, together with diglycollic acid, by the oxidation of triethylenic alcohol (p. 577). This compound is oxidised by nitric acid in the same way as diethylenic alcohol; and on neutralising the resulting acid liquid with milk of lime, and proceeding nearly as described at p. 911, two calcium-salts are obtained, viz. the diglycollate, which is sparingly soluble, and the diglycolethylenate, $C^6H^{10}Ca^2O^6$, which is much more soluble, and crystallises in silky tufts, having the aspect of asbestos. The aqueous solution of this salt gives with nitrate of silver a white precipitate, from which, by decomposition with sulphuretted hydrogen and evaporation, diglycolethylenic acid may be obtained in the form of a non-crystallising syrup.

GLYCOLLIC ETHERS. *Oxalactic Ethers*.—By treating chloracetic acid with sodium-alcohols (methylete, ethylete, &c. of sodium), Heintz (Pogg. Ann. cix. 301 and 489; cxi. 552; cxiv. 440; Jahresb. d. Chem. 1859, p. 358; 1860, p. 314; 1861, p. 445) has obtained a number of compounds having the composition of acid glycollic ethers, that is to say, ethers derivable from glycollic acid by the substitution of a monatomic alcohol-radicle for one of the typic atoms of hydrogen, their formation being precisely analogous to that of glycollic acid itself by treating chloracetic acid with hydrate of sodium or potassium, e.g.:

The compounds thus formed possess the essential character of the acid ethers of dibasic acids, that is to say, they are capable of exchanging one of their atoms of hydrogen, and no more, for an atom of a metal or another alcohol-radicle; ethyl-glycollic acid, for example, forms a potassium-salt, $C^4H^5K(C^2H^3O)^2$, and an amyl-salt, $C^4H^5(C^4H^9)(C^2H^3O)^2$. But they do not appear to be acid ethers of glycollic acid in exactly the same sense that ethyl-sulphuric acid is an acid ether of sulphuric acid: for when heated with excess of alkali, they are not resolved into glycollic acid and an alcohol. Methyl-glycollic acid, for example, heated with hydrate of sodium, does not yield methylic alcohol and glycollate of sodium; neither does it yield benzoglycollic acid when heated with benzoic acid.

The molecule of a monatomic alcohol-radicle which enters into the composition of these acid ethers appears then to be more intimately combined than in the ordinary acid ethers of dibasic acids; and for this reason Heintz supposes that this alcohol-radicle takes the place, not of an atom of typic hydrogen in the formula $\left(\frac{C^3H^5O^3}{H^2} \right) O^4$, but of an atom of hydrogen within the radicle of the acid; moreover, since the ethers thus formed are monobasic acids, he derives them from a monobasic oxalactic acid represented by the formula $\left(\frac{C^3H^5O^3}{H} \right) O$, and designates them as *methyl-oxalactic*,

ethyl-oxacetic acid, &c. Methyl-oxacetic acid, for example, is represented by the monatomic formula $\left[\begin{array}{c} \text{C}^2\text{H}^2(\text{CH}^3)\text{O}^2 \\ \text{H} \end{array} \right] \text{O}$.

Wurtz, on the other hand (Ann. Ch. Phys. [3] lix. 161), regards these compounds as true acid ethers of glycollic acid, analogous to acid sulphate of ethyl, &c., and attributes the non-formation of glycollic acid and an alcohol, when they are heated with potash, to the fact that the neutral potassium-salt of glycollic acid ($\text{C}^2\text{H}^2\text{K}^2\text{O}^2$), corresponding to the neutral glycollic ethers, does not exist, so that the decomposition represented in the case of ethyl-glycollic acid by the equation,

cannot take place. Heintz, however, has shown that when chloracetate of ethyl is heated with rather more than an equivalent quantity of glycolate of sodium, a true acid glycolate of ethyl, $\left(\begin{array}{c} \text{C}^2\text{H}^2\text{O}^2 \\ \text{C}^2\text{H}^2\text{H} \end{array} \right) \text{O}^2$, is obtained, which, when heated with excess of a metallic base, yields ethylic alcohol and a metallic glycolate. Moreover, the ethyl-salt of amyl-oxacetic acid, and the amyl-salt of ethyl-oxacetic acid, though identical in percentage composition, differ both in physical properties and chemical reactions, which could not be the case if the ethyl and amyl contained in them discharged precisely similar functions, like the two atoms of metal in an ordinary double salt.

The reactions of these bodies may, however, be accounted for, without supposing them to be derived from an acid different from glycollic acid, or to be formed on any peculiar type. Glycollic acid is intermediate in composition, and therefore in properties, between glycol and oxalic acid:

Each of these compounds contains two atoms of typic, that is, replaceable hydrogen; but in glycol both these atoms are *alcoholic*, i.e. easily replaceable by acid-radicles, much less easily, and only under the influence of powerful reagents, by metals or alcohol-radicles (p. 576); and these latter, when once forced into it, are not easily displaced, e.g. by boiling with potash. In oxalic acid, on the contrary, both atoms of typic hydrogen are *saline*, that is to say, easily replaced by metals by ordinary double decomposition; while in the intermediate compound, glycollic acid, one atom of typic hydrogen is alcoholic, and the other is saline. Hence it is that glycollic acid (like its homologue, lactic acid) exhibits with metals the characters of a monobasic acid (p. 910), while, on the other hand, it easily forms derived acids in which one atom of the typic hydrogen (placed, for distinction, at the top of the formula) is replaced by an

acid radicle, e.g. *benzoglycollic acid*, $\left(\begin{array}{c} \text{C}^2\text{H}^2\text{O}^2 \\ \text{C}^2\text{H}^2\text{O}^2 \\ \text{H} \end{array} \right) \text{O}$ (i. 548), the remaining atom of typic hydrogen (placed at the bottom) being still replaceable by metals, so that the derived acid is also monobasic. (Kokulé, *Lehrbuch*, i. 130.)

Now, when glycollic acid is formed from chloracetic acid, we may suppose that the original saline hydrogen-atom of the acetic acid retains the same functions in the glycollic acid, and that the hydrogen-atom which enters (as H₂O) into the place of the chlorine-atom, becomes the second (alcoholic) hydrogen-atom, replaceable by benzoyl and other acid-radicles, but not easily by metals or alcohol-radicles. The function of this hydrogen-atom is in fact almost exactly like that of the hydrogen in common alcohol. When either the one or the other is replaced by ethyl, the product does not yield alcohol by boiling with potash. Hence the following equations are not only comparable in form, but they likewise indicate similar changes of properties in the substances concerned:

We conclude, then, that ethyl-glycollic acid and its homologues (also the corresponding lactic ethers) differ from common ethers, and from isomeric compounds formed by similar replacement of the saline hydrogen (e.g. glycolate of ethyl [p. 917] by

the action of chloracetate of ethyl on glycollate of sodium), not because they are formed on a different type, but because the alcohol-radicles are introduced into their molecules in a different manner. (On the sense in which Heintz's formulae are admissible, see FORMULÆ, p. 704.)

Methyl-glycollic acid. *Methyl-oxacetic acid.* $\text{C}^3\text{H}^3\text{O}^3 = \left(\begin{array}{c} \text{CH}^3 \\ \text{C}^3\text{H}^3\text{O}^3 \\ \text{H} \end{array} \right) \left\{ \begin{array}{c} \text{O} \\ \text{O} \end{array} \right\}$ —Isomeric

with lactic acid. Prepared by dissolving 2 at. sodium in methylic alcohol, and mixing the solution with 1 at. chloracetic acid. The mixture becomes heated and deposits chloride of sodium, and on decanting the solution of methyl-glycollate of sodium, mixing it with solution of sulphate of zinc, evaporating to dryness, and treating the residue with alcohol, a solution of methyl-glycollate of zinc is obtained. On decomposing this salt with sulphuretted hydrogen and distilling the filtrate, pure methyl-glycollic acid passes over as a colourless viscid liquid, which is nearly inodorous at ordinary temperatures, mixes with water in all proportions, and absorbs moisture from the air. Specific gravity 1.180.

Methyl-glycollates.—The *ammonium-salt* of this salt is a very deliquescent crystalline mass.—The *barium-salt*, $\text{C}^3\text{H}^{10}\text{Ba}^2\text{O}^6$, forms colourless transparent prismatic crystals, easily soluble in water, nearly insoluble in alcohol.—The *calcium-salt*, $\text{C}^3\text{H}^{10}\text{Ca}^2\text{O}^6 \cdot 2\text{H}^2\text{O}$, is gummy, but gives off water and becomes crystalline when left over oil of vitriol.—The *copper-salt*, $\text{C}^3\text{H}^{10}\text{Cu}^2\text{O}^6 \cdot 12\text{H}^2\text{O}$, obtained by boiling the aqueous acid with carbonate of copper, forms greenish crystals soluble in water and in alcohol. The crystals are monoclinic prisms exhibiting the combination $\infty\text{P} \cdot \text{oP}$. [P ∞]. Inclination of ∞P to oP in the clinodiagonal principal section = $109^\circ - 111^\circ$; oP to oP = $84^\circ - 80^\circ$.—The *lead-salt*, $\text{C}^3\text{H}^{10}\text{Pb}^2\text{O}^6$, prepared in like manner, is soluble in water, and even in absolute alcohol, and dries up to a white crystalline mass resembling wavelite.—The *potassium-salt*, $\text{C}^3\text{H}^{10}\text{K}^2\text{O}^6 \cdot 4\text{H}^2\text{O}$, is soluble in water and in alcohol, has a great tendency to form supersaturated solutions, and crystallises from water in large transparent prisms permanent in the air. Ether precipitates from the alcoholic solution a salt containing a smaller proportion of water, probably 3 at. (29.7 per cent.).—The *silver-salt*, $\text{C}^3\text{H}^8\text{AgO}^3$, is a crystalline precipitate, which separates from solution in hot water in delicate flat needles, and does not melt at 100°C .—The *sodium-salt*, $\text{C}^3\text{H}^8\text{NaO}^3$, is anhydrous, deliquescent, and is precipitated by ether from its alcoholic solution as a syrup, which dries up to a crystalline mass under the air-pump.—The *zinc-salt*, $\text{C}^3\text{H}^{10}\text{Zn}^2\text{O}^6 \cdot 2\text{H}^2\text{O}$, forms acute rhombic octahedrons truncated by the face oP , parallel to which the crystals are perfectly cleavable. P: P in the terminal edges = $123^\circ 19'$ and $67^\circ 23'$; in the lateral edges = $146^\circ 43'$. 100 pts. of water at 18.4°C . dissolve 27.4 pts. of the hydrated salt. It is also soluble in alcohol.

Ethyl-glycollic acid. *Ethyl-oxacetic acid.* $\text{C}^3\text{H}^3\text{O}^3 = \left(\begin{array}{c} \text{C}^3\text{H}^3 \\ \text{C}^3\text{H}^3\text{O}^3 \\ \text{H} \end{array} \right) \left\{ \begin{array}{c} \text{O} \\ \text{O} \end{array} \right\}$ (Heintz,

Pogg. Ann. cix. 489; cxi. 552.—Jahresb. 1859, p. 360; 1860, p. 314.)—Prepared by the action of ethylate of sodium on chloracetic acid in presence of excess of absolute alcohol. The resulting mixture is filtered from the chloride of sodium, which separates out, and the alcohol is distilled off. The residue dissolved in water is mixed with a quantity of sulphate of copper rather more than equivalent to the quantity of sodium used; the mixture is evaporated to dryness over the water-bath, and the residue is exhausted with alcohol.* The resulting solution, which contains nothing but cupric ethyl-glycollate, together with cupric chloride, is evaporated, and the residue repeatedly crystallised from water. To prepare the acid, the copper-salt is decomposed in hot aqueous solution by sulphydric acid, and the clear liquid is distilled, the portion which goes over at about 200°C . being collected apart.

At a higher temperature the acid is decomposed, yielding a colourless distillate, which after a while deposits white pulverulent dioxyethylene, $\text{C}^2\text{H}^2\text{O}^2$ (see METHYL-ALKYL); but if the distillation be so conducted that the undecomposed acid can flow back again, it is for the most part resolved into glycollic acid, which remains in the retort, and ethyl-glycollate of ethyl, $\text{C}^3\text{H}^4(\text{C}^3\text{H}^3)(\text{C}^3\text{H}^3)\text{O}^6$, which distils over together with aqueous ethyl-glycollic acid, the two liquids forming separate layers in the receiver:

Ethyl-glycollic acid distilled with iodide of phosphorus gives off iodide of ethyl and acetic acid, and leaves a residue containing glycollic acid.

Ethyl-glycollates.—The *barium-salt*, $\text{C}^3\text{H}^{14}\text{Ba}^2\text{O}^6$, is very soluble in water and in alcohol, and crystallises after some time from the syrupy solution.

* The undissolved residue contains, besides sulphate of copper, a small quantity of a copper-salt, sparingly soluble in water, and having the composition of glycollate of copper, $\text{C}^3\text{H}^8\text{Cu}^2\text{O}^6$.

The *copper-salt*, $\text{C}^{\text{H}}^{\text{H}}^{\text{H}}\text{Cu}^{\text{O}}^{\text{O}} \cdot 2\text{H}^{\text{O}}$, crystallises in oblique rhombic prisms of a fine blue colour, which melt and give off their crystallisation-water when heated. 100 pts. water at 14°C . dissolve 12.34 pts. of the anhydrous, and 14.22 pts. of the crystallised salt; 100 pts. of alcohol of specific gravity 0.825 dissolve 1.74 pts. of the hydrated salt at 13.5°C .—The *silver* and *mercurous* salts are white precipitates formed in concentrated solutions and partially reduced at the boiling heat.—The *zinc-salt* is not crystallisable.

Ethyl-glycollate of Ethyl, $\text{C}^{\text{H}}^{\text{H}}^{\text{H}}\text{O}^{\text{O}} = \left(\begin{smallmatrix} \text{C}^{\text{H}}^{\text{H}} \\ \text{C}^{\text{H}}^{\text{H}}\text{O}^{\text{O}} \end{smallmatrix} \right)^{\text{O}}_{\text{O}}$ is obtained as already described by the decomposition of ethyl-glycollic acid. Its properties have not been examined.

Ethyl-glycollate of Amyl, $\text{C}^{\text{H}}^{\text{H}}^{\text{H}}\text{O}^{\text{O}} = \left(\begin{smallmatrix} \text{C}^{\text{H}}^{\text{H}} \\ \text{C}^{\text{H}}^{\text{H}}\text{O}^{\text{O}} \end{smallmatrix} \right)^{\text{O}}_{\text{O}}$, obtained by digesting a mixture of ethyl-glycollate of sodium and iodide of amyl diluted with absolute alcohol, in a sealed tube, decanting the resulting liquid from the iodide of sodium which separates, treating it with mercury to remove excess of iodine, and rectifying,—is a transparent, colourless, rather viscid liquid, sinking slowly in water, of agreeable fruity odour, boiling between 180° and 190°C ., soluble in all proportions in alcohol and ether. It is decomposed by alcoholic potash, emitting the penetrating odour of amylic alcohol. (O. Siemens.)

Glycollate of Ethyl. $\text{C}^{\text{H}}^{\text{H}}\text{O}^{\text{O}} = \left(\begin{smallmatrix} \text{H} \\ \text{C}^{\text{H}}^{\text{H}}\text{O}^{\text{O}} \end{smallmatrix} \right)^{\text{O}}_{\text{O}}$. (Heintz, Jahresb. 1861, p. 446.)

—This compound, isomeric, but not identical with ethyl-glycollic acid, is produced by heating chloracetate of ethyl with rather more than an equivalent quantity of glycollate of sodium to 130° — 150°C .:

It dissolves in water, forming a solution which does not exhibit an acid reaction. By boiling with alkalis, it is decomposed, yielding ethylic alcohol and an alkaline glycollate, a reaction by which it is distinguished from the preceding compound. With aqueous ammonia it forms glycollamide (p. 908).

Acetoglycollate of Ethyl, $\text{C}^{\text{H}}^{\text{H}}\text{O}^{\text{O}} = \left(\begin{smallmatrix} \text{C}^{\text{H}}^{\text{H}}\text{O}^{\text{O}} \\ \text{C}^{\text{H}}^{\text{H}} \end{smallmatrix} \right)^{\text{O}}_{\text{O}}$.—Produced by heating chlor-

acetate of ethyl with acetate of sodium. It is an oily, mobile liquid, of specific gravity 1.0093 at 17°C ., boiling at 179° . With alcoholic ammonia, it yields glycollamide and acetamide, together with glycollate and acetate of ammonium. With a small quantity of ammonia, the products are glycollamide and acetate of ethyl. Aqueous bases decompose it, for the most part, forming acetates and glycollates; but by mixing it with water, and somewhat less than an equivalent quantity of slaked lime, it may be converted into *acetoglycollate of calcium*, $\text{C}^{\text{H}}^{\text{H}}\text{CaO}^{\text{O}}$. (Heintz, Ann. Ch. Pharm. cxiii. 325.)

Amyl-glycollic acid. *Amyl-oxacetic acid.* $\text{C}^{\text{H}}^{\text{H}}\text{O}^{\text{O}} = \left(\begin{smallmatrix} \text{C}^{\text{H}}^{\text{H}} \\ \text{C}^{\text{H}}^{\text{H}}\text{O}^{\text{O}} \end{smallmatrix} \right)^{\text{O}}_{\text{O}}$. (Heintz,

Pogg. Ann. cix. 301; Jahresb. 1859, p. 358.—O. Siemens, *Inaugural Dissertation*, Göttingen, 1861; Jahresb. 1861, p. 449.)—Produced by the action of amylate of sodium on chloracetic acid. To obtain it in the pure state, 98.6 grms. of sodium are dissolved in amylic alcohol, and to the resulting amylate of sodium, kept in the liquid state by heat, is added a solution of 190 grms. chloracetic acid in amylic alcohol: the liquid, filtered from chloride of sodium, is freed from excess of amylic alcohol partly by distillation, partly by agitation with water. The aqueous solution of amyl-glycollate of sodium thus obtained is decomposed by excess of hydrochloric acid; the amyl-glycollic acid which rises to the surface is removed, and the portions of acid still remaining in the watery liquid are dissolved out by agitation with ether. The whole of the amyl-glycollic acid thus obtained is then subjected to fractional distillation till a distillate is obtained boiling at about 135°C . (Siemens.)

Amyl-glycollic acid is a not very mobile liquid, of specific gravity 1.003, boiling at 235°C ., sparingly soluble in water, but soluble in all proportions in alcohol and ether. It burns with a bright smoky flame, giving off a pungent odour.

Amyl-glycollates.—The *barium-salt* is not crystallisable (Heintz).—The *copper-salt*, $\text{C}^{\text{H}}^{\text{H}}\text{Cu}^{\text{O}}^{\text{O}}$, obtained by recrystallising the precipitate formed on mixing the solutions of equivalent quantities of amyl-glycollate of sodium and sulphate of copper, forms small blue-green crystals, appearing under the microscope as right

prisms with truncated end-faces. It is moderately soluble in alcohol, very slightly in water and in ether. It melts at 110°C . to a green liquid, and gradually decomposes (Siemens).—The *mercurous salt*, $\text{C}^4\text{H}^{26}(\text{Hg}^2)^2\text{O}^6$, is obtained by precipitation as a white powder, which melts with decomposition at 170°C ., is very sparingly soluble in water, more soluble in alcohol, insoluble in ether.—The *potassium-salt*, $\text{C}^4\text{H}^{12}\text{KO}^3 \cdot \text{H}^2\text{O}$, is obtained by neutralising the acid with alcoholic potash, removing the excess of potash by carbonic acid, filtering, evaporating, and crystallising from a small quantity of alcohol. It crystallises with difficulty in long oblique rhombic prisms with terminal faces very much inclined to the principal axis. At 10° to 15°C . it crystallises in thin, nearly rectangular plates, resembling the sodium-salt. It is very soluble in water and in alcohol, and is precipitated from the alcoholic solution by ether in the crystalline form. It gives off its water without melting at 120°C ., and melts, without decomposition, between 200° and 210°C . It deliquesces slowly when exposed to the air.—The *silver-salt*, $\text{C}^4\text{H}^{12}\text{AgO}^3$, is obtained, by double decomposition, as a white curdy precipitate, soon becoming light red, and, after being washed and dissolved in a large quantity of boiling water, separates, on cooling, in slender rose-red needles. It dissolves with moderate facility in alcohol, sparingly in water, not at all in ether. When perfectly pure it is white, but decomposes quickly in contact with the air; at 110°C . it melts and decomposes.—The *sodium-salt*, $\text{C}^4\text{H}^{12}\text{NaO}^3 + 2\text{H}^2\text{O}$, crystallises from alcohol in thin, colourless, rectangular plates, which dissolve readily in water and in alcohol, are insoluble in ether, give off their water of crystallisation without deliquescing, and melt without decomposition, between 190° and 200°C . They effloresce when exposed to the air, after a while. (Siemens.)

Amyl-glycollate of ethyl. $\text{C}^6\text{H}^{18}\text{O}^3 = \left(\begin{array}{c} \text{C}^6\text{H}^{11} \\ \text{C}^2\text{H}^2\text{O} \\ \text{C}^2\text{H}^3 \end{array} \right) \left\{ \begin{array}{c} \text{O} \\ \text{O} \end{array} \right\}$.—Prepared by digesting a mix-

ture of amyl-glycollate of sodium and iodide of ethyl diluted with absolute alcohol, in a sealed tube., at the heat of the water-bath, for four days; decanting the liquid from the iodide of sodium produced in the reaction; shaking it up with mercury to remove free iodine; subjecting it to fractional distillation; treating the distillate obtained between 205° and 210°C ., with carbonate of sodium, to remove free amyl-glycollic acid; dehydrating the neutral ether thus obtained; rectifying it, and collecting the portion which passes over at 212°C . It is a colourless, mobile liquid, having an ethereal odour. When decomposed by alcoholic potash, it does not emit the odour of amylic alcohol, by which character, as well as by its higher boiling point, it is distinguished from the isomeric compound ethyl-glycollate of amyl (p. 917).

Phenyl-glycollic acid. *Phenyl-oxacetic acid.* $\text{C}^6\text{H}^5\text{O}^3 = \left(\begin{array}{c} \text{C}^6\text{H}^5 \\ \text{C}^2\text{H}^2\text{O} \\ \text{H} \end{array} \right) \left\{ \begin{array}{c} \text{O} \\ \text{O} \end{array} \right\}$.—When

a mixture of phenylate of sodium and chloracetic acid is heated for a considerable time and then left to cool, phenyl-glycollate of sodium is obtained as a gradually solidifying mass; and by decomposing the aqueous solution of this salt with hydrochloric acid, impure phenyl-glycollic acid is obtained as a brown oily liquid, which, by repeated solution in lukewarm water and evaporation, yields very thin silky needles, melting in warm water to a heavy oil. These crystals yielded by analysis numbers intermediate between $\text{C}^6\text{H}^5\text{O}^3$ (phenyl-glycollic acid) and $\text{C}^9\text{H}^{10}\text{O}^3$ (cresyl-glycollic acid).

Phenyl-glycollate of barium, $\text{C}^6\text{H}^{11}\text{Ba}^2\text{O}^6 \cdot 3\text{H}^2\text{O}$, forms large, thin, very brittle laminae. The *copper-salt*, $\text{C}^6\text{H}^{14}\text{Cu}^2\text{O}^6 \cdot 2\text{H}^2\text{O}$, forms sparingly soluble, microscopic, prismatic or tabular crystals.—The *sodium-salt*, $\text{C}^6\text{H}^5\text{NaO}^3 \cdot \frac{1}{2}\text{H}^2\text{O}$, crystallises from absolute alcohol in extremely slender needles.—The aqueous solution of this salt forms with nitrate of silver a sparingly soluble precipitate, which, when crystallised from hot water, yields the *silver-salt*, $\text{C}^6\text{H}^5\text{AgO}^3$, in slender concentrically grouped needles.—The aqueous solution of the sodium-salt also yields precipitates with acetate of lead and mercurous nitrate.

When the warm concentrated aqueous solution of a phenyl-glycollate is mixed with hydrochloric acid, phenyl-glycollic acid separates from it as an oil; the cold solution heated with hydrochloric acid first becomes milky, and then on agitation yields crystalline flakes, which are easily fusible and likewise sublimed when heated for some time in the water-bath. 100 pts. of water dissolve rather more than 1 pt. of the acid; it is easily soluble in alcohol and ether. (Heintz.)

Cresyl-glycollic Acid. *Cresyl-oxacetic acid.* $\text{C}^9\text{H}^{10}\text{O}^3 = \left(\begin{array}{c} \text{C}^9\text{H}^7 \\ \text{C}^2\text{H}^2\text{O} \\ \text{H} \end{array} \right) \left\{ \begin{array}{c} \text{O} \\ \text{O} \end{array} \right\}$.—The

mother-liquor of the impure phenyl-glycollate of sodium, obtained as above described

(p. 918), yielded another sodium-salt, easily soluble in alcohol, difficult to crystallise, and separated by ether from the alcoholic solution, not in needles like the phenyl-glycollate, but as a gelatinous mass. From this salt the acid was separated by hydrochloric acid, and the solution of the ammonium-salt, and a sparingly soluble copper-salt, $C^{10}H^{10}Cu^2O^6 \cdot 2H^2O$, were prepared. (Heintz.)

GLYCOLLIDE. $C^2H^2O^2$. *Glycollic anhydride*.—A compound isomeric with glyoxal, and differing from glycollic acid by 1 at. water. It is produced:—1. By heating glycollic acid to 200° — 240° C., small quantities of diglycollic acid and dioxymethylene being formed at the same time. (Heintz, Pogg. Ann. cxv. 462; Jahresb. 1861, p. 444.)

2. By the action of heat on chloracetate of potassium:

If the crystallised chloracetate is used, the greater part of the glycollide thus produced unites with water contained in the salt, and is converted into glycollic acid. (Kekulé, Ann. Ch. Pharm. cxv. 288.)

3. By boiling chloracetic acid with water, and evaporating the acid liquid, which also contains hydrochloric acid, to dryness, a residue is obtained, containing glycollide. (Heintz, *loc. cit.*)

4. By heating tarttronic acid to 180° C., as long as carbonic anhydride continues to escape, pulverising the residual mass as soon as it has become solid, which takes several days, and washing it with hot water:

It was by this process that glycollide was first obtained. (Dessaignes, Compt. rend. xxxviii. 46.)

Glycollide is a white tasteless substance, insoluble in cold and very slightly soluble in hot water. It melts at 180° C. without loss of weight. It dissolves in potash, yielding glycollate of potassium. Heated with ammonia, it forms glycollamide (p. 909).

GLYCOLS. *Diatomic Alcohols*.—Bodies formed on the general type:

$n = 2$ giving the ethylenic, $n = 5$ the amylenic glycols, &c. The glycols of each series are di- or polyatomic, according as p is equal to or greater than unity. The general properties of these compounds are described under the articles ALCOHOLS (i. 102) and ETHERS (ii. 517, 522). The glycols of amylenic (i. 208; ii. 9), ethylenic (ii. 574), tetraylenic, or butylenic, and tritylenic, or propylenic, have been obtained; but the ethylenic compounds and their derivatives are the only ones that have been very completely studied.

GLYCOSINE. $C^6H^4N^1 = N^1(C^2H^2)^2$. (Debus, Ann. Ch. Pharm. cxvii. 199.)—An organic base produced by the action of ammonia on glyoxal:

When a syrupy solution of glyoxal, heated to 60° or 70° C., is mixed with three times its volume of strong aqueous ammonia at the same temperature, the liquid turns brown, effervesces slightly, and after a while deposits small crystalline needles. When the quantity of these crystals no longer increases at the temperature above-mentioned, the liquid is left to cool; the still strongly-coloured crystals are separated by filtration, washed with cold water, and dissolved in very dilute hydrochloric acid; the solution is decolorised by animal charcoal; and the filtrate is slowly mixed with very dilute ammonia; it then deposits glycosine as a crystalline powder; if it is not colourless, the solution in hydrochloric acid, &c. must be repeated.

Glycosine is a pulverulent substance, consisting of truncated striated prisms, becoming strongly electric by trituration, soft to the touch, tasteless and inodorous. When heated on platinum-foil, it volatilises without melting and leaves no residue; it may be sublimed by careful heating between two watch-glasses, and then forms a bulky sublimate consisting of needle-shaped crystals. It is nearly insoluble in cold, sparingly soluble in boiling water; easily in hydrochloric and acetic acids. The hydrochloric acid solution concentrated over the water-bath yields large crystals of *hydrochlorate of glycosine*; with oxalate of ammonium it forms, especially on stirring, a crystalline precipitate of *oxalate of glycosine*; with iodide of potassium, no precipitate; with cupric chloride, a green; with mercuric chloride, a heavy crystalline precipitate.

GLYCYRRHETIN. $C^{18}H^{20}O^4$? (Gorup-Besanez, Ann. Ch. Pharm. cxviii. 236.)—A substance obtained, together with glucose, by boiling glycyrrhizin with dilute acids.

It is a brownish-yellow brittle resin, which does not melt in boiling water, and is insoluble in water, but soluble in alcohol and in alkalis. It dissolves in strong sulphuric acid, forming an amaranth-red solution, the colour of which gradually changes to purple-violet, and becomes violet on dilution with water, a bluish-black substance being at the same time precipitated. The alcoholic solution may be decolorised by animal charcoal. No satisfactory analysis has yet been made of this substance.

GLYCYRRHIZIN. $C^{24}H^{36}O^9$. (A. Vogel, Jun., J. pr. Chem. xxviii. 1.—Lade, Ann. Ch. Pharm. lix. 224.—Gorup-Besanez, *ibid.* cxviii. 236.)—A saccharine substance contained in the root of liquorice (*Glycyrrhiza glabra* and *G. echinata*). It is best prepared from Russian liquorice-root (which yields a less coloured and more easily purified product than the Spanish root), by precipitating the filtered and concentrated aqueous infusion with dilute sulphuric acid; washing the dark brown precipitate with water till it is quite free from sulphuric acid; then dissolving it several times in alcohol of 82 per cent., and mixing the not too concentrated solution with small quantities of ether as long as a dark-coloured resinous substance is thereby separated. The filtrate on evaporation leaves glycyrrhizin, as an amorphous substance easily pulverised, and containing but a very small quantity (0.2 per cent.) of ash (Gorup-Besanez). Vogel and Lade adopted a similar process, but evaporated the alcoholic solution without first freeing it from the dark resinous substance by means of ether. S. Martin (Jahresb. 1860, p. 551) precipitates the aqueous extract of the root with acid tartrate of potassium (cream of tartar), digests the precipitate in alcohol, and evaporates the alcoholic filtrate to dryness.

Glycyrrhizin is a light yellow amorphous substance, having a sweet taste; sparingly soluble in cold, easily soluble in hot water, soluble also in alcohol, even in the cold, and in ether by the aid of a gentle heat; alkalis dissolve it with reddish-yellow colour; the solutions yield with acids a precipitate partially soluble in excess of the acid. The aqueous solution is precipitated by chloride of barium, sulphate of magnesium, sulphate of copper, chloride of copper, and basic acetate of lead.

The constitution of glycyrrhizin is determined by the following analyses:

	Calculation.	Mean of Analyses.	
		Vogel.	Gorup-Besanez.
C^{24}	288	61.6	61.6
H^{36}	36	7.6	7.7
O^9	144	30.8	30.8
$C^{24}H^{36}O^9$	468	100.0	100.0

The analytical numbers might of course be equally well represented by the simpler formula $C^8H^{12}O^3$; but the calcium-salt of glycyrrhizin contains, according to Gorup-Besanez, 53.9 per cent. C, 7.1 H, 30.77 O, and 8.29 CaO, agreeing with the formula $2C^8H^{12}O^3.3CaO.4H^2O$, and the lead-salt 24.0 C, 2.9 H, 16.10 and 56.9—56.45 PbO, agreeing with $C^8H^{12}O^3.PbO.4PbHO$. Hence the formula of glycyrrhizin appears to be $C^{24}H^{36}O^9$. Lade obtained, by the analysis of glycyrrhizin, 60.6—61.3 per cent. C, and 7.1 to 7.4 H; but his glycyrrhizin was impure, containing nitrogen.

Glycyrrhizin is not fermentable. Nitric acid acts upon it even in the cold, giving off abundant red fumes, and forming a light yellow substance; on applying heat, the action becomes stronger, and a pale yellow crystallisable nitro-acid is formed, probably oxypticric acid, together with oxalic acid. It is also violently oxidised by a mixture of chromate of potassium, or peroxide of manganese, and sulphuric acid. (Gorup-Besanez.)

By boiling with dilute sulphuric and other acids, glycyrrhizin is resolved into glycyrretin and glucose, probably thus:

GLYOXAL. $C^2H^2O^2 = (C^2O^2).H^2$. (Debus, Ann. Ch. Pharm. cii. 20; cxvii. 199; cx. 316; cxviii. 253.—Gm. xii. 503.)—This compound may be regarded as an aldehyde of glyoxylic and of oxalic acid, and stands between ethylenic glycol (hydrate of ethylene) and oxalic acid, in the same manner as common aldehyde between ethylic alcohol (hydrate of ethyl) and acetic acid.

It is produced, together with glyoxylic acid and other products, by the action of nitric acid upon alcohol. When the syrupy neutral liquid obtained in the preparation of glyoxylic acid, is mixed with several times its volume of acid sulphite of sodium, and the mixture is left to itself for some hours, the sides of the vessel become covered

with a white crystalline crust, consisting of a compound of glyoxal with the acid sulphite; and by dissolving this compound in the smallest possible quantity of boiling water, and leaving the filtrate to cool quietly, the compound is obtained in fine crystals, which may be purified by two recrystallisations. A further quantity may be obtained by treating the mother-liquors with alcohol. The sodium-compound, mixed with chloride of barium, yields, after two days, crystals of the corresponding barium-compound; and, by exactly decomposing the barium-compound with sulphuric acid, and evaporating the filtrate to remove water and sulphurous acid, glyoxal is obtained in the solid state.

Glyoxal appears, also, to occur among the products of the oxidation of ethylenic glycol by nitric acid; but its presence has not been distinctly proved.

Glyoxal is a transparent, slightly yellowish, amorphous mass, which deliquesces readily when exposed to the air, and dissolves with great facility in water, alcohol, and ether. The aqueous solution is merely clouded by neutral acetate of lead; but, on adding ammonia, a copious white precipitate is produced. With nitrate of silver and ammonia it forms a beautiful speculum of silver. A small quantity of very dilute nitric acid converts glyoxal into glyoxylic acid; by a larger quantity, even of very dilute nitric acid, it is converted into oxalic acid.

Caustic fixed alkalis convert it into a salt of glycollic acid, *e. g.*:

A syrupy solution of glyoxal, gently heated with strong aqueous ammonia, yields two bases—viz., glyoxaline, $\text{C}^4\text{H}^4\text{N}^2$, and glycosine, $\text{C}^4\text{H}^4\text{N}^2$,* according to the equations—

Glyoxaline. Formic acid.

Glycosine.

Glyoxaline is by far the more abundant product of the two.—Glyoxal is decomposed by sulphydric acid.

Compounds of Glyoxal.—When a stream of ammonia-gas is passed into an ethereal solution of glyoxal, a white precipitate is formed, consisting of glyoxal-ammonia.

Glyoxal, like other aldehydes, forms crystalline compounds with the acid sulphites of alkali-metals. The ammonium-salt, $\text{C}^2\text{H}^2\text{O}^2 \cdot 2(\text{NH}^4)\text{HSO}^3$ forms shining prismatic crystals, very soluble in water, insoluble in alcohol. The aqueous solution is precipitated by acetate of lead, but not by salts of zinc, copper, or silver.

The barium-salt is deposited from the hot saturated solution in concentrically-grouped masses, containing $\text{C}^4\text{H}^4\text{O}^4 \cdot \text{Ba}^2\text{H}^2\text{S}^2\text{O}^6 \cdot \frac{3}{2}\text{H}^2\text{O}$. The aqueous solution of this salt, boiled with a slight excess of caustic baryta, yields a precipitate of neutral sulphite of barium, while free baryta and glycolate of barium remain in solution:

The sodium-salt, $\text{C}^2\text{H}^2\text{O}^2 \cdot 2(\text{NaHSO}^3) \cdot \text{H}^2\text{O}$, forms small hard crystals, easily soluble in water, insoluble in alcohol. The aqueous solution, after boiling for some time, precipitates acetate of lead and chloride of barium.

GLYOXALINE. $\text{C}^4\text{H}^4\text{N}^2$. (Debus, Ann. Ch. Pharm. cvii. 199.)—An organic base produced simultaneously with glycosine by the action of strong aqueous ammonia on glyoxal. When the brown mother-liquor from which the glycosine has separated, is evaporated to a syrup at a gentle heat to expel free ammonia, a syrupy uncrystallisable residue is left, which, when mixed with twice its volume of a saturated solution of oxalic acid, soon deposits a large quantity of crystals of oxalate of glyoxaline (the mother-liquor retaining formic acid, *vid. sup.*), which may be purified by solution in water, treatment with animal charcoal, and recrystallisation. From this salt the base may be separated by mixing the solution with chalk, heating it for some time to 100°C ., and evaporating the filtered liquid.

Glyoxaline crystallises with difficulty, and only from a syrupy solution, in concentrically grouped crystals. It melts easily; has a faint fishy odour; volatilises at a higher temperature in thick white vapours; deliquesces in damp air; dissolves easily in water, forming a solution which turns turmeric brown and reddened litmus blue; neutralises strong acids; precipitates the chlorides of iron and copper (the latter precipitate re-dissolving with blue colour in excess of glyoxaline), and nitrate of silver, but not calcium-salts.

Chloroplatinate of glyoxaline, $2(\text{C}^4\text{H}^4\text{N}^2 \cdot \text{HCl}) \cdot \text{PtCl}^4$, is a yellow crystalline precipitate, which dissolves in hot water, and separates in orange-red prisms.

The oxalate, $\text{C}^4\text{H}^4\text{N}^2 \cdot \text{C}^2\text{H}^2\text{O}^4$, forms colourless prisms, which do not undergo any

* Kekulé (Zehrs. II. 33) suggests that glyoxaline and glycosine may possibly be isomeric, and related to one another in the same manner as hydrobenzamide and amarine.

alteration at 125° C., but when heated on platinum-foil, melt easily and volatilise in white fumes.

GLYOXYLIC ACID. $C^2H^2O^3$. Syn. *Glyoxalic acid*. (Kekulé, p. 923, footnote, Debus, Phil. Mag. [4] xii. 361; Ann. Ch. Pharm. c. 1; cii. 28; ex. 316.—Gm. xii. 505; xiii. 434.)—This acid is produced, together with glycollic acid and other compounds:

1. By the action of nitric acid upon alcohol, glycol, or glyoxal (Debus):

2. By the action of nascent hydrogen upon oxalic acid:

e.g. when oxalate of sodium is submitted to the action of sodium-amalgam in presence of water; or oxalate of zinc to that of zinc and dilute sulphuric acid. When the action is not accelerated by elevation of temperature, and a large quantity of salt is used, glyoxylic acid is the chief product; in the contrary case, glycollic acid. (Church, Chem. Soc. J. [2] i. 301.)

Preparation.—1. From Alcohol.—220 grms. of alcohol of 80 per cent. are poured into a tall narrow flask capable of holding about 1½ lb. of water; 100 grammes of water are introduced below the alcohol by means of a funnel having its neck finely drawn out; and below this are poured 200 grms. of red fuming nitric acid, so that the three liquids may remain one above the other and mix as little as possible at first. The bottle is then closed with a cork fitted with a gas-delivery tube dipping under water, and the whole is left for six or eight days, at a temperature of 20° to 22° C., till the liquids have become completely mixed, and the resulting nitrite of ethyl has volatilised. The residual liquid—containing nitric, acetic and formic acids, compound ethers, glyoxal and other aldehydes, glycollic acid and glyoxylic acid—is evaporated to a syrup over the water-bath in portions of 20 to 30 grms. each; the residues, containing oxalic, glycollic and glyoxylic acids, together with the less volatile aldehydes, are dissolved in small quantities of water; the united solutions are neutralised with chalk; the neutral liquid is mixed with an equal volume of alcohol; and the resulting precipitate of calcium-salts pressed and repeatedly boiled with water. The aqueous extract yields crystals of glyoxylate of calcium, and a further quantity of this salt may be obtained by concentrating the mother-liquor. The subsequent mother-liquors yield a double salt of glycolate and glyoxylate of calcium, and the last contain glycolate of calcium (p. 911).

2. From Oxalic acid.—A large quantity of oxalate of zinc is placed, together with a few pieces of pure zinc, in a beaker, the mixture covered with water, and dilute sulphuric acid added slowly drop by drop. Milk of lime is then added in slight excess, together with a large quantity of water; the mixture is warmed, filtered, supersaturated with carbonic acid, and again warmed and filtered; the filtrate thus obtained deposits on cooling needle-shaped crystals of glyoxylate of calcium. Or better: the mixture of zinc-salts is shaken up with ether, the syrupy ethereal extract thus obtained is treated with carbonate of calcium, and the various calcium-salts thus obtained are separated by Debus's method. (Church.)

The hydrated acid is obtained by decomposing the calcium-salt with oxalic acid, and evaporating the solution in vacuo, in the form of a viscid, transparent, slightly yellowish syrup, which dissolves readily in water. The solution heated to 100° C., gives off unaltered glyoxylic acid, together with the watery vapours. The syrupy acid, when strongly heated, gives off acid vapours and volatilises, leaving a scanty black residue. (Debus.)

A solution of glyoxylic acid treated with *sulphydric acid* yields nodular crystals apparently containing a sulphuretted acid. A strong solution of glyoxylate of calcium repeatedly treated with sulphydric acid yields the salt $C^2H^2Ca^2O^3S.3H^2O$, the acid of which consists of a double molecule of glyoxylic acid, having one-fifth of its oxygen replaced by sulphur. (Debus.)

Glyoxylic acid dissolves *zinc*, without evolving an equivalent quantity of hydrogen, the hydrogen in fact uniting with the glyoxylic acid to form glycollic acid. (Debus.)

The *glyoxylates*, C^2HMO^3 , are obtained by neutralising the bases or their carbonates with the aqueous acid. Most of them contain 1 at. of water, of which they cannot be deprived without undergoing further decomposition. For this reason, Debus at

first assigned to them the formula $C^2H^2MO^4$, regarding the acid as $C^2H^2O^4$. But the composition of the ammonium-salt shows that the true formula of the acid is $C^2H^2O^4$, which is likewise more in accordance with its general relations.*

It is not exactly known whether glyoxylic acid is capable of forming salts with 2 at. metal. An insoluble lead-salt, $C^2Pb^2O^4.H^2O$, is produced by double decomposition, but it is perhaps a basic salt, $C^2H^2Pb^2O^4.Pb^2H^2O^2$. From the solution of the calcium-salt, $C^2H^2Ca^2O^4.2H^2O$, lime-water throws down a white precipitate, which is perhaps the neutral calcium-salt $C^2Ca^2O^4$; but on the other hand it is possible that the original calcium-salt may simply be rendered insoluble by the addition of the lime-water. (Kekulé.)

The glyoxylates unite with sulphites. A strong solution of acid sulphite of sodium mixed with syrupy glyoxylic acid yields the double salt $C^2HNaO^3.NaHSO^3$; and by passing sulphurous acid gas into water in which glyoxylate of calcium is suspended, and concentrating the resulting solution, crystals of the salt $2C^2H^2Ca^2O^4.Ca^2H^2S^2O^6.10H^2O$ are obtained. (Debus.)

Glyoxylate of Ammonium, $C^2H(NH^4)O^3$, prepared by precipitating the calcium-salt with oxalate of ammonium, and evaporating in vacuo over sulphuric acid, forms small prismatic crystals, easily soluble in water. The concentrated solution turns yellow when boiled, or when evaporated at $100^\circ C$. It forms crystalline precipitates with nitrate of silver and acetate of lead, also with sulphate of copper after a while. Potash evolves ammonia from it even at ordinary temperatures. It gives by analysis 26.70 per cent. C, and 5.75 H (by calculation 26.4 C and 5.5 H).

Glyoxylate of Barium, $C^2H^2Ba^2O^4.4H^2O$.—Prepared by digesting diluted glyoxylic acid at ordinary temperatures with carbonate of barium till the acid is completely neutralised, and evaporating the filtrate in vacuo. At a certain degree of concentration, the salt begins to separate in small white crystals. It is partly resolved into glycollic acid, and oxalate of barium when heated to $120^\circ C$, or when its aqueous solution is raised to the boiling point. With lime-water, acetate of lead, and nitrate of silver, it behaves like the calcium-salt. By analysis it gives 39.4 per cent. barium, the above formula requiring 38.9 per cent.

Glyoxylate of Calcium, $C^2H^2Ca^2O^4.2H^2O$, crystallises in thin needles or hard prismatic crystals, soluble in 177 parts of water at $8^\circ C$, and yielding by analysis 18.2 per cent. calcium (calculation 18.01). It may be heated to between 160° and $170^\circ C$. without loss of weight, but at 180° it gives off water and carbonic anhydride, and yields glycollic acid and carbonate of calcium, together with a resinous substance. Lime-water added to the solution of this salt immediately produces a copious precipitate, which, immediately after its formation, dissolves readily in acetic acid, but if left to itself for awhile, or more quickly if boiled for a few seconds with the liquid, becomes insoluble in acetic acid, being in fact resolved into glycollic acid and oxalate of calcium :

This reaction affords the means of separating glyoxylic from glycollic acid, when the two occur together, a solution of pure glycollic acid of calcium not being precipitated by lime-water. It also serves for the quantitative estimation of glyoxylic acid, 128 pts. (1 at.) of oxalate of calcium ($C^2Ca^2O^4$) corresponding to 198 pts. (2 at.) of the glyoxylate ($C^2H^2Ca^2O^4.2H^2O$).

Glyoxylate of calcium forms double salts with glycollic acid and lactate of calcium. (See page 911, and LACTIC ACID.)

An *ammonio-glyoxylate of calcium*, $3C^2H^2Ca^2O^4.4NH^4.2H^2O$, is obtained in crystals on pouring chloride of calcium into a solution of glyoxylate of ammonium in the smallest possible quantity of water. The same salt is obtained in the anhydrous state by adding ammonia to a boiling saturated solution of glyoxylate of calcium.

Glyoxylate of Lead forms with ammonia a compound containing 7 at. $C^2H^2Pb^2O^4$ to $4NH^4$.

Glyoxylate of Potassium is deliquescent and difficult to crystallise.

Glyoxylate of Silver, $C^2HAgO^3.H^2O$, is obtained as a white crystalline powder, by precipitating nitrate of silver with glyoxylate of ammonium. It is but sparingly soluble in cold water, and is rapidly decomposed by light. Analysis gave 54.1 and 53.9 per cent. silver, the formula requiring 54.2 per cent. It unites with ammonia, forming a salt containing 4 at. C^2HAgO^3 to $3NH^4$. (Debus.)

Glyoxylate of Zinc, $C^2H^2Zn^2O^4.4H^2O$.—Produced as a white crystalline precipitate on adding a strong solution of glyoxylate of calcium to acetate of zinc. It dissolves sparingly in water, easily in acetic acid, hydrochloric acid, and caustic potash. After drying over oil of vitriol, it gave by analysis 38.09 and 38.73 per cent. zinc, the

* Kekulé (*Lehrb.* II. 20) applies the term glyoxalic acid to the compound $C^2H^2O^3$, and glyoxylic acid to the acid $C^2H^2O^4$, produced by the decomposition of bromoglycollic acid of silver (p. 915), and by the reduction of oxalic acid.

formula requiring 37·64 per cent. The 2 at. water cannot be removed without decomposing the salt.

GMELINITE. *Soda Chabasite. Hydrolite. Herschelite.*—A hydrated silicate of aluminium, calcium, and sodium, whose composition is expressed by the same general formula as that of chabasite, viz. $M^2O \cdot Al^2O^3 \cdot 4SiO^2 \cdot 6H^2O$, or $M^2(al'')Si^4O^{12} \cdot 6aq$, but with a larger proportion of sodium. It occurs crystallised in hexagonal pyramids, having the terminal summits and lateral edges truncated (P. oP. ∞ P). Angle P:P in the terminal edges = $142^\circ 26'$; in the lateral edges, $80^\circ 8'$; oP:P = $139^\circ 56'$. It is usually, however, regarded as rhombohedral, and the crystals as twins secondary to a rhombohedron of $86^\circ 18'$. It is distinguished from chabasite by its perfect cleavage parallel to the faces of a six-sided prism (G. Rose). Hardness = 4·5; specific gravity = 2·04–2·12; lustre vitreous; colourless, yellowish-white, reddish-white, or flesh-red; translucent; brittle. It behaves like chabasite before the blow-pipe, and gelatinises with hydrochloric acid.

The following are analyses of gmelinite from Glenarm:—a. By Connell (Edinb. N. Phil. J. 1838). *b* and *c* by Rammelsberg (Pogg. Ann. xlix. 211):

SiO ²	Al ² O ³	Fe ² O ³	CaO	Na ² O	K ² O	H ² O		
48·56	18·05	0·11	5·13	3·85	0·39	21·66	=	97·75
46·40	21·09	...	3·67	7·29	1·60	20·41	=	100·46
46·56	20·18	...	3·89	7·09	1·87	20·41	=	100·00

Gmelinite occurs in amygdaloid rocks at Montecchio Maggiore, and at Castel in the Vicentine, at Glenarm, county of Antrim, Ireland, and in the island Magee.

Herschelite from Etna has the same formula as gmelinite, but with $\frac{1}{2}$ less water.

Ledreite, from Jackson, Nova Scotia, has the form of gmelinite, and likewise the same composition, but with only one-third the amount of water. (Dana, ii. 321.)

GNAPHALIUM. The ash of *Gnaphalium leontopodium*, L., has been examined by A. Bauer (Wien, Akad. Ber. xxxvi. 200). 100 pts. of the plant (stem, leaves, and flowers) yielded 6·5 pts. ash, containing, after deduction of charcoal and sand:

K ² O	KCl	CaO	MgO	Fe ² O ³ P ² O ⁵	P ² O ⁵	SO ³	SiO ²	CO ²	
29·02	7·13	23·76	6·70	1·63	5·47	5·04	0·98	20·27	= 100·00

GNEISS. A rock having the same composition as granite, but distinguished from it by possessing a partially stratified structure. In granite, the quartz, felspar, and mica, are intergrown so as to form a crystallogranular mixture; but in gneiss only the quartz and felspar are thus intergrown, whereas the mica is disposed in parallel layers, giving the rock somewhat of a slaty character. The quantitative relations of the component minerals in gneiss are as various as in granite, and the mica is often more or less replaced by hornblende or talc, less frequently by chlorite or graphite. Gneiss also contains, as accessory constituents, garnet, tourmaline, epidote, cordierite, andalusite, serpentine, cyanite, iron pyrites, magnetic pyrites, specular iron, titaniferous iron, magnetic iron ore, rutile, fluor spar; it is peculiarly rich in metalliferous veins.

For Scheerer's examination of the red and grey gneiss of the Saxon Erzgebirg, see Jahresb. f. Chem. 1861, p. 1075.

GÖKUMITE. See IDOCRASE.

GOLD. Atomic weight, 196. Symbol, Au. (Gm. vi. 201.—Regnault, *Cours élémentaire de Chimie*, iii. 274.—Pelouze et Frémy, *Traité*, iii. 392.—Dana, ii. 7.—*Ure's Dictionary of Arts, Manufactures, and Mines*, ii. 381.)—Gold is widely distributed over the globe. It is almost always found native, sometimes pure, but generally more or less alloyed with silver. It occurs in the crystalline rocks, the compact metamorphic rocks, the trachytic and trap rocks, and alluvial grounds. It is sometimes found crystallised in cubes, octahedrons, and other forms belonging to the regular system; more commonly in filiform, reticulated, and arborescent shapes; also in thin laminae; often in flattened grains or scales, and in rolled masses in gravel or sand detritus. These masses, when of a certain size, are called *pepitas* or *nuggets*. In crystalline rocks, gold occurs chiefly in veins containing ores of other metals, such as iron-pyrites, copper-pyrites, galena, and sulphide of silver. In auriferous pyrites, the gold is generally present in too small a quantity to be visible when the mineral is in its natural state. Some varieties of this mineral contain not more than one five-millionth part of their weight of gold, which, nevertheless, may be profitably extracted. The greatest quantity of gold is obtained from the alluvial deposits formed by the disintegration of ancient auriferous strata. The rock deposits of California and Australia are chiefly of this kind. The sands of rivers issuing from primitive mountain chains almost always contain small quantities of gold. In Europe gold is most abundant in Hungary and Transylvania. It occurs also in the sand of the Rhine, the Renss, and the Aar; on the southern slope of the Pennine Alps, from the Simplon and Monte Rosa to the Val d'Aosta; in Piedmont; in Spain, the mines of Asturias having been in ancient times

the principal source of the gold obtained in Europe; in many of the streams of Cornwall; near Dolgelly and other parts of North Wales; in Scotland in considerable amount near Leadhills, and in Glen Coich and other parts of Perthshire; in Ireland, in the county of Wicklow; and in Sweden, at Edelfors. In Asia valuable mines exist in the Ural mountains at Beresof, and other places on the eastern flank of the range, and in the comparatively level portions of Siberia; also in the Altai mountains, and in the Cailas mountains in Little Thibet. Gold is also found in China, Japan, Formosa, Ceylon, Java, Sumatra, Borneo, and the Philippines. In Africa there are mines at Kordofan, between Darfour and Abyssinia; also south of Sahara from Senegal to Cape Palmas; also in the interior on the Somat, a day's journey from Cassen; also along the coast opposite Madagascar, supposed to have been the Ophir of Solomon. In South America the principal gold-producing districts are in Brazil, especially near Villa Rica, and in the province of Minas Geraes; in New Granada, and in Chile. In Peru gold is found but sparingly. In Central America, gold is found in Guatemala and near Panama; in North America, in Mexico, in the Southern United States, in British Columbia along the course of the Fraser River, in Nova Scotia, and very abundantly in California, between the Sierra Nevada and the Sacramento and San Joaquin. Lastly, very large quantities of gold are found in Australia, chiefly to the westward of Bathurst, about 150 miles from Sidney, and in the Victoria colony. Gold is also found in Van Diemen's Land and New Zealand. Formerly the chief supply of gold was obtained from the mines of Brazil, Hungary, and the Ural Mountains, but California and Australia now yield by far the largest quantity. The new gold-field of British Columbia is also very productive.

The purest specimens of native gold have been obtained from Schabrowski, near Katharinenburg, in the Ural. A specimen analysed by G. Rose was found to contain 98.96 per cent. of gold. Very pure gold has also been found in Nova Scotia; a specimen from Tangier was found by Marsh (Sill. Am. J. 1861, p. 395) to contain 98.13 per cent. gold; another from Lunenburg contained 92.04 per cent., the remainder, in both cases, being silver and copper, with traces of iron. The Californian gold averages from 87.5 to 88.5 per cent., and the Australian 96 to 96.6 per cent. In some varieties of native gold, e.g. from Linarowski, in the Altai, the percentage of gold is as low as 60 per cent., the remainder being chiefly silver. There is also an auriferous silver found at Konigsberg, in Hungary, containing 28 per cent. gold and 72 silver.

Extraction.—Gold is separated from the substances with which it is mechanically associated, either by washing with water, whereby the earthy matters are carried away, while the heavy gold remains behind, or by amalgamation. The rich ores in which the native gold is apparent, and merely disseminated in a stony gangue, are directly triturated with mercury, without any preparatory treatment. The poorer ores, in which the gold seems lost amid a mass of iron, sulphide of copper, &c., are roasted before amalgamation, to lay bare the gold. The small quantity of gold which occurs, generally associated with silver, in certain lead and copper ores, is extracted by eliquation and cupellation. By these processes (see COPPER, p. 32, and SILVER) gold is obtained free from all other metals except silver; and from this it may be separated by nitric acid, which dissolves the silver, but only when it forms a large proportion of the alloy. When nitric acid does not dissolve the silver, the alloy is submitted to an operation termed *parting or quartation*, which consists in fusing it with four times its weight of silver, after which the whole of the silver may be dissolved out by nitric acid.

Pure gold may be obtained from any alloy containing it, by dissolving the alloy in a mixture of two measures of hydrochloric and one measure of nitric acid; separating the solution from insoluble chloride of silver by filtration; evaporating it over the water-bath till acid vapours cease to be exhaled; then dissolving the residue in water acidulated with hydrochloric acid; and adding protosulphate of iron, which completely precipitates the gold in the form of a brown or brownish-yellow powder, the protosulphate of iron being at the same time converted into sesquisulphate and sesquichloride:

The gold thus precipitated is quite destitute of metallic lustre, but acquires that character by burnishing.

From alloys of gold and silver, or of gold, silver, and copper, the gold may be separated by the action of strong sulphuric acid. The alloy, after being granulated by pouring it in the melted state into water, is heated in a platinum or cast-iron vessel with $2\frac{1}{2}$ times its weight of sulphuric acid of specific gravity 1.815 (66° Baumé), the heat being continued as long as sulphurous acid is evolved. The silver and copper are thereby converted into sulphates, while the gold remains unattacked. The solution is boiled for a quarter of an hour with an additional quantity of sulphuric acid of specific gravity 1.653, or 58° Baumé (obtained by concentrating the acid mother-liquors of sulphate of copper produced in the operation), and afterwards left at rest.

The gold then settles down, and the liquid, after being diluted with water, is transferred to a leaden vessel and again boiled with sheets of copper immersed in it. The silver is then precipitated in the metallic state, while the copper is converted into sulphate, and dissolves. The gold deposited in the manner above described still retains a small quantity of silver, from which it is separated by treating it a second and a third time with strong sulphuric acid: it then retains only 0·006 of silver. This process is not applicable to alloys containing more than 20 per cent. of gold; richer alloys must first be fused with the requisite quantity of silver. It is applied on the large scale to the extraction of gold, chiefly from alloys which contain but little of that metal, such as native silver and old silver coins, and, as now practised, is economically available even when the amount of gold does not exceed one part in 2000.

Some specimens of Australian gold contain 2 or 3 per cent. of tin or antimony, or both. Gold thus alloyed is brittle, and not fit for rolling. The best mode of removing the tin and antimony is to oxidise them by fusing the impure gold with about 10 per cent. of oxide of copper and a small quantity of borax: a perfectly malleable gold is then obtained, containing a small percentage of copper. (Warington, Chem. Soc. Qu. J. xiii. 34.)

Properties.—Gold is the only metal of a yellow colour. When pure, it is more malleable than any other metal, and nearly as soft as lead. Its ductility appears to have scarcely a limit. A single grain of gold has been drawn into a wire 500 feet in length, and this metal is beaten out into leaves which have not more than 1-200,000th of an inch of thickness. The coating of gold on gilt silver wire is still thinner. Gold, when very thin, is transparent, thin gold leaf appearing green by transmitted light. The green colour passes into a ruby-red when highly attenuated gold is heated: in the red gold-glass, the gold is in the metallic state. (Faraday.)

The density of gold varies from 19·258 to 19·367, according as it has been more or less compressed. Its specific heat, referred to water as unity, is 0·324 (Regnault). Its heat-conducting power (silver = 100) is 53·2 (Wiedemann and Franz); and its electric conducting power (silver = 100) is 59·0 (Riess), 64·9 (Becquerel), 58·5 (Lenz), 55·19 at 21·8° C. (Matthiessen.)

Gold melts at 1200° C. (2192° F.) according to Pouillet; at 1380° C. (2518° F.) according to Guyton-Marveau; at 1425° C. (2596° F.) according to Daniell; it contracts considerably on becoming solid. Like most other metals, it is volatile at high temperatures. It was formerly supposed that the heat of a powerful burning-glass, or of the oxy-hydrogen blow-pipe, was required to volatilise gold, but from the experiments of Napier (Chem. Soc. Qu. J. x. 229; xi. 168) and Makins (*ibid.* xi. 97), it appears that the volatilisation takes place when alloys of gold and silver are cupelled with lead in an ordinary muffle-furnace. Deposits taken from the chimney of a small reverberatory furnace in which an alloy of silver and copper containing a very small proportion of gold had been melted almost daily for months together, were found to contain, on the average, about 14 per cent. of silver, and 7·1 grains of gold per mark (8 oz.) of silver.

Gold does not oxidise or tarnish in the air at common temperatures, or even when strongly ignited, but, like the other noble metals, it is dissipated and perhaps partly oxidised when a powerful charge of electricity is sent through thin leaves or wires of it (p. 396). Gold is not dissolved by nitric, hydrochloric, or sulphuric acid, or indeed by any single acid. It is acted upon by chlorine, which converts it into the trichloride, and by acid mixtures, such as nitromuriatic acid, which evolve chlorine.

Compounds of Gold.—Gold forms two series of compounds, viz. the *Aurous compounds*, in which it is monatomic, and the *Auric compounds*, in which it is triatomic. In its chemical relations it exhibits rather a chlorous than a basylous character, so that its oxides tend to unite with bases rather than with acids, and its chlorides and iodides readily form double salts with the chlorides and iodides of the more basylous metals.

GOLD, ALLOYS OF. Gold unites with nearly all metals; but its most important alloys are those which it forms with *silver* and *copper*. Gold which is used for coins, watches, articles of jewellery, &c., is always alloyed with copper, to increase its hardness, pure gold being much too soft for any of these purposes. The standard for coin in the United Kingdom is 11 gold with 1 alloy; in France and the United States of America, 9 gold to 1 alloy. For articles of jewellery gold is also frequently alloyed with silver, which gives it a lighter colour. The alloys of gold, both with silver and with copper, are more fusible than gold itself. The solder used for gold trinkets is composed of 5 parts gold and 1 part copper, or of 4 parts gold, 1 part copper, and 1 part silver.

It has already been observed (p. 925) that native gold almost always contains silver, varying in proportion from 0·2 to 62 per cent. The spectrum of the ancients is an

alloy of gold and silver, containing, according to Klaproth, 66·7 per cent. gold, or 2 gold to 1 silver.

Amalgam of Gold.—Gold unites readily with mercury, forming a white amalgam; the smallest quantity of mercurial vapour coming in contact with gold is sufficient to turn it white. Mercury is capable of dissolving a large quantity of gold without losing its fluidity, but when quite saturated it acquires a waxy consistence. When the liquid amalgam is strained through chamois-leather, mercury passes through, together with a very small quantity of gold, and there remains a white amalgam, of pasty consistence, containing about 2 parts of gold to 1 part of mercury. By dissolving 1 part of gold in 1000 parts of mercury, pressing through chamois-leather, and treating the residue with dilute nitric acid at a moderate heat, a solid amalgam, Au^2Hg^2 , is obtained, which crystallises in shining four-sided prisms, retains its lustre in the air, is not decomposed by boiling nitric acid, and does not melt even when heated till the mercury volatilises. (T. H. Henry, *Phil. Mag.* [4] ix. 468.)

A native amalgam of gold, Au^2Hg^2 , is found in small yellowish crystals of specific gravity 15·47 in the native mercury of Mariposa in California (gold, 39·02—41·63 per cent., mercury, 60·98—58·37). An amalgam of gold and silver is found in small white soft grains accompanying platinum, at Choco, New Granada. It contains 38·39 per cent. gold, 5·00 silver, and 57·40 mercury, agreeing nearly with the formula $(\frac{2}{3}\text{Au} \frac{1}{3}\text{Ag})^2\text{Hg}^2$. (*Rammelsberg's Mineralchemie*, p. 10.)

Gilding.—The pasty amalgam of 2 parts of gold and 1 part mercury is used for gilding ornamental articles of copper and bronze. The surface of the object is first thoroughly cleaned by heating it to redness, then plunging it into dilute sulphuric acid, and sometimes for an instant also into strong nitric acid; it is then *amalgamated* by washing it with a solution of nitrate of mercury, and afterwards pressed upon the pasty amalgam, a portion of which adheres to it. The mercury is then expelled by heat, and the gold-surface finally polished. Silver may be gilt by similar processes.

Articles of copper, chiefly copper trinkets, are also gilt by immersion in a boiling solution of chloride of gold in an alkaline carbonate, after having been cleaned by processes similar to those just described.

But the process now most generally adopted is that of *electro-gilding*, which is performed by immersing the objects to be gilt in a solution of 10 parts of cyanide of potassium and 1 part of cyanide of gold in 100 parts of distilled water, and connecting them with the negative pole of a voltaic battery, while the positive pole is connected with a bar of gold also immersed in the liquid. The solution is then decomposed by the current, the gold being deposited on the objects at the negative pole, while the gold connected with the positive pole dissolves and keeps the solution at a nearly uniform strength. (See **CYANIDES**, p. 213.) The cyanide of potassium in the solution is sometimes replaced by ferrocyanide of potassium, and the cyanide of gold by sesquioxide of gold, chloride of gold and potassium, or sulphide of gold; but the composition above given is that which is most generally adopted. This mode of gilding may be at once applied to copper, brass, bronze, silver, or platinum. To gild iron, steel, or tin, it is necessary first to deposit a layer of copper on the surface, which is effected by immersion for a few seconds in a bath of cyanide of copper and potassium. (See *Ure's Dictionary of Arts, &c.*, art. **ELECTRO-METALLURGY**, ii. 95.)

GOLD, BROMIDE OF, AuBr^3 , is produced by dissolving gold in bromine-water, or in a mixture of nitric and hydrobromic acids. It greatly resembles the trichloride, crystallises with tolerable facility, and forms, with the more basic metallic bromides, a series of double salts called *bromo-aurates*, e.g. *bromo-aurate of potassium*, $\text{KCl}.\text{AuBr}^3$.

GOLD, CHLORIDES OF. The *Protochloride*, or *Aurous chloride*, AuCl , is obtained by evaporating a solution of the trichloride to dryness, heating the residue to about the melting point of tin, and constantly stirring it as long as chlorine is evolved. It is a white saline mass, having a tinge of yellow, and quite insoluble in water. In the dry state it is permanent, but in contact with water, it is resolved—gradually at ordinary temperatures, instantaneously at the boiling-heat—into metallic gold and the trichloride.

Trichloride of Gold or *Auric Chloride*, AuCl^3 .—This compound is formed when gold is dissolved in nitromuriatic acid. The solution is yellow, and becomes paler with an excess of acid, but is of a deep red when neutral in composition. It is obtained in the last condition by evaporating the solution of gold, till the liquid is of a dark ruby colour, and begins to emit chlorine. It forms on cooling a dark red crystalline mass, which deliquesces quickly in air. But the only method of procuring auric chloride perfectly free from acid salt, is to decompose aurous chloride with water. An acid chloride of gold or chloride of gold and hydrogen, crystallises easily from an acid

solution, in long needles of a pale yellow colour, which are permanent in dry air, but run into a liquid in damp air. The solution of this salt (ordinary gold-solution) deposits gold on its surface, and on the side of the vessel turned to the light. The gold is also precipitated in the metallic state by *phosphorus*, by most *metals*, by *ferrous salts*, by *arsenious* and *antimonious acids*, and by many *vegetable and animal substances*, by *vegetable acids*, by *oxalate of potassium*, &c., carbonic anhydride then escaping. *Sulphydric acid* and *sulphide of ammonium* throw down black sulphide of gold, soluble in excess of the latter reagent. *Ammonia* and *carbonate of ammonium* produce a yellow precipitate of fulminating gold. *Potash* added in excess forms no precipitate, unless it contains organic matter, in which case a slight precipitate of aurous oxide is produced. *Cyanide of potassium* produces a yellow precipitate soluble in excess. *Ferrocyanide of potassium* colours the solution emerald-green. *Stannous chloride* produces a purple or brown precipitate (purple of Cassius), varying in colour according to the strength of the solutions and the proportions in which they are mixed. This reaction will indicate by a faint colouring the presence of 1 pt. of gold in 64,000 pts. of liquid. *Trichloride of antimony* produces a shining yellow precipitate of metallic gold. *Iodide of potassium* colours the liquid black, and then throws down a greenish precipitate of auric iodide. *Tincture of galls* throws down metallic gold.

Trichloride of gold is soluble in ether and in some essential oils. It unites with most other chlorides, forming double salts called chloro-aurates, which are almost all orange-coloured when crystallised; in efflorescing, they acquire a lemon-yellow colour, but in the anhydrous state they are of an intense red. They are obtained by evaporating the mixed solutions of the two salts.

Chloro-aurate of potassium, $2(\text{KCl}.\text{AuCl}^3).5\text{H}^2\text{O}$, crystallises in striated prisms with right summits, or in thin hexagonal tables, which are very efflorescent; it becomes anhydrous at 100°C . The anhydrous salt fuses readily when heated, but loses chlorine and becomes a liquid, which is black while hot, and yellow when cold. It is then a compound of aurous chloride with chloride of potassium. *Chloro-aurate of ammonium* crystallises in transparent prismatic needles, which become opaque in air. Johnston found their composition to be $\text{NH}^4\text{Cl}.\text{AuCl}^3.\text{H}^2\text{O}$. *Chloro-aurate of sodium* crystallises in long four-sided prisms, and is permanent in air. Its composition is $\text{NaCl}.\text{AuCl}^3.2\text{H}^2\text{O}$. Bonsdorff has prepared similar double salts with the chlorides of *barium*, *strontium*, *calcium*, *magnesium*, *manganese*, *zinc*, *cadmium*, *cobalt*, and *nickel*. The calcium-salt contains three, and the magnesium-salt six, atoms of water.

Trichloride of gold likewise forms crystalline double salts with the hydrochlorates of many organic bases, e. g. *chloro-aurate of ethylamine*, $\text{C}^2\text{H}^5\text{N}.\text{HCl}.\text{AuCl}^3$; and these gold-salts are in many instances more convenient than the corresponding platinum-salts for fixing the composition of the organic base, because they are less liable to decomposition. (Hofmann.)

GOLD, CYANIDES OF. (See CYANIDES, p. 212.)

GOLD, DETECTION AND ESTIMATION OF. 1. *Reactions.*—Gold-compounds heated on charcoal with borax or carbonate of sodium in the inner flame yield a yellow, very malleable button of metallic gold.

For the reactions of gold in solution see *Trichloride of Gold* above.

2. *Estimation and Separation.*—Gold is always estimated in the metallic state. It is generally precipitated from its solution in nitromuriatic acid by *protosulphate of iron* or *oxalic acid*. Protosulphate of iron throws down the gold in the form of a fine brown powder. If the gold-solution is quite neutral, it must be first acidulated with hydrochloric acid; otherwise the precipitated gold will be contaminated with ferric oxide formed by the action of the air on the ferrous sulphate. If the gold-solution contains much free nitric acid, there is a risk of some of the precipitated gold being redissolved by the nitromuriatic acid present. To prevent this, the excess of nitric acid must be destroyed by adding hydrochloric acid and boiling, before the iron-solution is added. Oxalic acid reduces gold slowly but completely; the gold-solution must be digested with it for 24 or 48 hours.

These methods of precipitation serve to separate gold from most other metals. In such cases, oxalic acid is mostly to be preferred as the precipitating agent, because, when the quantities of the other metals are also to be determined, the presence of a large amount of iron in solution is very inconvenient.

The separation of gold in alloys may generally be effected by dissolving out the base metals with nitric, or sometimes with hydrochloric or sulphuric acid. When, however, the proportion of gold is considerable, it may happen that the alloy is but very slowly attacked by nitric acid, especially if the other metal be silver or lead. In such a case, it is best to treat the alloy with nitromuriatic acid, and precipitate the gold with oxalic acid. Or, again, the alloy may be fused with a known weight of lead or silver, as in the method of quartation (p. 923), and thereby rendered decomposable by nitric acid. To separate gold from *tin*, H. Rose (Pogg. Ann. cxii. 163) boils the finely

divided alloy with rather strong sulphuric acid mixed with hydrochloric acid; heats the liquid till the acid is partly volatilised; precipitates with water; and dissolves out the stannic oxide by means of strong hydrochloric acid, the gold then remaining.

The analysis or *assay* of an alloy of gold and copper is usually made by cupellation with lead. The weight of the button remaining on the cupel gives directly the amount of gold in the alloy after certain corrections. Alloys containing both silver and copper are cupelled with lead and a quantity of silver sufficient to bring the proportion of gold and silver in the alloy to 1 pt. gold and 3 pts. silver. The button obtained by cupellation then consists of an alloy of gold and silver, from which the silver may be dissolved out by nitric acid. (See GOLD-ASSAY, p. 932.)

Small ornamental articles, which would be destroyed if submitted to any of the preceding processes, are approximately assayed by rubbing them on a peculiar kind of black stone, called the *touchstone*, so as to leave a streak of metal, the appearance of which may be compared with that of similar streaks produced from alloys of known composition. A further comparison is obtained by examining the appearance which the streaks present when treated with acids. This method is also sometimes used in the assaying of coins, to afford an indication of the quantity of silver required in the cupellation. The touchstone, which is a peculiar kind of bituminous quartz, was originally obtained from Lydia; but stones of similar quality are now found in Bohemia, Saxony, and Silesia.

3. *Atomic weight of gold.*—Berzelius determined the atomic weight of this metal: 1. By precipitating it from the trichloride with metallic mercury. In two experiments, 9.355 pts. gold were precipitated by 14.29 pts. mercury, and 6.557 pts. gold by 9.96 mercury. Assuming $\text{Hg} = 200$, and calculating from the equation $2\text{AuCl}^3 + 3\text{Hg} = 3\text{Hg}^2\text{Cl}^2 + \text{Au}^2$, the mean of these results gives for the atomic weight of gold the number 198.25.

2. By the analysis of chloro-aurate of potassium, KCl.AuCl^3 (Berz. Jahresb. xxv. 41). The salt was reduced by ignition in a stream of hydrogen; the residue of gold and chloride of potassium was weighed; the chloride of potassium then dissolved out by water; and the weight of the gold determined. Assuming the atomic weight of chloride of potassium to be 74.5, the mean of five experiments gave for gold the number 196.32.

Levol (Ann. Ch. Phys. [3] xxx. 355) determined the atomic weight of gold by dissolving a weighed quantity of the metal in nitromuriatic acid, removing the nitric acid by repeatedly boiling down the solution with hydrochloric acid, then passing sulphurous acid gas through it, and precipitating the resulting sulphuric acid with the solution of a barium-salt; 3 at. sulphate of barium thus produced correspond to 2 at. gold, thus:

From 1 gramme of gold Levol obtained 1.782 BaSO^4 , whence, if $\text{BaSO}^4 = 116.48$, the atomic weight of gold is found to be very nearly 196, which is the number now generally adopted.

GOLD, IODIDES OF. *Aurous Iodide*, AuI , is formed by the action of hydriodic acid on auric oxide, water being formed and two-thirds of the iodine set free:

also by adding iodide of potassium in equivalent proportions, and in successive small quantities, to an aqueous solution of auric chloride:

It is a lemon-yellow crystalline powder, insoluble in cold water, and very sparingly soluble in boiling water.

Auric Iodide, AuI^3 , is formed by gradually adding a neutral solution of auric chloride to a solution of iodide of potassium. The liquid then acquires a dark green colour, and yields a dark green precipitate of auric iodide, which redissolves on agitation; but after 1 at. of the auric chloride has been added to 4 at. iodide of potassium, a further addition of the gold-solution decolorises the liquid, and forms a permanent precipitate of auric iodide, because the iodide of gold and potassium at first produced is thereby decomposed. The successive actions are represented by the equations:

Auric iodide is a very unstable compound. When exposed to the air at ordinary temperatures, it is gradually converted into yellow aurous iodide, and afterwards into metallic gold. It combines with hydriodic acid, and with the more basic metallic iodides, forming double salts, called *iodo-aurates*: MI.AuI^3 .

The *potassium-salt*, KI.AuI^3 , produced by dissolving auric iodide in aqueous iodide of potassium, or by adding 1 at. auric chloride to 4 at. iodide of potassium in solution

and leaving the liquid to crystallise, forms long, slender, black, four-sided prisms, with dihedral summits, and having the lateral faces striated; they have a strong lustre, and are opaque even by candle-light. They give off iodine when heated, and leave a skeleton of gold together with iodide of potassium. In pure water they dissolve, with partial decomposition; aqueous hydriodic acid and iodide of potassium dissolve them perfectly.

GOLD, MANNHEIM. A brass containing about 4 parts copper to 1 part zinc. (See COPPER, ALLOYS OF, p. 47.)

GOLD, MOSAIC. An alloy of copper and zinc containing about equal parts of the two metals. (See COPPER, ALLOYS OF, p. 47; also *Ure's Dictionary of Arts*, &c. ii. 398.)

GOLD, METALLURGY OF. See p. 923, and for further details, *Ure's Dictionary of Arts*, &c. ii. 396.

GOLD, OXIDES OF. *Aurous Oxide*, Au^2O , is obtained as a green powder by decomposing auric chloride with cold potash-solution. It is partly dissolved by the alkali, and soon begins to decompose, being resolved into auric oxide and metallic gold, which is deposited on the sides of the vessel as a thin film, appearing green by transmitted light, like gold-leaf.

Auric Oxide, Au^3O_3 .—This oxide is precipitated from the solution of the trichloride by alkalis; but the precipitate always retains a portion of the alkali, which is difficult to remove. A good method of preparing it is to digest magnesia or oxide of zinc in the solution of the chloride, and decompose the resulting magnesium or zinc compound with cold nitric acid (Pelletier). Frémy (*Ann. Ch. Phys.* [3], xxxi. 478) recommends the following process:—The solution of the trichloride is mixed with a sufficient quantity of potash to redissolve the precipitate first produced, and boiled for a quarter of an hour, whereupon the liquid, which is at first dark brown, gradually assumes a yellow tint; sulphuric acid is then added in slight excess; and the resulting precipitate is collected on a filter, and washed with water till the wash-water no longer gives a precipitate with barium-salts. The precipitate consists of auric oxide. The first addition of the potash converts the chloride of gold into an oxychloride, which then forms a soluble compound with the potash; and if the solution be treated with an acid without previous boiling, a precipitate is obtained consisting of the oxychloride, which may be distinguished from the auric oxide by dissolving slowly, but completely, in pure water. It is only by continued boiling that the compound of the oxychloride with potash is converted into the aurate of potassium, the conversion being attended with the change of colour above noticed. The auric oxide obtained in the manner just described is not quite free from potash, even after long-continued washing. It may be purified completely by treating it with very strong nitric acid, which dissolves it readily—mixing the solution with water, which immediately precipitates the auric oxide—and washing the precipitate thoroughly with pure water.

Auric oxide dried at 100°C . is a brown-black powder, or a brown mass having a conchoidal fracture. When exposed to light, particularly to the direct rays of the sun, it is very quickly reduced. It is also decomposed by an incipient red heat. Hydrochloric acid is the only acid which dissolves and retains this oxide, and then trichloride of gold is formed. It is dissolved by concentrated nitric and sulphuric acids, but precipitated from these solutions by water. On the other hand, it possesses decided acid relations, its affinity for alkaline oxides being so great that, when boiled in a solution of chloride of potassium, it is dissolved, the liquid becomes alkaline, and *aurate of potassium*, $\text{K}^2\text{O}.\text{Au}^3\text{O}_3$, or AuKO^3 , is formed. The aurates of the alkali-metals and alkaline earth-metals are nearly colourless, and are not decomposed by water.

Aurate of ammonium. Fulminating gold.—When a solution of gold is precipitated by a small quantity of ammonia, a powder of a deep yellow colour is obtained, which is a compound of aurate of ammonium with a portion of the trichloride of gold. This compound explodes by heat, but the detonation is not strong. But when the solution of gold is treated with an ~~excess~~ of ammonia, and the precipitate well washed by ebullition in a solution of ammonia, or better in water containing potash, the fulminating gold has a yellowish-brown colour with a tinge of purple, and when dry, explodes very easily with a loud report, accompanied by a feeble flame. It may be exploded by a heat a little above the boiling point of water, or by the blow of a hammer. Its composition has not been exactly determined, but if the ammonia is present in double the proportion that would contain the hydrogen necessary to burn the oxygen of the auric oxide, which Berzelius considers probable, its constituents may be $\text{Au}(\text{NH}^4)^3\text{O}^3.\text{NH}^3$ or $\text{AuHO}^3.2\text{NH}^3$. The affinity of auric oxide for ammonia is so great, that it takes that alkali from all acids. Thus, when auric oxide is digested in sulphate of ammonium, fulminating gold is formed, and the liquid becomes acid.

Aurate of potassium, $\text{K}^2\text{O}.\text{Au}^3\text{O}_3.3\text{H}^2\text{O}$, or $\text{AuKO}^3.3\text{H}^2\text{O}$, is obtained in the

crystalline state by evaporating a solution of auric acid in a slight excess of pure potash, first over the open fire and afterwards in vacuo: the crystals may be freed from adhering potash by recrystallisation from water, then drained on unglazed porcelain and dried in vacuo. Aurate of potassium is very soluble in water, and forms a yellowish strongly alkaline solution, which is decomposed by nearly all organic bodies, the gold being precipitated in the metallic state: it is also decomposed by heat. With most metallic salts it forms precipitates of aurates, which are insoluble in water, but soluble in excess of the precipitant; thus, chloride of calcium forms a precipitate of aurate of calcium, soluble in excess of chloride of calcium. The solution of aurate of potassium may be used as a bath for electro-gilding.

Aurosulphite of Potassium, $\text{AuK}^{\text{O}}_2 \cdot 4\text{KHSO}_4 \cdot 4\text{H}_2\text{O}$, is deposited in beautiful yellow needles when sulphite of potassium is added drop by drop to an alkaline solution of aurate of potassium. It is nearly insoluble in alkaline solutions, but dissolves with decomposition in pure water, especially if hot, giving off sulphurous anhydride and depositing metallic gold. Acids decompose it in a similar manner. After drying in vacuo, it may be preserved for two or three months, in well closed bottles, but ultimately decomposes, giving off sulphurous anhydride, and leaving metallic gold and sulphate of potassium. The same decomposition takes place more quickly when the salt is heated. (Frémy, Ann. Ch. Pharm. lvi. 315.)

A purple oxide of gold, intermediate in composition between the protoxide and trioxide, probably Au_2O_3 , is produced by the action of certain reagents, *e. g.* dichloride of tin and organic substances on solutions of gold. Chloride of gold stains the skin purple, probably in consequence of the formation of this oxide.

GOLD, OXYGEN-SALTS OF. The oxides of gold show but little tendency to unite with oxygen-acids. The trioxide dissolves in strong nitric acid, but the solution is decomposed by evaporation or dilution. Two double hypsulphites of gold and sodium are known:

sodium are known:
Sodio-aurous Hyposulphite. $\text{Au}^2\text{S}^{2}\text{O}^3 \cdot 3\text{Na}^2\text{S}^{2}\text{O}^3 \cdot 4\text{H}^2\text{O}$, or $\left. \begin{matrix} (\text{S}^{2}\text{O}^3)^2 \\ \text{Na}^2 \cdot \text{Au}^2 \end{matrix} \right\} 0.2\text{H}^2\text{O}$.—This salt is prepared by mixing concentrated solutions of trichloride of gold and hyposulphite of sodium, and precipitating with alcohol. When purified by repeated solution in water and precipitation by alcohol, it forms delicate, colourless needles. It has a sweetish taste, is very soluble in water, but sparingly in alcohol. It is decomposed by heat and by nitric acid, with deposition of metallic gold. Its solution gives a blackish precipitate with sulphydric acid and soluble sulphides. The presence of gold in this solution is not indicated by ferrous sulphate, stannous chloride, or oxalic acid; and, on the other hand, sulphuric acid, hydrochloric acid, and the vegetable acids, neither precipitate sulphur nor expel sulphurous acid from it. When mixed with chloride of barium, it yields a gelatinous precipitate of *baryto-aurous hyposulphite*.

sulphite, containing $(\text{S}^{\text{IV}}\text{O})^{\text{II}}$ O⁴. Sulphuric acid removes all the baryta from this salt, and leaves *hydrated aurous hyposulphite*, which is uncrystallisable, strongly acid, and tolerably stable at ordinary temperatures. The solution of the sodium-salt is used for fixing daguerreotype pictures. (Fördes and Göllis, Ann. Ch. Phys. [3] xiii. 394.)

[3] xiii. 394.)
A *sodio-auric hyposulphite* appears also to be formed by dropping a neutral solution of chloride of gold into aqueous hyposulphite of sodium. (Fordos and Gélis.)

GOLD, PHOSPHIDE OF. Gold unites readily with phosphorus by the dry way, forming a pale yellow compound more fusible than gold. Phosphuretted hydrogen passed into a solution of gold forms a precipitate of metallic gold, which then absorbs phosphuretted hydrogen, and changes to a black non-metallic mass containing phosphorus.

GOLD, SULPHIDES OF. Aurous Sulphide, Au_2S , is formed when sulphydric acid gas is passed into a boiling solution of the trichloride of gold. It is dark-brown, almost black. Aurous sulphide combines with the protosulphides of potassium and sodium, forming double salts containing 1 at. of aurous sulphide with 1 at. of the alkaline sulphide. The *sodium-salt* is obtained by fusing together 2 at. protosulphide of sodium, 1 at. gold, and 6 at. sulphur; digesting the fused mass in water; filtering the yellow solution in an atmosphere of nitrogen; and concentrating in vacuo over sulphuric acid. Yellow crystals are then obtained, having the form of oblique hexagonal prisms with trilateral or quadrilateral summits, and containing $\text{NaAuS}_2 \cdot 2\text{H}_2\text{O}$. They are soluble in water and alcohol. The *potassium-salt*, which is obtained in a similar manner, forms indistinct crystals. (Col. Yorke, Chem. Soc. Qu. J. i. 236.)

Auric Sulphide, Au_2S_3 , is formed by passing sulphydric acid gas into a cold dilute solution of gold. It is a flocculent substance of a strong yellow colour, which becomes deeper by drying; it loses its sulphur at a moderate heat.

GOLD, TELLURIDE OF. Precipitated on mixing a solution of auric chloride with tellurhydric acid or telluride of potassium. It likewise remains as a grey, brittle, easily fusible mass, when auric sulphotellurite, Au^2TeS_2 , is heated. (Berzelius.)

GOLD-AMALGAM. See page 927.

GOLD-ASSAY. A description of the common processes of assaying, and of the furnaces and other instruments employed, will be found in *Ure's Dictionary of Arts, &c.* (article ASSAYING), in *Mitchell's Manual of Assaying*, *Phillips' Metallurgy*, and many other works. We propose here to confine ourselves to a somewhat detailed account of the gold-assay process in its highest refinements, as it is at present practised by the Assayers to the Royal Mint, the Bank of England, Colonial Mints, &c., thus supplying, as we believe, a considerable deficiency in the publications on the subject.

We think, also, that the process here described may serve as an example to analytical chemists and experimentalists, of the degree of *method* which may be introduced when many similar operations have to be frequently performed.

The gold-assayer, receiving a great number of samples of gold alloyed with copper and silver, not differing, however, very widely in composition, is required to report the exact proportion of pure gold which each sample contains. To accomplish this the ancient processes of *cupellation* and *parting* are still, and probably ever will be, used. They are as follows:—A given weight of the alloy, say, 10,000, is weighed out, and being placed in a small porous cup or cupel heated in the muffle of the furnace, is melted up with a certain quantity of lead, and with about three times as much pure silver as the alloy contains of pure gold. The new alloy of gold, silver, copper, and lead, with traces, perhaps, of other metals, being now exposed at a strong red heat to a current of air, the copper, lead, &c., are gradually oxidised, and the very fusible oxide of lead, dissolving the other oxides, carries them down into the porous substance of the cupel. There remains a button of very malleable alloy, containing three parts of silver to one part of gold, which, after being laminated, is placed in boiling nitric acid. By an action which it is difficult to explain, the silver is now almost totally dissolved away, together with any other soluble metals which may be present. The gold is left as a kind of skeleton, or spongy yet coherent mass, and may be at once solidified by drying and raising to a red heat. The result of the assay is then obtained, decimally expressed, by a simple weighing.

The result, however, may, or must, be affected by numerous errors, arising from the following chief sources:—

1. Errors of weighing.
2. Loss of gold by slight absorption in the cupel, and by volatilisation.
3. Slight solution of the gold by impurity in the acid.*
4. Impossibility of dissolving the whole of the silver from its alloy with the gold.

Of these the first depend on the balance and weights employed, and the skill of the operator; they must for the most part be eliminated by attention to the rules given under the article BALANCE. The second and third sources of error would tend to give a result slightly below the truth; the last, and by far the most important, would cause a considerable excess in the result.

All such errors may, however, be very nearly eliminated from the results of any number of assays, on condition that the process is performed with perfect uniformity in the case of all the assays, and that the total resulting error in any one case is known; for then a correction to the amount of this error can at once be applied to every other result, and the actual truth attained. Now the process can be rendered approximately uniform by arrangements afterwards described, and the constant aggregate error is at once known if such process be performed upon any one alloy of exactly known composition. Thus, suppose 10,000 parts of each of the alloys A, B, C, to give the respective results 9207, 9416, 9077, parts of gold—but let it be known that the true result for A would have been 9200 parts—then the true results for the others would have been 9409, 9070 parts. More strictly, indeed, the corrections for B and C would have been $-7 \times 9409 + 9200$ and $-7 \times 9070 + 9200$; but we may neglect anything less than 1 part, and use the same corrections for all alloys which are likely to be assayed together.

It still remains to be shown how a single specimen of gold of known composition can be obtained. *Perfectly pure gold* is this required standard; for if we assay 10,000 of pure gold and obtain the result—10,007, for instance, the error of the process is obviously, at least, 7 parts. It is better, however, on the score of uniformity, to weigh out about as much pure gold as the ordinary alloys usually contain, say 9200, and adding about 800 of silver, to perform the process as usual. If we get 9207 parts of

* Nitric acid containing nitrous acid will dissolve gold (Berzelius). Now when an alloy of silver and gold is boiled in nitric acid, considerable quantities of nitrous acid are generated, and the production of this acid is still further promoted by the practice of introducing small bits of charcoal towards the end of the ebullition to prevent bumping. (Makin, Chem. Soc. Qu. J. xiii. 101.)

pure gold as the apparent result, the error of the assay is plainly seven parts. The difficulty now occurs of obtaining pure gold and proving it to be perfectly pure; but practically we attain the desired end if we assume that to be pure gold which is *the purest that can be attained by any known chemical process*. Prepare then, samples of gold of the utmost purity, and compare these against each other by numerous careful assays; assuming the purest to be absolutely pure or nearly so, the composition of each becomes known. This task, too, once performed, is not again necessary so long as the specimens of pure gold last, or their standard of purity can be transmitted by sufficiently careful comparison with new samples of pure gold.

Strict *uniformity of operation* then, combined with the *comparison of the results* with the known purity of certain specimens of pure gold, is the mode in which alone the accuracy of large numbers of assays can be obtained. Such being the *rational*, we now describe the practice of the process.

In the first place, the balance employed must be not only extremely sensitive and sure, but also quick, qualities which can only be combined in a very light and beautifully constructed beam. The instrument which we shall recommend is one by CEriling, of Bishopsgate Street, London, with a ten-inch skeleton beam resting on an agate edge in the centre, and with very light pans suspended upon ruby points working into a small steel cross-piece (see the figure under article BALANCE). The scale-pan is loose, so that it may be taken up with the forceps and emptied of the pieces of metal it contains. It lies in a kind of stirrup formed of light elastic bands of palladium, and the weight of the whole is borne, when the balance is not in action, by an agate convex support which just touches the under surface of the stirrup. The balance, arranged exactly as in use, is shown in *fig. 518*, where at *a*, are two cornet trays; *b*, a box of assay-weights; *c*, the handle of the rider movement; *d*, a file lying in a metal tray.

Fig. 518.

This balance when new will indicate $\frac{1}{10,000}$ part of the assay-weight (10,000 = $\frac{1}{10,000}$ gm.), and will always give $\frac{1}{10,000}$ or 1 part correctly.

The samples of gold are received wrapped up in numbered papers, and have first to be separately flattened out with a suitable hammer and anvil to the thickness of a sixpence, each piece being carefully restored to its right paper.

Commencing with the first sample in numerical order, an assay-piece of the unit weight 10,000—the absolute weight usually adopted being $\frac{1}{10}$ gm., or 7.717 grains—has to be weighed off each sample. The process is one entirely of trial, a small piece of alloy being cut off by a pair of hand-shears, and small pieces being repeatedly

clipped off, or added, as the beam is seen to turn one way or the other on trial. When a weight a little in excess of the 10,000 is obtained, the largest piece of gold in the pan is carefully reduced by rubbing on the fine file laid in front of the balance. Great care must be taken not to file off too much, otherwise a fresh addition of gold will have to be made, and a repetition of the adjusting process be necessary. When the weighing is correct within 1 part, it may be considered completed; but we prefer to allow an error of 1 or 2 parts, and to determine its amount by observing once or twice the oscillation of the index of the balance, amounting, say to $\frac{1}{2}$, 1, or $1\frac{1}{2}$ divisions on either side of the zero point of the scale, and recording this in a book opposite the number of the assay sample. This weighing process is extremely slow and tedious to a novice, but the practised hand may accomplish from 30 to 40 weighings in an hour. The work may be accelerated, as is often necessary, by one or two assistants, who weigh out the assay-pieces a very little above the weight 10,000, in light assay balances of simpler construction, the chief assayer then going over the whole and completing the adjustment in the best balance. The small weighed assay-pieces may be kept in order between the weighings by being placed in little glass tubes an inch long, easily made in the laboratory and supported in a piece of wood 3 inches square. (See *fig. 519.*)

Fig. 519.

Fig. 520.

The assay-piece of gold thus weighed out is to be at once wrapped up in a bit of pure lead foil $\frac{1}{2}$ -inch square, weighing about 0.8 grm., and placed in its due place in a little metal tray with sixteen hollows, mounted on wood $2\frac{1}{2}$ inches square (see *fig. 520*). When, however, a sample of gold contains little or no copper, a small bit of copper must be wrapped up in the lead-foil, namely, about as much copper as the other assay-pieces contain on the average.

The tray being filled with assay-packets, is carried at once to the muffle furnace, already containing 16 cupels arranged in square order. In each cupel is first placed a piece of pure lead weighing 3.2 grms. (supposing the assays to be of English standard gold), wrapped up in a piece of paper $\frac{1}{2}$ -inch square, together with two small pieces of pure silver weighing in all 1.37 grm. The paper instantly burns away, and the lead alloying with the silver soon forms a bath of liquid metal; the lead oxide indeed at first appears as a solid crust, but in a few moments more also melts and swims off the surface of the metal, which is then said to have *uncovered*. With a little dexterity, lead and silver may thus be placed by the assay tongs in each of the sixteen cupels, beginning with the foremost on the left hand side, almost before any of them is completely melted and uncovered. The adjoining figures will sufficiently explain the order of the assays both in and out of the furnace.

1	2	3	4	13	14	15	16
5	6	7	8	9	10	11	12
9	10	11	12	5	6	7	8
13	14	15	16	1	2	3	4

Order of assays
in the trays.

Order of assays in
the muffle.

When cupel (1) is ready, assay piece (1) wrapped in the lead foil is taken up in the tongs (the ends of which must be kept cool with water), and then adroitly dropped into the bath of lead and silver, without causing any splashing. The other fifteen assays are similarly treated in their due order as rapidly as possible. Almost instantaneously the lead-foil of each melts, and the whole of the gold is seized by the liquid metal. The oxidation of the lead then proceeds rapidly, and the completion may be known by

Fig. 521.

Fig. 522.

the liquid button becoming covered with an iridescent film, which shortly afterwards passing off, leaves the button with a bright metallic surface. The assays will thus

finish cupelling nearly in their numerical order, and the cupels are to be withdrawn successively from the muffle and placed in order in the sheet-iron tray (*fig. 521*).

Having become solid, each button is removed from its cupel by a pair of pliers, and any dirt remaining on its under-surface is to be removed by squeezing the button in the pliers, and brushing the bottom with a *scratch-brush* (*gratte-brosse*). Each button has now to be hammered out into the form shown in *fig. 522*, raised to a low red heat in the muffle, and then rolled out in a pair of goldsmith's rolls to the form *a* in *fig. 523*. The metallic slips have again to be annealed at a low red heat, and finally curled up into a *cornet*, as in *fig. 524*. All the sixteen assays which we suppose to be

Fig. 523.*Fig. 524.**Fig. 525.*

under operation, are to be carried through these processes in company, being always kept in due order by the iron tray, except, of course, when they are in the furnace. It requires, however, some dexterity to place all the sixteen buttons or slips in the muffle in due order, and remove them again before they grow too hot and melt.

It is very necessary that the metallic slips now obtained should be smooth at the edges, and, consequently, perfectly malleable. That they are sometimes not so, may arise from the furnace being too hot or cold, the assays being too long or too short a time in it, or the quantity of lead not being correctly proportioned to the copper in the alloy.

The boiling process is now to be carried on in a row of French assay flasks, each heated by a small rose gas-burner, the fumes of the acid being carried off by an earthenware flue, or by other means. A quantity (25 grms.) of nitric acid, of the specific gravity 1.20, is to be poured into each flask from the pipette measure (*fig. 526*); one ounce measure of acid is the quantity used by many assayers. The acid is to be heated nearly to the boiling point, so that when the cornet is placed in it, violent solution of the silver at once commences. This being done, considerable heat may be applied, until in two or three minutes the whole of the orange-coloured nitrous gas is driven off. The clear acid is boiled slowly for five minutes, and then poured off into a jug, distilled or other pure water being used to

Fig. 526.*Fig. 527.*

wash the adhering silver solution out of the flask. A second ounce of very pure nitric acid, of specific gravity 1.32, is now added, together with a small piece of charcoal (a calcined *pea* answers best), to prevent explosive ebullition, and the boiling of the cornet is continued as tranquilly as possible for twenty or thirty minutes. By this time the cornet will consist of a soft but coherent brownish-coloured metallic skeleton, containing the whole of the gold in the original assay piece, almost perfectly freed from silver and every other impurity. The acid is to be poured off from the *cornet*, which is done by gently inclining the flask, and the flask is filled up to the top with pure water. For this purpose it is convenient to have a small tin or copper water cistern with a stopcock, and an india-rubber tube. Each cornet must now be removed to a little crucible, which is done as in *fig. 527*, by dexterously decanting it—that is, inverting the flask into the crucible, allowing the cornet to fall through the water to the bottom of the crucible, and then quickly removing the flask before much water can run out. Lastly, the crucible is drained of water, and raised to a red heat in the muffle. As before, each operation is to be performed on the sixteen assays in company, before the next operation is begun, and the numerical order is always maintained mechanically.

Withdrawing the crucibles from the furnace, we find in each a small cornet of bright gold (*fig. 525*), which, if unrolled, would have the form *b* in *fig. 523*. It is then the exact counterpart of the original alloy, contracted to a much smaller size. The cornets are to be removed by a pair of weighing forceps from the crucibles, and placed in due order in the small tray (*fig. 520*). They are then to be carried back to the balance,

and successively weighed. Of course, the same pan of the balance, the right-hand pan, must be used as in weighing out the original assay pieces, in order to eliminate error of the balance. In this weighing, too, we may eliminate, without any additional trouble, the error in the initial weighing (if any were observed and recorded) by simply adjusting the weight so that the beam shall not stand at zero, but swing to the same point of the index as it did in the prior weighing. The weights used may be the ordinary series, 10,000, 5000, 2000, &c., but it is much preferable to have a series of weights, as 9000, 9100, 9200, prepared by the balance maker to suit the results expected. A rider-weight (see article BALANCE) equal to 100 being then used on a divided beam, gives the result with great facility, within one part, being the $\frac{1}{10,000}$ part of the original assay piece taken.

For the purpose of correcting the results of the assays thus performed, we may suppose that one of the sixteen assays was what we may call a *proof* or *check* assay, performed on nearly pure gold of known standard. Thus, suppose this comparison gold contained 9997 pts. in 10,000 of absolutely pure gold, and that an assay piece of 9154, containing therefore very nearly 9151 pts. of pure gold, was weighed out and assayed, giving as a result 9158. The error then of the assay process is seven in excess, which amount must be subtracted from the result of each of the other fifteen assays. This error being known or determined each day previously to the weighing up of the regular assays, the subtraction of the error may be conveniently and accurately made, without calculation, by placing a small correction-rider of proper weight on the lower branch of the beam, on the opposite arm to that which bears the cornet. The results thus obtained are ready to be reported. With the same operators, apparatus, and materials, this correction for *surcharge* should remain nearly constant for weeks or months together. To ensure this constancy should be the great aim of the assayer; but the correctness of the results must be almost daily tested, and especially when any change in the process or materials takes place. The *surcharge* should not exceed about 10 parts.

Whatever the number of assays to be done, they must all be arranged in lots of sixteen each, with proof or correction assays interspersed if necessary. Each page of the assay-book, too, may be devoted to a lot of sixteen, and ruled accordingly. A symmetrical numerical arrangement is thus maintained throughout by mere mechanical means; mistake or disorder is rendered nearly impossible, and reference to any assay during the process most easy and certain. Some might prefer a decimal arrangement from its numerical simplicity; but, in the mechanical parts of the process, it would be found comparatively awkward. In the furnacing operations, only sixteen can generally be in progress at once; but in the other parts of the process as many assays—100 or 200 if necessary—may and ought to be performed in company as there are trays to hold, or gas-burners and flasks to accommodate. The order of the numerous trays and other apparatus must therefore be preserved by numbers on them. It is obvious that the last tray of any lot of assays will generally not be full. Any assays subject to irregularity should be at once repeated, and, if possible, joined to the original lot.

The quantities of silver and lead stated in the above description are adapted for English standard gold, consisting of 9167 pts. of gold and 833 pts. of copper. Any set of samples, varying in fineness say from 8500 to 10,000, would be assayed with the same quantities, the variation in the resulting alloy not being sufficient to affect the result materially. Each assayer must, however, estimate the average fineness of the samples he receives, and make the quantity of silver three times that of the average weight of gold in the assay piece. The lead must be that given as sufficient in the following table, to remove the largest quantity of copper commonly present in the assay piece:

Gold in 10,000 parts.	Lead, grammes.	Gold in 10,000 parts.	Lead, grammes.
10,000	5	8,700	60
9,800	10	8,300	70
9,600	20	8,000	80
9,400	30	7,700	90
9,200	40	7,300	100
9,000	50	7,000	110

To secure uniformity, the same quantity of lead should be used for all ordinary assays; but when the gold contains much less copper than usual, or perhaps none, a small piece of copper wire, the size of a large pin's head, must be added, when wrapping up the assay piece in lead-foil. This will prevent failure in the cupelling.

Improved process.—The process above described is, for the most part, such as many of the best London assayers now adopt. We have ourselves, however, employed for several years a modification of the boiling process, which is at once quicker, less troublesome, and more accurate. It is only to be recommended, however, where the

samples are pretty uniform in composition, so that proper adjustments may be made to obtain the cornets always smooth-edged and strong. In this process, each metallic slip, after lamination, is stamped with a small number at one end, as shown in *figs.* 523, 524, 525, a series of small numeral punches, from 1 to 16, being kept for this purpose. The assays from this point need no longer be kept separate. After annealing in a crucible, and coiling up as usual, each lot of sixteen is put into an English flat-bottomed assay-flask, containing say sixteen ounces of the weak acid (specific gravity 1.20), already heated over a sand-bath or gas flame. The solution and boiling proceed just as if each assay were in a separate flask. The labour of manipulation being reduced nearly to the $\frac{1}{16}$ part, the washing with distilled water may be several times repeated, and the sixteen ounces of strong acid may be applied in two equal parts, with an intermediate washing, each portion being boiled ten minutes. Several bits of charcoal must be always in the acid to prevent bumping. The decantation is performed by filling the flask with water, closing its mouth with the thumb, inverting it into a basin full of water, and then withdrawing the thumb. The cornets fall out uninjured. By a pair of light forceps they may be safely picked out, placed in rows on a piece of tile, and annealed. The figures originally impressed on the alloy of 3 pts. of silver to 1 pt. of gold remain as legible as before, now that the 3 pts. of silver are gone; the order of the assays is thus known. Occasionally, but rarely, it may happen that a cornet is broken up, and its fragments spoil the remainder of the sixteen. Yet, having performed many thousand assays by this method, we may state that it is, on conditions already stated, not more liable to accidents than the separate method, while it is rather more speedy, effects a great and obvious saving of labour, and, by allowing perfect uniformity of action in the boiling process, admits of greater accuracy than can be otherwise attained. When the assays in the flask are less than sixteen in number, the acid used must be proportionally less; marks may easily be made on the flask with black varnish, to indicate the proper quantity of acid for each number of assays. The fumes from the flasks may easily be carried off by a $\frac{3}{4}$ inch glass tube fitting into the mouth of the flask, and communicating with a flue. Other arrangements for supplying a good heat, as well as hot acid and hot distilled water, may easily be contrived by any person who requires to carry on the process on a large scale.

Standard Pure Gold.—To prepare the pure gold necessary for comparison assays, as already described, cornets or other fine gold must be dissolved in aqua-regia, and the excess of acid must be driven off as completely as possible by slow evaporation. The chloride of gold is then dissolved in a large body of pure water, say two or three gallons to each ounce of gold, and the whole left undisturbed for a week. A sediment of chloride of silver, a little insoluble subchloride of gold, and any other impurity present will then have perfectly settled down. The clear liquor is carefully drawn off by a siphon, filtered through thick paper into a perfectly clean vessel, and the precipitation of the metallic gold effected by oxalic acid, solution of protosulphate of iron, or sulphurous acid. Of these reagents we prefer the last, which is to be slowly passed through a wash-bottle and into the gold-solution, at as low a temperature as possible, and up to saturation. It is still better to precipitate the gold fractionally in three parts, of which the middle and largest part only is to be used. The soft gold powder is to be well washed, boiled in pure hydrochloric acid, again washed and dried, finally melted in a strongly heated muffle in a crucible of white French clay with a little acid sulphate of potassium and crystallised borax. Gold of at least the fineness 9997 or 9998 will generally be obtained in this way.

To perform the assays with despatch, every possible preparation must be made beforehand. The pieces of assay-lead of uniform weight may be most easily obtained by use of a bullet-mould made to cast pistol shots of the proper weight and five or six at a time.

The assay-silver must be rolled out at a flattening mill to the thickness of a fourpenny piece, and then cut up into square pieces of uniform size and of the required weight, by means of a pair of fixed shears, with an adjustable guide or gauge on the lower blade. It is necessary of course to recover the silver after its solution in the nitric acid, and use it again repeatedly. This may be done by precipitating with common salt, collecting and washing the chloride of silver, and when free from nitric acid, reducing it by pieces of zinc or iron laid in it and caused to evolve hydrogen by adding a little sulphuric acid. The metallic silver-powder which is in a little time obtained may be melted down as soon as it is cleared of the zinc or iron and the acid solution.

Much economy may be practised, if desired, in the use of the nitric acid. Thus the stronger acid (specific gravity 1.32) after being used for one assay, may be preserved, diluted with a proper quantity of distilled water, and again used as the weaker acid for another assay.

Even after being used as weak acid, the silver it contains may be precipitated by hydrochloric acid, and both the silver and nitric acid become again serviceable. The

most extreme care, however, must be taken that no nitric acid used in an assay contains the slightest trace of chlorine; otherwise gold will be dissolved and the assay entirely falsified. The presence of chlorine may of course be known by a cloudy white precipitate when silver is added to the clear liquid; but we prefer as a precaution to reverse the test, and never use any acid which does not contain a *very minute trace of silver*, and yet remain clear. If a larger quantity of silver were in the strong acid, it would, from an action not properly understood, increase the *surcharge*, or quantity of silver remaining undissolved in the cornet. By the alternate use of hydrochloric acid and silver solution, any good nitric acid may be prepared for the assay process, the chloride of silver produced, however small in quantity, being allowed entirely to subside.

The cupels used by the gold assayer should be of the finest bone-dust, made by Deleuil et Fils, of Paris, who also supply, directly or through the London dealers, the best furnaces, muffles, crucibles, flasks, and other such apparatus, that is to be had. The cupels may be had ready made, or may be made in the laboratory with a proper mould. When large numbers are required, it is usual to employ a press resembling a small embossing press. Inferior English bone-earth is apt to disengage carbonic acid in the furnace, which spirts out small quantities of the melted metal and hopelessly falsifies the assay.

Of course in practice no purchase of bullion must be made on the result of a single assay, so liable as it is to accidents or mistakes; but the mean result of several assays, not differing more than ten or twenty parts among themselves, must be adopted. Thus the Bank of England carry on the whole of their enormous transactions in bullion upon triple assays of each ingot made by some scientific assayer of high standing. In every mint, two or more assayers are employed to check each other's results.

A clear idea of the accuracy of the process above described may be gained from the following table, which shows the differences of the reports of two assayers upon 1161 samples from gold ingots, each assayer making only a single assay on each.

Differences.	Number of Assays differing.	Differences.	Number of Assays differing.	Differences.	Number of Assays differing.	Differences.	Number of Assays differing.
0	123	9	28	18	1	27	1
1	257	10	29	19	1	28	2
2	240	11	28	20	2	29	2
3	205	12	15	21	4	30	1
4	156	13	11	22	2	31	2
5	117	14	8	23	2	35	1
6	79	15	7	24	0	44	1
7	65	16	8	25	6	45	1
8	52	17	1	26	2	49	1

The differences are expressed in parts of 10,000.

The mean difference of those which do not differ more than 16 parts is 3·8. Such differences arise from a want of perfect uniformity in the process. The differences beyond 16 parts obviously assume a different and unconvergent character, arising from particles of gold detached from the soft cornets; only 33 assays are thus erroneous, and these would be corrected by a repetition of the assays. Of course a difference of one part in the assay report corresponds to no more than a difference of 1% in 10,000% in the bullion transaction. The reduction of the result of an assay decimally expressed to the *trade report* in *carats, grains, and eighths*, is a simple question of arithmetic.

W. S. J.

GOLD-BEATERS' SKIN. The peritoneal or serous membrane separated from the intestinal tube of the ox and other animals. It is attenuated by being beaten with a hammer, and subsequently prepared so as to resist putrefaction.

GOLD-BEATING. See *Ure's Dictionary of Arts*, vol. ii. 398.

GOLD-PURPLE. *Purple or Powder of Cassius.*—When dichloride of tin is added to a dilute solution of gold, a purple-coloured powder falls, which has received these names. It is obtained of a finer tint when dichloride of tin is added to a solution of sesquichloride of iron, till the colour of the liquid takes a shade of green, and the mixture is added, drop by drop, to a solution of trichloride of gold; the liquid, in that state, is free from nitric acid, and very dilute. After 24 hours, a brown powder is deposited, which is slightly transparent, and purple-red by transmitted light, but assumes a dull blue colour when dried. Heated to redness, it loses a little water, but no oxygen, and retains its former appearance. If washed with ammonia on the filter while still moist, it is dissolved, and a purple liquid passes

through, which rivals in beauty the permanganate of potassium. From this liquid, the colouring matter separates very gradually, weeks elapsing before the upper strata of the liquid becomes colourless; but it is precipitated more rapidly when heated in a close vessel between 140° and 180° F. The powder of Cassius is insoluble in solutions of potash and soda. It may also be formed by fusing together 2 parts of gold, $3\frac{1}{2}$ parts of tin, and 15 parts of silver, under borax, to prevent the oxidation of the tin, and treating the alloy with nitric acid to dissolve out the silver; a purple residue is left containing the tin and gold that were employed.

The powder of Cassius is certainly, after ignition, a mixture of stannic oxide and metallic gold, from which the gold can be dissolved out by nitromuriatic acid, while the stannic oxide is left; and the last mode of preparing it favours the idea that its constitution is the same before ignition; but the solubility of the unignited powder in ammonia, and the fact that mercury does not dissolve out gold from the powder when properly prepared, appear to be conclusive against that opinion. The proportions of its constituents vary so much, that there must be more than one compound; or more likely the colouring compound combines with more than one proportion of stannic oxide. Berzelius proposed the theory that the powder of Cassius may contain the purple dioxide of gold combined with sesquioxide of tin, $\text{Au}_2\text{O}_3 \cdot \text{Sn}_2\text{O}_3$. A glance at its formula shows how readily the powder of Cassius, as thus represented, may pass into gold and stannic oxide: $\text{Au}_2\text{O}_3 \cdot \text{Sn}_2\text{O}_3 = \text{Au} + 2\text{SnO}_2$. The existence of a purple oxide of gold, AuO , is not established; but it is probably the substance formed when a solution of gold is applied to the skin or nails, and which dyes them purple.

Pelletier gives the following method of preparing a purple of Cassius of constant composition:—20 grammes of gold are dissolved in 100 grammes of aqua-regia, containing 20 parts nitric to 80 parts of commercial hydrochloric acid; the solution is evaporated to dryness over the water-bath; the residue dissolved in water; the filtered solution diluted with 7 or 8 decilitres of water; and tin filings introduced into it: in a few minutes the liquid becomes brown and turbid, and deposits a purple precipitate, which merely requires to be washed and dried at a gentle heat. The purple thus prepared contains in 100 parts: 32.746 stannic oxide, 14.618 stannous oxide, 44.772 aurous oxide (Au^2O) and 7.864 water. The precipitate obtained by treating trichloride of gold with pure stannous chloride is always brown. To obtain a fine purple precipitate, the chloride of gold should be treated with a mixture of stannous and stannic chlorides. The following process gives a fine purple:—*a.* A neutral solution is prepared of 1 pt. of tin in hydrochloric acid; *b.* A solution of 2 pts. of tin in cold nitromuriatic acid (1 pt. hydrochloric to 3 pts. nitric acid), the liquid being merely heated towards the end of the process that it may not contain any protoxide of tin; *c.* 7 parts of gold are dissolved in nitromuriatic acid (6 hydrochloric to 1 nitric acid), and the solution, which is nearly neutral, is diluted with 3500 parts of water. To this solution *c* the solution *b* is first added, and then the solution *a* drop by drop, till the proper colour is produced. If the quantity of *a* is too small, the precipitate is violet; if too large it is brown. It must be washed quickly, so that the liquid may not act upon it too long. (*Graham's Elements*, 2nd ed. ii. 354.)

GOLDEN MARCASITE. An old name of zinc. (See *Ure's Dictionary of Arts*, &c. ii. 399.)

GOLDEN SULPHURET OF ANTIMONY. *Sulphur Antimonii auratum.*—Pentasulphide of antimony (i. 334).

GONG-GONG or *Tam-tam* of the Chinese. A kind of cymbal which makes a very loud sound on being struck. It is composed of an alloy of copper and tin, containing, according to Thénard's analysis, 80 per cent. copper and 20 tin.

GONGYLITE. A mineral occurring in yellow or brown grains on the shore of Yli Kittajärvi, in Finland. It is indistinctly crystalline, and cleaves with moderate facility in two directions. Lustre waxy. Translucent on the edges. Streak white. Fracture conchoidal or splintery. Specific gravity = 2.7. Hardness = 4 to 5. Before the blowpipe it gives off water, and melts to a blistered glass at a stronger heat. According to Thoreld's analysis it contains:

SiO_2	Al_2O_3	Fe_2O_3	MnO	MgO	CaO	K_2O	Na_2O	H_2O
55.22	21.80	4.80	0.32	5.00	0.77	4.46	0.45	5.77 = 98.59

which by substituting protoxides, m^2O for sesquioxides, M^2O , may be reduced to the general form ($\text{M}^m\text{Si}^n\text{O}^p$), which is that of a metasilicate, R^rSiO^s . (*Jahresb. f. Chem.* 1867, p. 677; *Rammelsberg's Mineralchemie*, p. 861.)

GONIOMETER. An instrument for measuring the angles of crystals. See CRYSTALLOGRAPHY (p. 169).

GORGONIA NOBILIS. The red coral. It consists of an interior stem, com-

posed of gelatinous matter and carbonate of calcium, with a cortex consisting of membrane with carbonate of calcium, coloured by some unknown substance. U.

GOSHEKITE. Syn. with BERYL.

GOSLARITE. Native sulphate of zinc. (See SULPHATES.)

GOSSAN. A Cornish mining term for an oxide of iron mixed with other metals. (See *Ure's Dictionary of Arts*, &c. ii. 399.)

GOSSYPIUM. The cotton plant. (See COTTON, p. 91.)

GÖTHITE. A variety of native ferric hydrate, $\text{Fe}^2\text{O}_3 \cdot \text{H}_2\text{O}$ or Fe^2HIO_3 , crystallised in prisms belonging to the trimetric system, longitudinally striated, and often flattened parallel to the brachydiagonal. Cleavage very perfect parallel to the brachydiagonal; also fibrous, reniform, foliated, or in scales; massive. Hardness = 5 to 5.5. Specific gravity 4.0 to 4.4. Lustre imperfect adamantine. Colour yellowish, reddish, and blackish brown, often blood-red by transmitted light. Streak brownish-yellow to ochre-yellow. It is found at Eisenfeld in Nassau in foliated crystallisations of a hyacinth-red colour (*Rubinglimmer*), together with brown hæmatite. It occurs also at Clifton, near Bristol, at Lostwithiel and Botallack in Cornwall, at Lake Onega (*Ongite*) in Siberia, at Oberkirchen in the Westerwald, Zwicklen in Saxony, Eisfeld in Siegen, Przibram, &c. A capillary variety (*Sammetblende*) occurs at Przibram and elsewhere.

GOTTHARDITE. *Dufrenoyite*.—Native sulpharsenite of lead. It occurs crystallised in regular dodecahedrons, with truncated edges. Cleavage not distinct. Specific gravity 5.549. Lustre metallic. Colour steel-grey. Streak reddish-brown. Brittle. The mean of two analyses by Darcour gave 22.39 per cent. S, 20.78 As, 55.30 Pb, 0.19 Ag, 0.26 Ca, and 0.38 Fe, agreeing nearly with the formula $2\text{PbS} \cdot \text{As}_2\text{S}_3$, which is analogous to that of heteromorphite, arsenic taking the place of antimony. The mineral is found in the dolomite of St. Gothard, together with realgar, orpiment, blende, and pyrites. (Dana, ii. 77.)

GOULARD'S EXTRACT. A saturated solution of basic acetate of lead. (See ACETATES, i. 16.)

GOUTY CONCRETIONS. Concretions of acid urate of ammonium, formerly called chalk-stones, from their resemblance to chalk. (See URIC ACID.)

GRADUATED SOLUTIONS. Solutions of acids, alkalis, &c., of known strength for volumetric analysis. (i. 255.)

GRADUATION OF GLASS TUBES, &c. See ANALYSIS, VOLUMETRIC (i. 256, 269.)

GRADUATION OF SALT WATERS. The concentration of sea-water and the water of brine-springs previous to boiling, by causing it to fall from a trough or cistern over a wall of twigs or thorns, by which it is distributed and exposed to the air in the form of rain. (See SODIUM, CHLORIDE OF.)

GRAINER. The lixivium obtained by infusing pigeon's dung in water is used for giving flexibility to skins in the process of tanning, and is called the grainer. U.

GRAINS OF PARADISE. *Mallaguetia pepper*. The fruit of several zingiberaceous plants, used to give a factitious strength to beer and cordials.

GRAIN-TIN. See TIN.

GRAMMATITE. Syn. with TREMOLITE.

GRAMMITE. Syn. with WOLLASTONITE.

GRANATIN. *Granadin*, *Grenadin*.—A bitter crystalline substance, obtained by Landerer from the husks of unripe pomegranates. It crystallises in stellate groups of needles, and when heated emits the odour of burnt bread. To prepare it, the aqueous decoction of the alcoholic extract of the husks is boiled with white of egg to precipitate tannin, then evaporated; the residue is exhausted with dilute sulphuric acid, and the granatin, precipitated from the acid liquid by potash, is purified by recrystallisation.

The name granatin was also applied by Latour de Trie to a sweet substance which he obtained from the root-bark of the pomegranate tree; but this was shown by Boutron-Charlard, and Guillemette to be identical with mannite. (*Handw. d. Chem.* iii. 685.)

GRANITE. A crystalline rock composed of quartz, felspar, and mica, crystallised promiscuously together. The felspar constitutes ordinarily about 40 per cent., but varies very widely, while the quartz usually amounts to 30–40 per cent. Ordinary granite contains about 72.3 per cent. silica, 15.3 alumina, 7.4 alkalis, 5.0 lime, magnesia and oxide of iron. *Pegmatite* is graphic granite. [Respecting the supposed formation of granite, see GEOLOGY, CHEMISTRY OF, p. 832. Localities and uses of the various kinds of granite found in the United Kingdom; *Ure's Dictionary of Arts*, &c. ii. 400. On the composition of the granites of the south-west of Ireland, see a paper by the Rev. S. Haughton, *Phil. Mag.* [4] x. 23.]

GRANULATION. The method of dividing metallic substances into grains or small particles, in order to facilitate their combination with other substances, and sometimes for the purpose of readily subdividing them by weight.

This is done either by pouring the melted metal into water, or by agitating it in a box until the moment of congelation, at which instant it becomes converted into a powder.

Various contrivances are used to prevent danger and ensure success in the several manufactures that require granulation. Copper is granulated for making brass by pouring it through a perforated ladle into a covered vessel of water with a movable false bottom. For making small shot, a compound metal, consisting chiefly of lead, is poured into water through a perforated vessel of another kind, in which the height above the surface of the fluid requires particular adjustment. In some manufactures of this kind, the height is upward of 100 feet.

GRANULITE. *Purite. Leptynite.*—A rock consisting of a granular mixture of felspar and quartz, sometimes with garnet.

GRANULOSE. According to Nägeli (*Die Stärkemehlkörner*, 1868), starch-granules consist of two substances, which may be separated by certain solvents, especially by saliva, which dissolve out the substance that gives the blue colour with iodine (the true starch, called *granulose* by Nägeli), and leave a skeleton of cellulose. Nägeli's results have, however, been called in question by other observers. (See STARCH.)

GRAPE. See VINE.

GRAPE-SUGAR. See GLUCOSE.

GRAPHIC GOLD. *Graphic Ore. Graphic Tellurium. Sylvanite.*—A telluride of gold and silver found at Nagyag and Offenbanya, in Transylvania. (See SYLVANITE.)

GRAPHITE. A variety of native carbon occurring in opaque masses of an iron black or steel-grey colour, sometimes crystalline, sometimes amorphous. (See CARBON, i. 758.)

GRAPHITIC ACID. $C^H^4O^3$, or $Gr^H^4O^3$.—An acid discovered by Brodie (Ann. Ch. Pharm. cxiv. 6), and produced from graphite by the repeated action of chlorate of potassium and nitric acid. Graphite, carefully purified by boiling with acids and fusion with hydrate of potassium in a silver crucible, is intimately mixed with 3 at. chlorate of potassium; the strongest nitric acid is added in sufficient quantity to render the mixture fluid; and the whole is either exposed to sunshine or heated on the water-bath to $60^{\circ}C$, for three or four days. If at the end of this time, no more yellow vapours are evolved, the mixture is shaken out into a large quantity of water, the undissolved portion completely washed by decantation, dried on the water-bath, and again brought in contact with the same quantities of nitric acid and chlorate of potassium; and the same treatment is repeated four times, or as often as any further alteration of the substance appears to be produced. Graphite cannot be completely converted into graphitic acid by one warming with chlorate of potassium and nitric acid, even for a long time. Graphitic acid obtained as above contains about $\frac{1}{2}$ per cent. ash, probably derived from the glass vessels.

Graphitic acid forms perfectly transparent, thin crystals, belonging either to the trimetric or the monoclinic system. It is somewhat soluble in pure water; insoluble in water containing acids or salts. After drying at $100^{\circ}C$. or in vacuo, it gives, by analysis (after deducting 1.5 per cent. ash), 61.04 per cent. carbon, and 1.85 hydrogen, agreeing with the formula above given, which requires 61.01 C, 1.85 H, and 37.04 O.

Decompositions.—Graphitic acid decomposes when heated, with explosion, incandescence, and evolution of gas, and leaves a black finely-divided residue. When it is suspended in Rangoon naphtha (rectified over sodium and boiling at $270^{\circ}C$.) and heated, a large quantity of water distils over between 100° and 200° , whilst at first a small and afterwards a larger quantity of carbonic anhydride escapes, the naphtha acquires a deep red colour, and a black residue is left having the appearance of charcoal. This residue, collected after 3 or 4 hours' heating of the graphitic acid with the naphtha to 280° , weighed 66.77 to 66.98 per cent., but still contained traces of transparent crystals; after fourteen hours' heating, it weighed 65.77 per cent., and had then the composition $C^H^4O^3$.

When a solution of *sulphate of ammonium* or *sulphide of potassium* is poured upon graphitic acid, it decomposes with decrepitation, forming a graphitoidal substance having the metallic lustre:

Graphitic acid is decomposed in like manner by boiling with acid solutions of *cuprous* or *stannous chloride*.

Graphitates.—Graphitic acid unites with *alkalis*. Shaken up with *aqueous ammonia* is transformed into a transparent jelly, without dissolving, and on addition

of acids, is precipitated as a jelly, like silicic acid, which, after drying in vacuo, has the same weight as the graphitic acid originally employed.

Graphite of barium.—Moist graphitic acid, shaken up with baryta-water, then washed and dried at 100° C., yielded a compound which contained 21.19 per cent. Ba, and after being suspended in water and decomposed by a stream of carbonic acid, still contained at 100° , 13.30 per cent. Ba. Hence Brodie regards the former salt as essentially containing $C^2H^4Ba^1O^{10}$ (calculation 24.13 per cent. Ba), and the latter as $C^4H^4Ba^1O^{20}$ (calculation 13.73 per cent. Ba), and graphitic acid probably as dibasic. The barium-salts are hygroscopic, and detonate with violence when heated.

GRAPHON. *Symbol, Gr.* Atomic weight, 33.—A modification of carbon, supposed by Brodie to exist in graphite and graphitic acid. If the latter compound be regarded as analogous to the acid, $Si^1H^1O^3$, which Wöhler obtained by the action of oxidising agents on graphitoid silicon, it must contain 4 atoms of carbon or graphon, its formula then becoming $Gr^4H^1O^3$, and the graphon entering into it with the atomic weight above given ($Gr^1 = 4 \times 33 = C^{11} = 11 \times 12$).

GRASSES. The composition of cereal grasses, and of the ash which they leave when incinerated, has already been given in the article CEREALS (i. 823). The following table (p. 943) exhibits the composition of the ash of a considerable number of meadow and pasture grasses, as determined by Messrs. Way and Ogston. (Roy. Agr. Soc. J. vol. ix. pt. i.; and vol. xii. pt. ii. pp. 616, 630, 638, 639; Jahresb. f. Chem. 1849, p. 698, 1850, p. 668.)

GRASS-OIL, EAST INDIAN. An ethereal yellow neutral oil, having a sharp agreeable taste, and an odour like that of rose-oil; it is said to be obtained from *Andropogon Iwarancusa*. By rectifying it with water, Stenhouse obtained a resinous residue, and a colourless distillate having a less agreeable odour. This distillate, after being dehydrated by chloride of calcium, began to boil at 147° C., after which the boiling point rose to 160° , where it remained stationary for a while, and then rose higher. Analysis gave 83.76 per cent. C, 11.47 H, and 4.77 O. By treating the same distillate with sodium, a brown resin was separated; and the oil decanted therefrom, and again rectified, gave 88.57 per cent. C and 11.5 H, = C^8H^8 .

GRATIOLA OFFICINALIS. According to Walz (Jahresb. pr. Pharm. xxi. 1; N. Jahresb. Pharm. x. 65), this plant contains gratiolin (discovered by Marchand [J. Chim. méd. 1846, p. 357]), gratiosolin, gratioline, several resins, tannic acid, and antirrhinic acid.

Gratiolin is a very brittle substance, insoluble in ether, slightly soluble in water, easily in alcohol, from which it separates in warty masses. It melts in boiling water. It dissolves in hydrochloric and in nitric acid, and with purple colour in sulphuric acid, the colour being destroyed by water. Potash and ammonia colour it green without dissolving it, but the colour is not permanent. The aqueous solution of gratiolin is precipitated by tannic acid. (Marchand.)

According to Walz, gratiolin is a glucoside, having the composition $C^{20}H^{34}O^7$, and being resolved by boiling with dilute sulphuric acid into gratioletin, $C^{17}H^{28}O^5$, a crystallisable substance, insoluble in water and in ether, gratioleretin, $C^{17}H^{28}O^5$, a resinous substance, insoluble in water, but soluble in ether, and glucose (p. 869).

Gratiosolin, $C^{24}H^{40}O^{12}$, is another glucoside contained in the same plant, and is easily resolved by acids, alkalis (and even oxide of lead), into glucose and gratiosoletin, $C^{22}H^{36}O^{11}$, a substance soluble in water, and precipitated by tannic acid; and gratiosoletin is further resolved by boiling with dilute acids into glucose, and a resinous mixture of gratiosoleretin, $C^{21}H^{32}O^9$, soluble in ether, and hydro-gratiosoleretin, $C^{21}H^{32}O^{11}$, insoluble in ether (p. 869). (Walz.)

GRAULITE. See TECTITE.

GRAUWACKE or *Greywacke*, is a rock composed of pieces of quartz, flinty slate, felspar, and clay-slate, cemented by a clay-slate basis. These pieces vary in size from a hen's egg to little grains. When the texture becomes exceedingly fine-grained the rock constitutes greywacke-slate. Its colour is usually ash or smoke-grey, without the yellowish-grey or greenish tinge frequent in primitive slate. It has not the continuous lustre of primitive slate, but glimmers from interspersed scales of mica. It contains quartz veins, but no beds of quartz. Petrifications are found in it.

The term grauwacke formation is applied to a group of rocks between the carboniferous strata and the primitive rocks, the true grauwacke being only an individual member of this group.

GRAVITY, SPECIFIC. See SPECIFIC GRAVITY.

GREEK FIRE. An inflammable compound, supposed by some to have been composed of asphaltum with nitre and sulphur, by others to have had nearly the same composition as gunpowder.

GRASSES.

943

GREEN-EARTH or SCLADOWITE. An altered form of augite. Colour celadine green or green of various shades. Massive and in globular and amygdaloidal-shaped masses, sometimes hollow. Fracture earthy. Opaque. Feebly glistening in the streak. Soft and sectile. Greasy. Adheres slightly to the tongue. Becomes greasy. Before the blow-pipe it is converted into a black vesicular slag.

Green-earth appears to have been produced from augite by the action of alkaline carbonates in solution, the change consisting in the removal of lime and magnesia, and the substitution of alkalis in their place. It consists chiefly of ferrous silicate, as will be seen from the preceding analyses: *a*, *b*, from Iceland (Waltershausen); *c*, from Mount Baldo (Delesse); *d*, from the neighbourhood of Verona (Jameson); *e*, *f*, from Passa in the Tyrol. (Rammeisberg.)

It is a frequent mineral in the amygdaloid of Scotland, England, Ireland, Iceland, and the Faroe Islands. It occurs also in Saxony, the Tyrol, Hungary, and near Verona. (Dana, ii. 165; Bischof's *Chemical Geology*, ii. 130, 328.)

GREEN IRON ORE. Native ferric phosphate. (See IRON.)

GREEN LEAD ORE. Arsenio-phosphate of lead with chloride of lead. (See LEAD.)

GREEN PIGMENTS. *Bremen green* is either a basic carbonate of copper, obtained by precipitating sulphate of copper with a mixture of carbonate of sodium and caustic soda or potash, or a hydrated oxide prepared by precipitating with caustic alkali alone.—*Bruswick green* is an oxychloride of copper, prepared by exposing copper foil to the air, mellowing it repeatedly with hydrochloric acid or sal-ammoniac, and exhausting the product with water (i. 70).—*Chrome green* is either anhydrous chromic oxide, or a mixture of chrome-yellow with Prussian-blue (i. 934, 948).—*Cobalt-green*, or *Rinmann's green*, is a mixture, or perhaps a compound, of the oxides of zinc and cobalt (i. 1057).—*Crystallised green* is neutral acetate of copper (i. 14).—*Emerald-green*, or *Vert pannerier* is a hydrated chromic oxide (i. 950).—*English-green* (*Vert anglaise*) is a mixture of arsenite of copper with various white substances, such as sulphate of barium or calcium.—*Iris green*, a colour formerly used in miniature painting, was prepared by macerating in cold solution of alum or gum-water the satiny epidermis of the petals of the iris, filtering the liquid through a fine calico, and leaving it to evaporate on plates in a shady place.—*Mineral green*. This term is now generally applied to Scheele's green, but it originally denoted a mixture of 2 pts. Scheele's green with 6 pts. white lead, 2 pts. black oxide of copper, 3 pts. malachite, and $\frac{1}{2}$ pt. acetate of lead. This mixture has an apple-green colour, with bluish reflex.—*Milroy's green* (*Vert en grains*) is a very fine green pigment, containing chromic acid, sulphuric acid, cyanogen, potassium, iron, and lead. Its preparation is kept secret, but it may be imitated by mixing the solutions of ferrocyanide of potassium, protosulphate of iron, acetate of lead, and bichromate of potash. A precipitate is thus obtained of a very fine green colour, but not so durable as that prepared by the inventor's process.—*Sap green* (*Vert de vessie, vert végétal*) is the juice of buckthorn berries combined with lime or alumina.—*Mittis, Vienna, or Kirchberger's green* is an arsenate of copper $2\text{Cu}^{\circ}\text{O}.\text{As}^{\circ}\text{O}_3$, prepared by precipitating sulphate of copper with arsenate of potassium.—*Mountain green* is green carbonate of copper, either native or prepared by precipitation (i. 783).—*Prussian green* is ferrocyanide of cobalt; it has a very rich green colour when recently prepared, but quickly turns red-grey on exposure to the air: hence it is but rarely used.—*Scheele's green* is arsenite of copper (i. 376).—*Schweinfurt green* is aceto-arsenite of copper (i. 15, 376).—*Veronese green* (*Vert de Paul Veronese*). An arsenate of copper prepared in this country and in Alace by a process which is kept secret.—*Zinc green*. This term is applied to cobalt or Rinmann's green, and to a cyanide of zinc and iron obtained by macerating finely pounded Prussian blue in a strong solution of chloride of zinc. A fine colour is thus obtained, but, like all other colours formed from cyanides, it is not permanent. (See *Chimie des Couleurs*, par J. Lefort, Paris, 1855; also *Ure's Dictionary of Arts*, &c. i. 803, ii. 402.)

GREEN VITRIOL. Protosulphate of iron. (See SULPHATES.)

GREENLANDITE. Garnet from Greenland.

GREENOCKITE. Native sulphide of cadmium. (See CADMIUM.)

GREENOVITE. Syn. with SPINEL.

GREENSAND. This term is commonly applied to a series of beds lying between the chalk and the Wealden deposits, but is strictly applicable only to certain minor portions of them, marked by the presence of minute grains of green silicate of iron (the glauconite of American mineralogists). The upper portion of the series contains a calcareous sand, very rich in soluble silica, and forming an excellent agricultural soil. (See GLAUCONITE; also *Ure's Dictionary of Arts*, &c. ii. 402.)

GREENSTONE or *Diabase* is a rock composed of augite with labradorite and oligoclase. The term greenstone is also applied to certain varieties of trap, consisting of dark and heavy blackish-green or brownish rock composed of felspar and hornblende, usually having a crystalline structure, but sometimes compact. When albite (soda-felspar) replaces orthoclase (potash-felspar), the rock is called diorite. (Dana, ii. 162, 247.)

GRENADIN. Syn. with GRANATIN.

GRENATITE. Syn. with STAUROTIDE.

GRENGESITE. A silicate from Grengeshögen in Dalecarlia, containing, according to Hisinger's analysis, 27·01 per cent. silica, 14·31 alumina, 2·18 manganous oxide, 25·63 ferrous oxide, 14·21 magnesia, and 12·53 water. It is allied to delessite. Colour dark-green. (Dana, ii. 296.)

GREY ANTIMONY. Native trisulphide of antimony (i. 329).

GREY COPPER. Syn. with TETRAHEDRITE.

GREYWACKE. Syn. with GRAUWACKE (p. 941).

GREY DYE. See DYEING (p. 359); also *Ure's Dictionary of Arts*, &c. (ii. 403).

GROPPITE. A silicate found in the limestone of Gropptorp, in Sweden. It is crystalline, with one distinct cleavage, affording a broad cleavage-surface, and two others less distinct. Hardness = 2·5. Specific gravity = 2·73. Thin splinters translucent. Colour rose-red to brownish-red. Streak paler. Fracture splintery. According to Svanberg's analysis (*Öfversigt af Kongl. Vetenskaps Akad. Förhandlingar*, iii. 14) it contains:

SiO ²	Al ² O ³	Fe ² O ³	CaO	MgO	K ² O	Na ² O	H ² O
45·01	22·55	3·06	4·55	18·28	5·23	0·22	7·11

together with 0·13 of undissolved matter (total 100·13), whence Svanberg deduces the formula $3MO \cdot 2AlO \cdot 3\frac{1}{2}H^2O + 3HO$ or $6M^2O \cdot 4Al^2O^3 \cdot 9SiO^2 + 6H^2O$, which by substituting al^2 for Al^2 may be reduced to $2M^2O \cdot 4al^2O \cdot 3SiO^2 + 2H^2O$, or (including M and al under the general symbol R), to $R^2SiO^{12} + 2H^2O$ or $R^4SiO^4 + \frac{1}{2}H^2O$, which is the formula of an orthosilicate.

GROROLITE. A variety of Wad or Earthy Manganese, found at Groroi, in Mayenne; also at Videssos and Cautern, in France. (See MANGANESE.)

GROSSULAR or *Grossulara*.—A variety of lime-garnet. (See GARNET, p. 772.)

GRÜNAUITE or *Nickel-bismuth glance*.—Native sulphide of nickel and bismuth, found at Grünau, near Sayn Altenkirchen, with quartz and copper pyrites.

GRÜNERITE. A nearly pure iron augite, $FeSiO^2$. A specimen from Collobrières, analysed by Gruner (*Compt. rend.* xxiv. 794), yielded 43·9 SiO^2 , 52·2 FeO , 1·1 MgO , 0·5 CaO , and 1·9 Al^2O^3 = 99·6.

GUACIN. A bitter substance extracted from Guaco, the leaves and stems of the *Mikania Guaco*, a plant nearly allied to the genus *Eupatorium*, growing in Mexico and South America, whence it has been imported into Europe and used as a remedy against cholera. Guacin is obtained, according to Pettenkofer, by exhausting guaco with alcohol, decolorising with animal charcoal, distilling off the alcohol, dissolving the residue in ether, and leaving the solution to evaporate. It then remains as a light brown resinous mass, perfectly soluble in alcohol, partially in water, having a very bitter taste and emetic action, and emitting an intoxicating odour when triturated with sulphuric acid. (*Handw. d. Chem.* iii. 714.)

GUAIAIC. See GUAIAICUM.

GUAIAICENE. CH^2O . *Guaiacene*. *Guajol*.—The light oil obtained in the dry distillation of guaiac resin. It is colourless, and has an agreeable odour, like that of bitter almonds. Specific gravity 0·874. Boiling point $118^{\circ}C$. Vapour-density 2·92. When exposed to the air it oxidises, and is converted into beautiful crystalline laminae (Deville, *Compt. rend.* xvii. 1143; xix. 134). It is not altered by caustic potash solution, or by an alcoholic solution of sesquichloride of iron (if it contains guaiacol, Vol. II.

the iron-solution colours it green). It is insoluble in ammonia, and does not combine with the acid sulphites of alkali-metals. It is oxidised by chromic acid and by nitric acid, the latter acid being produced in the former case, and oxalic acid in the latter. According to its composition, guaiacene might be regarded as the aldehyde of angelic acid ($C^8H^8O^2$), but it is not converted into that acid by fusion with hydrate of potassium. (Gilm., Ann. Ch. Pharm. cvi. 279.)

GUAIAIC ACID. See GUAIAERTIC ACID.

GUAIACOL. *Hydride of Guaiacyl. Guaiacylous acid. Pyroguaiacic acid.* (Gm. xii. 350.—Gerh. iii. 780.—Hlasiwetz, Ann. Ch. Pharm. cvi. 361.)—Produced, together with guaiacene and pyroguaiacin, by the dry distillation of guaiac resin. When the crude oil obtained by this distillation is washed with water and rectified at a moderate heat, guaiacene passes over first, and afterwards, when the heat is increased, the guaiacol distils. It may be purified by repeated rectification, or, according to Vöckel, by dissolving it in potash, boiling it with water as long as any light oil passes over, then mixing it with a quantity of sulphuric acid not quite sufficient to combine with the whole of the potash, redissolving the separated oil in potash, boiling the solution in a retort, till the milky oil which passes over becomes perfectly clear on the addition of a small quantity of potash, again separating the oil by sulphuric acid, and drying it in *vacuo* over sulphuric acid.

Guaiacol is a colourless oil, having a specific gravity of 1.119 at 22° C. (Sobrero); 1.125 at 16° (Vöckel). It has a peculiar faint odour, somewhat like that of creosote, and a pungent peppery taste like cloves. It boils at 210° C. (Sobrero), at 205° (Vöckel). It does not redden litmus. It burns with a white smoky flame. Nitric acid, even when very dilute, attacks it violently at ordinary temperatures, forming oxalic acid and a brown resin. With chlorine and bromine it forms crystallisable substitution-products. It does not yield an acid when treated with oxide of silver, differing in that respect from the homologous compound furfural (p. 750), which yields pyromucic acid when thus treated. (Schwanert, Ann. Ch. Pharm. cxvi. 257.)

Guaiacol is soluble in alcohol, and sparingly soluble in water. The alcoholic solution reduces the salts of gold and silver to the metallic state, and ferric and cupric salts to ferrous and cuprous salts.

Guaiacol dissolves in potash, and combines also with other bases, forming crystallisable salts, which turn black when exposed to air and moisture. It does not decompose carbonates.

Regarding the composition of guaiacol various statements have been given. According to Vöckel's analyses, it contains 68.9 per cent. carbon, 6.4 hydrogen, and 24.7 oxygen. According to Sobrero, 68.7 per cent. C, 6.8 H, and 25.4 O, whence Vöckel deduces the formula $C^{12}H^{10}O^4$, and Sobrero, $C^{12}H^{10}O^4$. Pelletier and Deville agree with the more probable formula, $C^8H^8O^2$, or $C^{12}H^{10}O^4$ (calculation, 67.74 per cent. C, 6.45 H, and 25.81 O), which likewise agrees nearly with the vapour-density as determined by these chemists (exp. 4.49; calc. for 2 volumes, 4.30).

According to Hlasiwetz, guaiacol, obtained as above, is not a definite compound, but a mixture in variable proportions of the two homologous compounds, $C^8H^8O^2$ and $C^{12}H^{10}O^4$. By agitating the purified oil with strong ammonia, or passing ammonia-gas into it, pressing the resulting crystalline mass, dissolving it in warm ether, and treating the solution in an air-tight vessel with strong alcoholic potash, Hlasiwetz obtained a white crystalline mass, consisting essentially of $C^8H^8O^2K^2$, or $C^8H^8KO^2$, according to the quantity of potash used. The latter salt was likewise obtained by repeatedly agitating the oil with moderately strong aqueous ammonia, washing the oil which separated from the watery liquid, repeatedly rectifying it, dissolving it in an equal volume of ether, and treating the solution with a slight excess of very strong alcoholic potash. On decomposing the resulting potassium-salt with oxalic or dilute sulphuric acid, a colourless oil was obtained, having an agreeable odour, and varying in boiling point from 203° to 230° C. The portion which distilled between 205° to 210° had a specific gravity = 1.117 at 13°, and exhibited nearly the composition $C^8H^8O^2$; between 216° and 218°, a distillate was obtained of specific gravity 1.116 and composition $C^{12}H^{10}O^4$; and between 219° and 220°, a distillate of specific gravity 1.089 and composition $C^8H^8O^2$.

From 205° to 210°.			From 216° to 218°.			From 219° to 220°.		
	Calc.	Exp.		Calc.	Exp.		Calc.	Exp.

	100.00	100.00		100.00	100.00		100.00	100.00

The formula $C^{12}H^{10}O^4$ is exactly intermediate between the other two ($C^8H^8O^2$ and $C^{12}H^{10}O^4$). The proportions in which these two compounds (which are homologous

with furfural, $C_5H_4O_2$, are present varies with the nature of the resin from which the guaiacol is obtained. The compound $C_9H_8O_2$ is likewise contained in wood-tar creosote.

GUAIACONIC ACID. $C_{10}H_{12}O_3$.—This acid, according to Hadelich (J. pr. Chem. cxxvii. 321), constitutes 70·35 per cent. of guaiac resin, and remains in the mother-liquor obtained in the preparation of guaiaretic acid (p. 948). To separate it, the mother-liquor is evaporated to dryness, the residue treated with boiling alcohol, the alcoholic solution evaporated, and the remaining brittle mass treated with ether (in which it is only partly soluble). The ethereal solution when evaporated yields guaiaconic acid, as an uncrystallisable mass, melting at $100^{\circ}C$, insoluble in water, possessing laevo-rotatory power, precipitable from its alcoholic solution by barium- and lead-salts. The lead-precipitate contains $C_{10}H_{12}PbO_3$. There is also another lead-salt containing a larger proportion of lead.

Guaiaconic acid is instantly turned blue by oxidising agents. (Hadelich.)

GUAIAECUM. *Guaiac.* *Guajaharz.* *Resina guajaci nativa.* (Handw. d. Chem. iii. 718.—Gerh. iii. 778.—Hlasiwetz, Ann. Ch. Pharm. cvi. 361; cxii. 182.)—A resinous substance obtained from the *Guajacum officinale*, a tree growing in Jamaica, St. Domingo, and others of the West Indian Islands. It exudes spontaneously or from incisions made in the stem (*Guaiacum in granis*), and is likewise obtained by melting it out from the more resinous parts of the tree (*Gu. in massis*); the latter is ~~impure~~, containing chips of wood and bark.

Guaiacum has a yellowish or reddish brown colour, and is transparent in small lumps, but is generally covered with a greenish-grey powder, which renders it opaque. It is hard and brittle, with a vitreous fracture; specific gravity = 1·205 to 1·226. Its powder is white, but soon turns green when exposed to the air. Its taste is faint at first, but soon becomes acrid and produces a burning sensation in the throat. It has scarcely any odour when cold, but when heated gives off a peculiar aromatic odour, something like that of gum benzoin; it melts easily, and at a higher temperature gives off a vapour which strongly irritates the lungs.

Alcohol dissolves about $\frac{1}{10}$ of the resin of guaiacum, and the solution is precipitated by water. Ether and oil of turpentine likewise dissolve it, but leave a more considerable residue. In pure water it is nearly insoluble; but when its alcoholic solution is poured into a considerable quantity of cold water, the resin separates in white flakes, leaving a colourless liquid which possesses in a high degree the aromatic odour of the resin. It is immediately coloured deep yellow by a few drops of ammonia, and is again rendered colourless by acids.

Guaiacum dissolves in potash and in strong sulphuric acid. The latter solution has a splendid red colour, and yields a violet precipitate with water; alcohol first colours the liquid violet-blue, and in larger quantity imparts to it a dirty bluish-green tint (Schiff, Ann. Ch. Pharm. cxi. 372). According to Kossmann (J. Pharm. [8] xxxviii. 81; Rép. Chim. pure, 1863, p. 391), it is resolved by sulphuric acid into sugar and a resinous body called *guaiaretin*.

Guaiacum is distinguished by the facility with which it oxidises and the changes of colour thereby produced. Both the powder and the alcoholic solution turn green when exposed to the air, the change taking place most quickly, according to Wollaston, under the influence of the violet rays of the spectrum, whereas the red rays restore the yellow colour. Nitrous acid colours guaiacum blue, and this reaction may be used to detect the presence of a small quantity of nitric acid in sulphuric acid. If the concentrated acid to be tested be heated in a test-tube with a small quantity of iron filings, and the vapour passed into tincture of guaiacum, a blue colour will be produced if nitric acid is present, but if the sulphuric acid is pure, no change of colour will take place (Schiff). Guaiacum is coloured green by fuming nitric acid, and on adding to the liquid a moderate quantity of water, a green precipitate is formed, while the liquid becomes colourless; a larger quantity of water colours the precipitate blue and the solution brown.

The alcoholic solution of guaiacum is precipitated green by sulphuric acid and blue by chlorine. Iodine added to the alcoholic tincture of guaiacum produces either a dirty greenish colour or none at all; but the liquid turns blue on addition of water. The production of this blue colour is prevented if an acid be previously added; but neutral salts do not prevent it. Tincture of guaiacum is coloured blue by sesquichloride of iron, and on adding to the liquid a solution of hyposulphite of sodium, a very fine violet colour is at first produced, but this soon disappears and leaves a colourless liquid. A solution of sulphurous acid which has been digested with zinc, immediately decolorises the tincture of guaiacum turned blue by ferric chloride, without at first producing the violet colour. Unaltered sulphurous acid also decolorises the liquid, but much more slowly. (Schiff.)

According to Ure's analysis, guaiacum contains 67·9 per cent. carbon, 7·05 hydrogen, and 26·1 oxygen. Pelletier found, in a very pure specimen, 71·0 per cent. C, 7·03

H, and 23.97 O; Johnston, who analysed the portion of resin soluble in alcohol, obtained 70.35 to 70.66 per cent. C, 6.80 to 6.87 H, and 22.57 O, whence he deduced the formula $C^{20}H^{20}O^4$.

Guaiacum is not, however, a definite compound. According to Unverdorben (Ann. Ch. Pharm. xvi. 369), it is separated by ammonia into two resinous principles, one of which is very soluble in aqueous ammonia, while the other forms with that alkali a tarry compound, which requires 6,000 parts of water to dissolve it. According to Pelletier, ammonia dissolves $\frac{2}{3}$ of guaiac resin. According to Hlasiwetz also, a colourless crystalline resin, guaiaretic acid (see below), amounting to a large proportion of the whole, may be obtained by treating guaiacum with alkalis, and decomposing the resulting salt with hydrochloric acid.

According to Hadelich (J. pr. Chem. lxxxvii. 321), guaiaretic acid constitutes only about $\frac{1}{10}$ of guaiac resin, and the mother-liquors from which it has separated yield about 70 per cent. of an uncrystallisable acid (guaiaconic acid, p. 947) soluble in ether, and a resin distinguished as β -resin, insoluble in ether, but soluble in alkalis, and precipitated by acids. The composition of guaiacum, according to Hadelich's analysis, is as follows:

Guaiaretic acid (crystallisable)	10.50
Guaiaconic acid (uncrystallisable)	70.35
β -resin, $C^{14}H^{14}O^3$ or $C^{20}H^{20}O^4$	9.76
Gum	3.70
Woody matter	2.57
Fixed constituents insoluble in water	0.79
Guaiacic acid, colouring matter, and loss	2.33
	<hr/> 100.00

The colouring matter, which contains nitrogen, crystallises in small quadratic octahedrons on saturating with acetic acid the liquor obtained by boiling guaiac resin with milk of lime. It is a weak acid, soluble in alkalis, and precipitated by basic acetate of lead; soluble also in alcohol and ether, very sparingly in water and benzene. The colour is deepened by alkalis. The colouring matter is not altered by acids. Strong sulphuric acid dissolves it with deep blue colour, which however soon disappears. (Hadelich.)

Guaiacum subjected to dry distillation yields *guaiacene*, *guaiacol*, and *pyroguaiacin*. On rectifying the crude distillate, the guaiacene passes over below $120^{\circ} C$., the guaiacol at higher temperatures, and the pyroguaiacin is found among the last portions of the distillate.

Guaiaretic acid subjected to dry distillation yields a mixture of pyroguaiacin and guaiacol.

Pyroguaiacin is a crystalline substance, insoluble in water, easily soluble in alcohol. From the latter solution, it separates in iridescent laminae, generally having a reddish colour. It melts at $183^{\circ} C$., and solidifies in the crystalline state. When strongly heated, it volatilises and forms a crystalline sublimate like benzoic acid. With *nitric* and *chromic acids* it forms a purple-red solution. Its alcoholic solution is coloured green by *sesquichloride of iron*. (Pelletier and Deville, Compt. rend. xvii. 1143; Ebermaier, J. pr. Chem. lxii. 291; Nachbauer, Ann. Ch. Pharm. cvi. 382.) With strong *sulphuric acid*, it forms a yellow solution, which, when warmed, becomes reddish at first, then green, and ultimately dark blue; water added to it throws down a dark blue powder, and renders the supernatant liquid colourless. If a small quantity of peroxide of manganese be added, the blue colouring is produced, even without the aid of heat. An alcoholic solution of pyroguaiacin heated with *chlorine* acquires a dingy red colour; with *ferric chloride* a green colour.

Pyroguaiacin dissolves in hot *potash*- and *soda-ley*, and the solutions, on cooling, yield capillary crystals or iridescent laminae, which, when dry, contain $C^{10}H^{10}KO^3.3H^2O$ and $C^{10}H^{10}NaO^3.H^2O$ respectively. The solutions of these salts form with nitrate of *silver* a precipitate which soon turns black. (Hlasiwetz.)

GUAIARETIC ACID. $C^{20}H^{20}O^4$.—This acid is the crystallisable constituent of guaiacum, and amounts, according to Hlasiwetz, to $\frac{1}{10}$ of the entire resin. Thierry (J. Pharm. xxvii. 381), by treating the concentrated alcoholic extract of guaiacum with baryta-water, precipitating the baryta with sulphuric acid, concentrating the filtrate to a syrup, dissolving in ether, and leaving the ether to evaporate, obtained crystalline warty masses, which were converted by sublimation into beautiful needles resembling cinnamic or benzoic acid, and very soluble in water, alcohol, and ether. The acid thus obtained, called by Thierry guaiacic acid, was found by Deville to have the composition $C^8H^8O^2$. By dry distillation, it was resolved into carbonic anhydride and guaiacene: $C^8H^8O^2 = CO^2 + C^8H^8O$.

Hlasiwetz (Ann. Ch. Pharm. cxii. 182), by treating the alcoholic extract of

guaiacum with potash and decomposing the resulting potassium-salt with hydrochloric acid, obtained a cream-coloured resin, which crystallised from alcohol in needles of scaly crystals, having a peculiar taste and a faint but agreeable odour of vanilla. This product was regarded by Hlasiwetz as probably identical with Thierry's guaiacic acid.

A more complete investigation of this crystalline acid by Hlasiwetz and Gilm (Ann. Ch. Pharm. cxix. 266; Jahresb. f. Chem. 1861, p. 685) has shown, however, that it has the composition $C^{10}H^{12}O^4$. Hence Hlasiwetz now regards it as distinct from Thierry's acid, and designates it as guaiaretic acid.

To prepare guaiaretic acid, Hlasiwetz and Gilm boil pulverised guaiac resin with milk of lime for half an hour, and exhaust the dried insoluble residue in a percolator with hot alcohol; evaporate the alcoholic solution, and dissolve the residue in warm soda-ley of specific gravity 1.3; purify the sodium-salt, which separates on cooling, by recrystallisation from water containing soda; decompose it with hydrochloric acid; and purify the guaiaretic acid thus separated by recrystallisation from strong acetic acid.

Guaiaretic acid forms brittle, concentrically-grouped needles, which are colourless and inodorous, permanent in the air, and melt between 75° and 80° C. It dissolves in alcohol, ether, warm acetic acid, sulphide of carbon, and dilute potash, but not in ammonia, and is precipitated from the potash solution by sal-ammoniac. Its alcoholic solution is coloured grass-green (not blue) by sesquichloride of iron; chlorine-water does not colour it either green or blue; and its aqueous emulsion is not coloured blue by fuming nitric acid. Hence it appears that guaiaretic acid is not the constituent of guaiac resin which produces the blue colour with oxidising agents. (Hlasiwetz and Gilm.)

The solutions of guaiaretic acid turn the plane of polarisation to the left. (Hadelich.)

Guaiaretic acid, when quickly heated, distils for the most part unaltered; but by slower distillation, it yields a yellow oily distillate, which is a mixture of guaiacol and pyroguaiacin (p. 948).

Guaiaretates.—Guaiaretic acid forms neutral and acid salts. The guaiaretates of the alkali-metals are crystallisable; those of the alkaline earth-metals and heavy metals are amorphous precipitates. The neutral salts are stable only in presence of excess of alkali; when boiled with water, they are converted into acid salts. The neutral barium-salt, $C^{10}H^{12}Ba^{10}O^4$ (at 160° C.), is formed by decomposing the neutral potassium-salt with chloride of barium. The neutral potassium-salt, $C^{10}H^{12}K^1O^4$ with $2H^2O$ or $3H^2O$, according to the mode of preparation, crystallises from alcohol in scales and gives off its water at 100° C. The acid potassium-salt, $C^{10}H^{12}KO^4.H^2O$, obtained by boiling the neutral salt with dilute alcohol, or by mixing an alcoholic solution of the acid with carbonate of potassium, and dissolving the precipitate in aqueous alcohol, is a crystalline precipitate which gives off its water at 120° C. The neutral sodium-salt, $C^{10}H^{12}Na^1O^4.2H^2O$, forms shining crystalline laminae, which become anhydrous at 120° C. The acid sodium-salt has the composition $C^{10}H^{12}NaO^4.H^2O$.

Hadelich has obtained a lead-salt containing $C^{10}H^{12}Pb^1O^4$, whence he regards the acid as tetrabasic.

Bromoguaiaretic acid, $C^{10}H^{12}Br^1O^4$, is obtained in loosely aggregated colourless needles, by dropping bromine into a solution of guaiaretic acid in sulphide of carbon till the liquid acquires a brown colour, evaporating to dryness, washing the residue with cold alcohol, and dissolving it in hot alcohol.

A similar product is obtained with chlorine, but it is difficult to purify. Pentachloride of phosphorus also forms with guaiaretic acid a tenacious resinous mass difficult to purify.

An organic base discovered and investigated by Strecker (Ann. Ch. Pharm. cxviii. 151). It is produced: 1. Together with parabanic acid and small quantities of xanthine, oxaluric acid, and urea, by the action of hypochlorous acid on guanine. When guanine is immersed in hydrochloric acid of specific gravity 1.10, and crystals of chlorate of potassium are gradually added (12 grms. of the chlorate to 20 grms. of guanine in 2 or 3 days) till the base is gradually dissolved, with evolution of gas, the solution then evaporated over the water-bath, and the pasty residue treated with ether-alcohol, a solution is obtained, containing hydrochlorate of guanidine, together with the other products above-mentioned. The parabanic acid crystallises out first; and on diluting the mother-liquor with water, warming it with carbonate of barium, mixing the neutral solution with absolute alcohol, filtering from the resulting precipitate of oxalurate of barium, xanthine-baryta, and chloride of barium, evaporating the filtrate, and treating the residue with absolute alcohol, hydrochlorate of guanidine dissolves, and after removal of the alcohol, may be converted into sulphate by treatment with sulphate of silver. The excess of silver-salt is then removed by adding an exactly equivalent quantity of chloride of barium; the concentrated filtrate is mixed with

absolute alcohol, which soon throws down crystalline sulphate of guanidine (urea remaining in solution), and from this salt the base may be separated, by precipitating the sulphuric acid with baryta-water, and evaporating the filtrate in vacuo.

2. By heating biuret (i. 600) to 160° — 170° C. in dry hydrochloric acid gas; also, in small quantity, by boiling that compound with the strong aqueous acid: $C^2H^2N^2O^2 = CH^2N^2 + CO^2$. (Finckh, Ann. Ch. Pharm. cxiv. 335.)

Guanidine thus obtained is a crystalline, strongly alkaline mass, having a caustic taste. When exposed to the air, it deliquesces and absorbs carbonic acid. It unites with acids, forming crystalline salts.

Carbonate of Guanidine, $C^2H^2N^2O^2 = \left\{ \begin{smallmatrix} (CO)^2 \\ (CH^2N^2)^2 \end{smallmatrix} \right\} O^2$, obtained by evaporating the solution of the base in an open vessel, or by decomposing the sulphate with carbonate of barium, crystallises in quadratic octahedrons, or in quadratic prisms with the faces ∞P , $\infty P\infty$ and P . It is very soluble in water, insoluble in alcohol, permanent in the air, and when heated above 125° C. gives off water, carbonic anhydride, and carbonate of ammonium, together with a white difficultly volatile sublimate, and leaves a yellow residue resembling mellone. The alkaline solution of the salt forms white precipitates with calcium-, barium- and silver-salts.

Hydrochlorate of Guanidine crystallises with difficulty in slender needles. The chloroplatinate, $2(CH^2N^2.HCl).PtCl^4$, crystallises from water in yellow needles or prisms.

Nitrate of Guanidine forms prismatic crystals which dissolve sparingly in cold water, and when heated with nitric acid appear to be converted into nitrate of urea.

Acid Oxalate of Guanidine, $CH^2N^2.C^2H^2O^4.H^2O = \left\{ \begin{smallmatrix} (C^2O^2)^2 \\ CH^2N^2 \end{smallmatrix} \right\} O^2.H^2O$ forms colourless

crystals, sparingly soluble in water. The sulphate is also crystallisable, easily soluble in water, insoluble in alcohol.

Guanidine is related in composition to several other organic bases, thus:

Carbo- tri-amine. (Guanidine.)	Methylcarbo- tri-amine. (Methyluramine.)	Diphenylcarbo- tri-amine. (Melaniline.)	Triphenylcarbo- tri-amine.	Triethylcarbo- tri-amine.
$\left\{ \begin{smallmatrix} C^2 \\ H^2 \end{smallmatrix} \right\} N^2$	$\left\{ \begin{smallmatrix} C^1 \\ CH^1 \\ H^1 \end{smallmatrix} \right\} N^2$	$\left\{ \begin{smallmatrix} C^1 \\ (C^6H^5)^2 \\ H^1 \end{smallmatrix} \right\} N^2$	$\left\{ \begin{smallmatrix} C^1 \\ (C^6H^5)^3 \\ H^1 \end{smallmatrix} \right\} N^2$	$\left\{ \begin{smallmatrix} C^1 \\ (C^2H^5)^3 \\ H^1 \end{smallmatrix} \right\} N^2$

GUANINE. $C^2H^2N^2O$. (Bodo Unger [1844], Ann. Ch. Pharm. 4, 395.—Reubauer and Kerner, *ibid.* ci. 318.—Strecker, *ibid.* cviii. 141; cxviii. 151.)—An organic basic obtained from guano. It exists in all kinds of guano, abundantly in the Peruvian, sparingly in the African (Unger). It constitutes the essential part of the excrements of the garden spider, and is found in the green organ of the river crab, and in the Bojanian organ of the pond mussel (Gorup-Besanez and Fr. Will, Ann. Ch. Pharm. lx. 117); also in the pancreas of horses (Scherer, *ibid.* cxii. 251), and in the scales of the bleak. (Barreswil, Compt. rend. liii. 246.)

Preparation from Guano.—1. Guano is boiled with thin milk of lime till a filtered sample exhibits no longer a brown but a greenish-yellow colour; the liquid is then filtered; the filtrate neutralised with hydrochloric acid; the reddish mixture of uric acid and guanine, which is completely precipitated after some hours, is heated with hydrochloric acid to extract the latter; the filtrate cooled till the hydrochlorate of guanine crystallises out, the crystals purified by several recrystallisations; and the guanine precipitated from the aqueous solution of this salt by ammonia. The product, after washing and drying, amounts to $\frac{1}{3}$ per cent. of the guano. The still yellowish guano thus obtained is treated with excess of concentrated hydrochloric acid, with aid of heat; the liquid is decanted before the whole is dissolved; and the undissolved portion, already a purer salt, is collected and repeatedly treated in the same manner till ammonia precipitates white guanine from it (Unger).—2. Guano suspended in water is gradually mixed with milk of lime; the liquid is heated to boiling, and the brown solution is strained through a cloth filter, this treatment being repeated till the liquid becomes colourless. By this means colouring matters, ammonia, volatile acids and other substances (including nitrate of urea and a body related to xanthine) are removed, while guanine and uric acid remain almost wholly undissolved. The residue is now repeatedly boiled with carbonate of sodium, and the united solutions are mixed with acetate of sodium, and then with hydrochloric acid in sufficient quantity to produce a strong acid reaction. The precipitate, consisting of guanine and uric acid, is washed with moderately dilute hydrochloric acid, then boiled with the acid, and the solution of hydrochlorate of guanine, filtered from the uric acid, is evaporated. The hydrochlorate of guanine thus obtained still contains uric acid, to remove which, the guanine is precipitated from the solution by boiling with dilute ammonia, then dis-

solved in hot nitric acid to decompose the uric acid; and from the nitrate of guanine, which crystallises from this solution, the pure base is precipitated by ammonia.

3. According to Neubauer and Kerner, pure guanine is most easily obtained by dissolving the compound of guanine with mercuric chloride in very dilute hydrochloric acid, decomposing the compound with sulphydric acid gas, and precipitating the colourless filtrate with ammonia.

Guanine is a white amorphous powder insoluble in water, alcohol and ether. A hydrate of the base, containing 7.1 per cent. water, is obtained by decomposing the sulphate with a large quantity of water. It resembles the anhydrous base, retains its water at 100° C., but gives up the whole of it at 125°.

Guanine is decomposed by digestion with *hydrochloric acid and chlorate of potassium*, yielding guanidine and parabanic acid, together with smaller quantities of oxaluric acid, xanthine and urea. The formation of guanidine and parabanic acid is represented by the equation:

that of xanthine, which is formed in small quantity only, by

Nitrous acid converts guanine into xanthine, the transformation being explained by the equation just given (Strecker).

Permanganate of potassium, added to a solution of guanine in caustic soda, converts it into oxyguanine, $\text{C}^5\text{H}^3\text{N}^2\text{O}^3$, with formation of carbonic anhydride, oxalic acid, ammonia, and urea. (Kerner.)

Guanine appears to be sometimes converted in the animal organism into urea: when added to the food of rabbits, it increases the quantity of urea excreted in the urine, which, moreover, does not, under the same circumstances, contain either guanine, uric acid, or hippuric acid: part of the guanine was, however, found in the solid excrements. (Kerner, Ann. Ch. Pharm. ciii. 249.)

Compounds of Guanine.—Guanine unites with acids, with alkalis and other metallic oxides, and with metallic salts and chlorides. It dissolves in the stronger acids, but not in formic, acetic, lactic, citric, succinic, or hippuric acid (Neubauer and Kerner). The compounds of guanine with acids are very unstable; they are all decomposed by water, and those which contain volatile acids are likewise decomposed by heat. (Unger.)

Hydriobromate of Guanine, $6(\text{C}^5\text{H}^4\text{N}^2\text{O}.\text{HBr}).7\text{H}^2\text{O}$ (?), crystallises from a hot solution of recently precipitated guanine in hydrobromic acid, in yellowish-white prismatic needles, which effloresce below 100° C., melt at about 180°, and give off their acid at a stronger heat. (Kerner.)

Hydrochlorate of Guanine, $\text{C}^5\text{H}^4\text{N}^2\text{O}.\text{HCl}.2\text{H}^2\text{O}$, is obtained in delicate needles by dissolving guanine in strong boiling hydrochloric acid, and leaving the solution to cool. The water of crystallisation is expelled at 100°, and the acid at 200°. Guanine absorbs hydrochloric acid gas and forms a dihydrochlorate, $\text{C}^5\text{H}^4\text{N}^2\text{O}.2\text{HCl}$, which gives off half its acid at 100° or in vacuo. (Unger.)

Monohydrochlorate of guanine forms crystalline compounds with the chlorides of cadmium, zinc, mercury, and platinum. The *cadmium-salt*, $4(\text{C}^5\text{H}^4\text{N}^2\text{O}.\text{HCl}).5\text{CdCl}^2 + 9\text{aq.}$, separates on mixing the moderately-concentrated solutions of the component salts, in drusy aggregates of thin white laminae. The *zinc-salt*, $2(\text{C}^5\text{H}^4\text{N}^2\text{O}.\text{HCl}).\text{ZnCl}^2.3\text{H}^2\text{O}$, is obtained in large crystals on adding hydrochlorate of guanine to a very strong solution of chloride of zinc. The *mercury-salt*, $2(\text{C}^5\text{H}^4\text{N}^2\text{O}.\text{HCl}).\text{Hg}^2\text{Cl}^2.\text{H}^2\text{O}$, is obtained by adding an alcoholic solution of mercuric chloride to a strong solution of hydrochlorate of guanine (Neubauer and Kerner). The *platinum-salt*, $\text{C}^5\text{H}^4\text{N}^2\text{O}.\text{HCl}.\text{PtCl}^4.2\text{H}^2\text{O}$, is deposited in orange-yellow crystals on mixing a boiling solution of the hydrochlorate with tetrachloride of platinum. (Unger.)

Hydriodate of Guanine, $6(\text{C}^5\text{H}^4\text{N}^2\text{O}.\text{HI}).7\text{H}^2\text{O}$ (?), crystallises in the same form as the hydriobromate; it is sparingly soluble in pure water, easily in dilute hydriodic acid. When exposed to air and light, it turns yellow. The mother-liquor yields lemon-yellow concentrically-grouped laminae, containing a larger quantity of iodine. (Neubauer and Kerner.)

Nitrate of Guanine. A solution of guanine and boiling nitric acid deposits on cooling capillary interlaced crystals of the neutral nitrate, $\text{C}^5\text{H}^4\text{N}^2\text{O}.\text{NH}^2\text{O}.3\text{H}^2\text{O}$, and shortened prisms of an acid salt, $\text{C}^5\text{H}^3\text{N}^2\text{O}.2\text{NH}^2\text{O}.2\text{H}^2\text{O}$. Several intermediate nitrates appear also to exist. A *nitrate of mercurousum and guanine* is obtained on mixing the solutions of the compound salts in crystals, which dissolve sparingly in water, and deflagrate, emitting white fumes when heated. (Unger.)

Oxalate of Guanine, $3\text{C}^5\text{H}^4\text{N}^2\text{O}.2\text{C}^2\text{H}^2\text{O}^4$, separates on mixing a solution of the

hydrochlorate with oxalate of ammonium, in crystals which do not give off anything at 100°C . (Unger.)

Phosphate of Guanine separates in crystals from its solution, but is difficult to obtain pure.

Sulphate of Guanine, $2\text{C}^{\circ}\text{H}^{\circ}\text{N}^{\circ}\text{O}^{\circ}\cdot\text{H}^{\circ}\text{SO}^{\circ}\cdot 2\text{H}^{\circ}\text{O}$, obtained by diluting with water a solution of guanine in strong sulphuric acid, forms yellowish needles sometimes an inch long, which give off their water at 120°C . (Unger.) A *sulphate of silver and guanine* is obtained on adding nitrate of silver to a very dilute solution of sulphate of guanine, as a bulky translucent precipitate, which shrinks very much in drying, and leaves a hard mass of a pale flesh-colour. (Unger.)

Tartrate of Guanine, $3\text{C}^{\circ}\text{H}^{\circ}\text{N}^{\circ}\text{O}^{\circ}\cdot 2\text{C}^{\circ}\text{H}^{\circ}\text{O}^{\circ}\cdot 2\text{H}^{\circ}\text{O}$, separates from a dilute and strongly acid solution, in yellowish radiated nodules, which do not give off anything at 120°C .

Compounds of Guanine with Metallic oxides and salts. Guanine dissolves in aqueous solutions of the caustic fused alkalis. A strong solution of caustic soda, saturated with guanine, and then mixed with a large quantity of alcohol, deposits the compound $\text{C}^{\circ}\text{H}^{\circ}\text{N}^{\circ}\text{O}^{\circ}\cdot\text{Na}^{\circ}\text{HO}\cdot 2\text{H}^{\circ}\text{O}$, in confused laminae, which effloresce in the air, and rapidly absorb carbonic acid. Water decomposes them, dissolving the soda and separating the guanine (Unger). A *barium-compound of guanine*, $\text{C}^{\circ}\text{H}^{\circ}\text{Ba}^{\circ}\text{N}^{\circ}\text{O}^{\circ}$, separates on cooling from a solution of guanine in baryta-water, in needle-shaped prisms, which become opaque when dried over oil of vitriol.

A compound of guanine with *mercuric chloride*, $\text{C}^{\circ}\text{H}^{\circ}\text{N}^{\circ}\text{O}^{\circ}\cdot\text{Hg}^{\circ}\text{Cl}^{\circ}\cdot\frac{1}{2}\text{H}^{\circ}\text{O}$, is obtained as a white crystalline powder on adding a cold-saturated aqueous solution of mercuric chloride in slight excess to a moderately concentrated solution of hydrochlorate of guanine. It dissolves readily in acids and in cyanide of potassium (Neubauer and Kerner). A compound of guanine with *nitrate of silver*, $\text{C}^{\circ}\text{H}^{\circ}\text{N}^{\circ}\text{O}^{\circ}\cdot\text{Ag}^{\circ}\text{NO}^{\circ}$, is produced on mixing the solutions of nitrate of silver and nitrate of guanine (Strecker). On adding nitrate of silver to a very dilute solution of *sulphate of guanine*, a bulky translucent precipitate is formed, which shrinks very much in drying. When decomposed by zinc, it yields silver, guanine, and sulphuric acid, but no nitric acid. (Unger.)

Nitroguanine. When guanine is dissolved in nitric acid of specific gravity 1.15–1.20 at the boiling heat, and the solution, after boiling till it no longer gives a permanent precipitate with ammonia, is left to cool, or evaporated to a syrup and precipitated with water, golden-yellow flocks are obtained, having the composition of *nitrate of nitro-guanine*, $\text{C}^{\circ}\text{H}^{\circ}(\text{NO}^{\circ})^2\text{N}^{\circ}\text{O}^{\circ}\cdot\text{HNO}^{\circ}$, the mother-liquor retaining a portion of the same compound, together with oxalic acid. A slightly alkaline solution of the nitro-compound yields orange-yellow precipitates with acetate of lead, and a dingy yellow-green precipitate with acetate of copper. The silver compound has the formula $2\text{C}^{\circ}\text{H}^{\circ}(\text{NO}^{\circ})^2\text{N}^{\circ}\text{O}^{\circ}\cdot 3\text{Ag}^{\circ}\text{O}$. (Neubauer and Kerner.)

When to the warm solution of nitrate of nitroguanine, crystals of nitrite of potassium are gradually added till a brisk evolution of nitrous fumes takes place, and the solution is then poured into a large quantity of cold water, lemon-yellow flocks are precipitated, which appear to consist of a mixture of xanthine and nitroxanthine. (Strecker.)

Oxyguanine. $\text{C}^{\circ}\text{H}^{\circ}\text{N}^{\circ}\text{O}^{\circ}$ (?).—When a solution of guanine in caustic soda is treated with a solution of permanganate of potassium till the liquid assumes a reddish-yellow colour, oxyguanine is formed, together with carbonic acid, oxalic acid, ammonia, and urea, and separates from the alkaline solution, on addition of hydrochloric acid, as an amorphous, gelatinous, reddish-white precipitate. It is inodorous and tasteless, insoluble in water, alcohol, and ether, and dissolves but partially when heated with acids: from the nitric acid solution it separates unaltered on evaporation. It dissolves with facility in ammonia, potash, soda, lime-water, and baryta-water, and is precipitated from these solutions by carbonic acid; it is, however, slightly soluble in the acid carbonates of the alkali-metals. Its solubility in ammonia distinguishes it from guanine. It does not unite with acids. The ammoniacal solution forms precipitates with acetate of lead and nitrate of silver. The silver-compound appears to contain $\text{C}^{\circ}\text{H}^{\circ}\text{N}^{\circ}\text{O}^{\circ}\cdot\text{Ag}^{\circ}\text{O}$. (Kerner, Ann. Ch. Pharm. ciii. 249.)

GUANITE. Syn. with STRUVITE.

GUANO. A substance found on many of the small islands of the Southern Ocean, near the coasts of Peru and Bolivia, and on the south-west of Africa. It consists of the excrementitious deposit of sea-birds, and occurs in beds 50 or 60 feet thick. It forms a very powerful and valuable manure, for which purpose it has been used for ages in Peru, and within the last twenty years enormous quantities of it have been imported into England and other countries of Europe for agricultural use.

Guano contains a considerable quantity of ammonia, in combination with uric

oxalic, phosphoric, and carbonic acids; also phosphates and sulphates of earthy and alkaline bases, together with water, organic matter, clay and sand. Its composition is very variable, and it is often adulterated.

The following table will give some idea of the variations in the composition of unadulterated guano (Pelouze et Frémy, *Traité*, 2^{me} éd. vi. 595):

Composition of Guano.

	African.			American.		
Combustible organic matter, uric, oxalic, ulmic acid, &c.	39.5	37.0	42.59	11.3	36.5	35.0
Ammonia in the form of carbonate, urate, &c.	9.5	9.5		31.7	8.6	7.5
Fixed alkaline salts, sulphates, phosphates, chlorides, &c.	7.3	6.5	7.08	8.1	6.5	8.2
Phosphates of calcium and magnesium	17.5	18.0	22.39	22.5	20.5	22.5
Oxalate of calcium	2.6		
Sand and earthy matters	1.3	0.5	0.81	1.6	1.5	2.6
Water	25.0	28.5	27.13	22.2	26.0	25.0
	100.1	100.0	100.00	100.0	99.6	100.8

The value of guano depends chiefly on the quantities of ammonia and phosphoric acid which it contains.

For further details on the composition of guano, and for the method of estimating its commercial value, see *Ure's Dictionary of Arts, Manufactures, and Mines*, ii. 413; also *Anderson's Agricultural Chemistry*, Edinburgh, 1853, p. 204.

GUARINITE. A silicotitanate of calcium, having the same composition as sphene (*q. v.*), from Monte Somma, where it occurs, together with sphene, in blocks imbedded in tufa, and chiefly consisting of glassy felspar and nephelin. The crystals are dimetric ($c=0.3712$), exhibiting the faces oP , $P\infty$ (with lateral edge-angle = $40^\circ 44'$), $2P\infty$, $\infty P\infty$, ∞P , $\infty P2$, $\infty P3$. They are tabular between oP or $\infty P\infty$, and cleave, not very perfectly, parallel to $\infty P\infty$. Colour sulphur-yellow. Lustre adamantine. Transparent to translucent. Streak dull. Powder whitish-grey. Fracture irregular. Hardness = 6. Specific gravity = 3.487. The mineral melts before the blow-pipe, without much change of colour; floats in small pieces without alteration, in a bend of phosphorus-salt or borax. Strong hydrochloric acid dissolves it partially, leaving a residue of silica. It gives by analysis 33.64 per cent. SiO_2 , 33.92 TiO_2 , 28.011 CaO , with traces of ferric and manganic oxides.

Guarinite likewise occurs (without sphene) in a greyish-violet trachyte, implanted on nephelin; rarely, together with sphene, in the mixture of augite and mica which is so frequent on Somma. (Guiscardi, *Cimento*, vii. 448.)

GUAYACANITE. See ENARGITE (p. 488).

GUIZOTIA OLEIFERA. The oleaginous seeds of this plant contain 7.02 per cent. water, 43.22 oil, 19.37 albuminous substances, 13.37 sugar, gum, &c., 14.33 cellulose, and 3.48 ash, = 100.08. Nitrogen = 3.10 per cent. (Anderson, *Highland Agr. Soc. J.* new series, No. 69, p. 376.)

GUM. *Gomme. Gummi. Pflanzenschleim.* (Gm. xv. 193.—Gerh. ii. 497.)—A vegetable substance which forms a thick glutinous liquid with water, is insoluble in alcohol, and is converted by nitric acid into oxalic and mucic acids. Gums are very abundant in the vegetable kingdom, existing indeed more or less in all kinds of plants. Six kinds of gum are known, viz. *gum-arabic*, *gum Senegal*, *cherry-tree* or *native gum*, *gum of Bassora*, *gum tragacanth*, and *gum of seeds*. The first five, which are called *gums proper*, exude spontaneously from the stems and branches of trees, and sometimes from the fruit; they are more or less soluble in water, both hot and cold. The sixth kind, the *gum of seeds*, also called mucilage, differs from the gums proper, in not being soluble in water, but merely swelling up when boiled with water.

1. *Gum Arabic.* This gum exudes spontaneously from several kinds of acacia (*A. vera*, *A. arabica*, &c.) growing in Arabia and in Egypt. It forms small transparent tears, white when pure, but generally having a yellowish or brownish colour, and cracking in all directions on exposure to the air. It dissolves readily in water, and the solution acidulated with hydrochloric acid and then mixed with alcohol, deposits white flakes of arabin or arabic acid, $C_{12}H_{22}O_{11}$ (i. 552), Frémy's gummie

acid. This acid, in combination with lime, magnesia, and potash, constitutes, in fact, the essential part of gum-arabic. When a solution of gum is treated with a soluble salt of lead, copper, &c., a precipitate is formed consisting of an *arabate* of the metal. The lead-compound contains $C^{12}H^{20}Pb^{20}O^{11}H^2O$. The corresponding salts of the alkalis and earths are soluble in water, but are precipitated by alcohol.

The specific gravity of gum-arabic is 1.356. It contains 70.40 per cent. arabin and 17.60 water, the remainder consisting of saline and earthy matters, viz. acid malate of calcium, which may be extracted by hot alcohol, the chlorides of calcium and potassium, acetate of potassium, and traces of silica, iron, and phosphate of calcium.

The aqueous solution of gum-arabic, and of the other natural gums, so far as they are soluble in water, turns the plane of polarisation of a ray of light to the left; for pure arabin $[\alpha] = -36^\circ$ (Béchamp). The solution turns acid when exposed to the air, and, according to Fermond (*Berthelot's Chim. org.* ii. 250), is converted, after a long time, into a peculiar sugar, which is dextro-rotatory; according to Mauméné, on the other hand (*Compt. rend.* xxxix, 914), the solution preserves its lavo-rotatory power unaltered for months.

Gum-arabic left for some time in contact with *dilute sulphuric acid*, is converted into dextrin, and on boiling, into a fermentable dextro-rotatory sugar, probably identical with *galactose*, the product obtained from milk-sugar by the action of acids (*Berthelot, Chim. org.* ii. 219).

When *strong sulphuric acid* is covered with a layer of very strong solution of ordinary gum, the gum, after standing for some hours, is completely converted into metagummic acid; but gum-arabic, previously freed from lime by oxalic acid, is not converted into metagummic acid under these circumstances (Frémy). When pulverised gum-arabic is triturated with strong sulphuric acid, it becomes coloured, after some hours; and on diluting with water, neutralising with chalk, then filtering the solution, and evaporating, sulphogummic acid remains, together with a peculiar gum resembling that which is produced from linen by the action of sulphuric acid (Bracconnot), and not capable of fermenting with yeast. (Guérin-Varry.)

Gum-arabic, heated with moderately strong *nitric acid*, is oxidised, with formation of mucic, saccharic, oxalic and tartaric acids. With *fuming nitric acid*, it yields substitution-products.

Gum, heated in sealed tubes with *bromine*, yields a colourless or yellowish liquid, probably $C^{12}H^{20}O^{12}Br^4$, which, when treated with oxide of silver, oxide of lead, or caustic soda, is converted into isodiglycolethyleneic acid, $C^{12}H^{20}O^{12}$ (Barth and Hlasiwetz, *Ann. Ch. Pharm.* cxxii. 96). Gum-arabic in the solid state is not acted upon by *chlorine*, either moist or dry, and very slowly in aqueous solution, a small quantity of carbonic anhydride being evolved. Gum-arabic heated with water, acid carbonate of potassium, and *iodine*, yields iodoform. (Miller, *Compt. rend.* xxi. 828.)

Gum solution does not ferment with yeast. Gum is not altered by *saliva* or by the *gastric juices*. Left in contact with *chalk* and *cheese* for a month in a warm place, it yields alcohol and a small quantity of lactic acid, without previous formation of mannite or glycerin. (*Berthelot*.)

Gum-arabic is much used in medicine to form emollient pastes and syrups, and in numerous processes in the arts. It is added to ink to hold in suspension the tannate of iron, which would otherwise separate from the water; also to blacking for a similar purpose. Large quantities of it are also used for giving lustre to grape and silk, for thickening colours, &c.

2. *Gum Senegal*, obtained from a species of acacia growing in Senegal (*A. Senegal*) is very much like gum-arabic. It occurs in commerce in rather larger masses, about the size of a partridge's egg, or sometimes larger, with a hollow centre. Specific gravity, 1.436. It contains 81.10 per cent. arabin, 16.10 water, and 2 or 3 per cent. saline matters. It forms a somewhat stronger mucilage than gum-arabic, and is much used in calico-printing for thickening the colours and mordants.

3. *Cherry-tree gum*, which exudes from the bark of the amygdaloid tree, occurs in commerce in large shining reddish lumps, often crystallised with impurities. It forms a thick mucilage with water, but is only partially soluble. The soluble portion contains arabin, and the insoluble portion contains cerasin, a substance of similar character, which, according to Frémy, is a compound of metagummic acid with lime. Cherry-tree gum contains 52.1 per cent. arabin, 34.9 cerasin, 12 water, and 1 saline matter. It is used by hatters for smoothing the nap.

Metagummic acid, the organic constituent of cerasin, may be formed from gum-arabic by leaving a syrupy solution of that substance in contact with oil of vitriol (see above), by heating the solid gum for some time to $160^\circ C$, and by treating it with oxalic acid.

cent.
is im

with *alkaline water* or with a small quantity of *lime*, it is converted into a salt of *arabic acid*. In like manner, natural cerasin, and metagummate of calcium obtained by heating gum-arabic, are dissolved by boiling with water. Natural cerasin likewise dissolves more easily when boiled with water, after addition of an alkaline carbonate, and with separation of carbonate of calcium (Frémy). Cerasin boiled with *nitric acid* of specific gravity 1.139 yields as much mucic acid as gum-arabic. (Guérin-Varry.)

4. *Gum of Bassora*, which appears to be the produce of a cactus, is white or honey-coloured, mealy and silvery on the surface, and in the form of somewhat flattened and elongated masses. It is insipid, and crackles between the teeth. In water it swells up to a transparent jelly, but only a small portion dissolves. The soluble portion contains arabin, amounting to about 1 per cent. of the gum; the insoluble portion contains bassorin (i. 619); it dissolves with the aid of heat in potash and in weak acids.

5. *Gum Tragacanth* or *Adragant* exudes from the *Astragalus verus*, a tree growing in Armenia and the north of Persia. It is met with in contorted or vermiculated threads, white or yellow, and opaque; specific gravity 1.384. It swells up in water and dissolves to about one-half. The soluble portion contains arabin; the insoluble portion contains grains of starch, and is turned blue by tincture of iodine. It is dissolved almost completely by dilute sulphuric, hydrochloric and oxalic acids at a temperature of 90° or 100° C. The filtered liquid treated with alcohol deposits flocks of arabin, and a considerable quantity of glucose remains in solution. Gum tragacanth dissolves almost entirely in water when boiled with it for some time. It contains 53.3 per cent. arabin, 33.3 bassorin and starch, 11.0 water, and 2 to 3 saline matters. It is used in medicine and in calico-printing, also by shoemakers.

6. *Gum of seeds and roots*, or *Mucilage*.—This substance appears to be a universally diffused constituent of plants, and is especially abundant in marsh-mallow root, in the tubers of various species of orchis (*Salep mucilage*), the seeds of *Plantago psyllium*, linseed, the seeds of quinces, and of various species of *Salvia* and other *Labiatae*, in the bark and leaves of the lime and elm, and in certain algae, especially *Sphaerococcus crispus*, of which it forms nearly the entire substance, and *Fucus saccharinus*. By steeping either of these seeds, roots, &c., in hot water, the mucilage is obtained in the form of a thick jelly, consisting of minute cells enclosing a soluble substance, and swollen by absorption of water. On digesting it with dilute sulphuric acid at 80° to 100° C., it dissolves completely, and the solution contains glucose. To obtain the soluble part of mucilage, linseed is shaken up with cold acidulated water, the liquid filtered and heated to coagulate albumin, then concentrated and precipitated by alcohol. The substance thus obtained is less transparent and brittle than ordinary gum. It is soluble in cold water, but the solution is not so clear or so ductile as that of gum. According to Nägeli and Cramer (*Pharm. Centr.* 1856, p. 426), it swells up when water is poured upon it, but does not form a true solution. It is insoluble in alcohol, and is precipitated from its aqueous solution, or infusion, by *tincture of galls*.

The aqueous solution of the mucilage of *Plantago psyllium* is not altered by dilute acids, but quince-mucilage is coagulated by acids, alkalis, and many salts. Mucilage boiled with *nitric acid* yields oxalic acid, and, according to older authorities, likewise mucic acid. According to Nägeli and Cramer, quince-mucilage yields, with nitric acid, nothing but oxalic acid. The ash of mucilage contains carbonate and phosphate of calcium, sometimes, also, magnesia, iron, and potash.

7. *Artificial gums*.—a. *British Gum*, *Artificial Gum*, or *Dextrin*, produced by the torrefaction of starch, resembles gum in forming a viscid solution with water; but this solution turns the plane of polarisation of a ray of light to the right, whereas the solutions of all natural gums turn it to the left. (See Dextrin.)

b. *Gum from Sugar*, $C_6H_{12}O_6$.—This gum is produced, together with Reichenhardt's gummie acid, in the oxidation of glucose by cupric salts. It is precipitated by basic acetate of lead (p. 443) and freed from lead by sulphydric acid and from adhering gummie acid by evaporation (the gummie acid being then carbonised) and filtration, and then precipitated by alcohol. It essentially retains a portion of the alkali used in the preparation.—It is very hygroscopic, nearly tasteless, and easily soluble in water, forming a solution which may be used for the same purposes as ordinary gum. Nitric acid converts it into oxalic acid. By boiling with sulphuric acid, it is reconverted into a sugar which reduces cupric salts. With cupric acetate and excess of alkali, the gum forms a transparent blue liquid, which when boiled deposits a greenish precipitate not altered by prolonged boiling. (Reichenhardt.)

GUMMICO ACID. See Lac.

GUMMICO ACID. Frémy's name for the organic acid (Neubauer's *arabin* or *arabic acid*) which in combination with lime (and according to Neubauer, also with magnesia and potash) constitutes gum arabic. Frémy regards the relation between

gummic and metagummic acid (p. 954) as similar to that which exists between soluble pectin-substances and insoluble pectose.

The same name is applied by Reichardt (Ann. Ch. Pharm. cxxvii. 300) to a crystalline acid, $C^6H^{10}O^{10}$, which he finds to be produced, together with a peculiar kind of gum, in the oxidation of glucose by cupric oxide in alkaline solution (p. 860), the reaction taking place in the manner shown by the equation:

To prepare gummic acid, cupric acetate mixed with a slight excess of alkali is heated to about $60^\circ C$. and glucose added till the reduction is complete, small portions of alkali being added from time to time, to replace that which has been neutralised by the gummic acid formed. The filtered liquid is then neutralised with acetic acid; the gummic acid is precipitated by sulphydric acid or chloride of barium; and the gum from the filtrate by basic acetate of lead.

Gummic acid separated from the lead-precipitate by sulphydric acid or from the barium precipitate by sulphuric acid, crystallises by evaporation, first at a gentle heat, afterwards over chloride of calcium, in rhombic prisms having a strong acid taste like that of citric or tartaric acid. At $100^\circ C$. it does not give off water, but begins to emit acid vapours; it turns brown at 130° , and melts with intumescence at 150° , giving off water in continually increasing proportion together with acid vapours. Of the residue left after heating the acid to 210° , only a small portion is soluble in water.

The gummates of the alkali-metals are soluble in water; the other salts sparingly soluble. To the barium- and silver-salts, Reichardt assigns the formula $2MO.C^6H^5O^{10}.HO$, and to the lead-salt, $3PbO.C^6H^5O^{10}.HO$.

GUM-RESINS. When incisions are made in the stems, branches, or roots of some vegetables, there exudes a milky juice, which gradually hardens in the air, and seems to be formed of resin and essential oil, kept in suspension by water, often loaded with gum and several other vegetable matters. To this solidified juice the name gum-resin is given,—an improper one, since it gives a false notion of the body it represents. All the gum-resins are solid, denser than water, opaque and brittle; the greater number have an acrid taste and a strong smell. Their colour is very variable. Water dissolves them in part, and so does alcohol. The aqueous solution becomes transparent with difficulty. When water is poured into the alcoholic solution, it becomes immediately turbid, the resinous matter separating in a state of extreme division, and giving to the liquor a milky aspect. The principal gum-resins are frankincense, scammony, asafetida, aloes, euphorbium, galbanum, myrrh, olibanum, opoponax, gum-ammoniac, and gamboge. U.

GUN-COTTON. See PYROXYLIN.

GUNPOWDER. The invention of gunpowder, which has been ascribed by popular tradition, in Germany to Berthold Schwartz, a Benedictine monk who lived about the beginning of the fourteenth century, and in this country to Roger Bacon in the latter part of the thirteenth century, has been found by recent investigations to date from a much earlier time. Rockets and other incendiary projectiles appear to have been known to the Chinese at least two centuries before the Christian era; and the Greek historians relate that Alexander, in his expedition into India, was deterred from attacking the Oxydracæ, a tribe dwelling between the Hyphasis and the Ganges, because they were under the care of the gods, and overthrew their enemies with thunder and lightning, which they shot from their walls. We know with certainty that gunpowder was used in the eighth century of the Christian era: for the work of Marcus Græcus, entitled "*Liber ignium ad comburendos hostes*," contains exact directions for making a rocket and preparing the powder for charging it, and even recommends that the charcoal should be prepared from willow-wood, which modern experience has shown to be one of the best woods for the purpose. Roger Bacon, writing in the thirteenth century, speaks of gunpowder as a composition well known in all countries for making squibs and other fireworks.

The rocket appears to have been for a long time the only form of incendiary projectile used in war. The first mention of cannon is by an Arabian author, who speaks of them as having been used by the King of Granada at the siege of Baza in 1323. An authentic record of the republic of Florence shows that fire-arms were known in that city in 1325; and in France the public accounts of expenditure from 1335 to 1345 show that fire-arms were then employed in war. Field artillery appears to have been first used by the English at the battle of Cressy in 1346. (*Encyclopædia Britannica*.—*Traité de Chimie générale par Pelouze et Trémy*, 3^{me} éd. ii. 261.)

Composition of Gunpowder, and of the products formed by its combustion. Gunpowder, as everybody knows, is a mixture of nitre, sulphur, and charcoal; and its explosive power depends upon its property of burning rapidly and with great rise of temperature, and evolving by its combustion a quantity of gas which occupies more than 1000 times

the volume of the original powder. The quantity and chemical composition of the gases thus evolved depend upon the proportions in which the nitre, sulphur, and charcoal are mixed.

It was formerly supposed that, in the combustion of gunpowder, the whole of the nitrogen was set free, and that the whole of the oxygen of the nitre entered into combination with the charcoal, forming carbonic anhydride, carbonic oxide, or a mixture of the two, while the potassium of the nitre combined with the sulphur, forming sulphide of potassium, thus:

Powder composed according to the first of these formulae contains 74.9 per cent. nitre, 11.8 sulphur, 13.3 charcoal; and yields, according to theory, 48.9 per cent. by weight of carbonic anhydride, 10.3 nitrogen, and 40.7 sulphide of potassium. A cubic inch of this powder* should yield 74.6 cubic inches nitrogen, and 22.13 carbonic anhydride, or 296 cubic inches of gas in all.

The second kind of powder contains by weight 65.4 per cent. nitre, 10.4 sulphur, and 24.2 charcoal, and should yield, according to the second of the above equations, 54.9 per cent. by weight of carbonic oxide, 9.1 nitrogen, and 36.0 sulphide of potassium, or 1 volume of it should yield 66 vols. nitrogen and 391 vols. carbonic oxide = 457 vols. gas.

It appears, then, that the second kind of powder is capable of yielding $1\frac{1}{2}$ times as great a volume of gas at the same pressure and temperature; but on the other hand, carbon, in burning to carbonic anhydride, evolves a far greater quantity of heat than in burning only to carbonic oxide, and the greater expansion of the gases thence resulting more than compensates for the smaller quantity of gas originally produced. Moreover, the second kind of powder burns so slowly, that the combustion is not complete by the time the ball issues from the gun, so that part of the projectile force is lost.

The actual products of the combustion of gunpowder are in reality much more complicated than they appear to be from the preceding theoretical considerations; nevertheless experience has shown that the best kinds of powder for fire-arms, both large and small, are composed very nearly in the proportions indicated by the first of the formulae above given, as may be seen by comparing the percentage composition of the various kinds of powder for fire-arms given in the following table, with the theoretical composition of the powder No. 1.

Composition of Gunpowder.

Description of Powder.	Charcoal.	Sulphur.	Nitre.	Authority.
Swedish war powder . . .	9.0	16.0	75.0	Meyer

Powder from Champy . . .	18.9	4.8	76.3	Meyer
Chinese powder . . .	23.1	16.4	61.5	Prechtl

* According to Gay-Lussac, the weight of a given volume of gunpowder is 0.9 that of an equal bulk of water.

In all these kinds of powder, excepting the Chinese, which approaches nearly to No. 2 (p. 957), the proportions of the ingredients are nearly the same, the variations arising chiefly from the different degrees of purity of the materials used; in some the proportion of charcoal is increased, and that of sulphur diminished, to allow for the smaller percentage of carbon in the charcoal employed; in others the percentage of nitre is somewhat increased, probably to obtain a more rapidly burning powder.

Blasting powder usually contains a larger proportion of sulphur, which is a cheaper material than charcoal, and may be used in excess in the composition of this powder; but if present in large quantity in powder for fire-arms, would corrode the metal. The composition of French blasting powder, and of its products of combustion, is approximately that which is indicated by the equation:

100 pts. of this powder contain 64.3 pts. nitre, 20.4 sulphur, and 14.7 charcoal, and should yield by combustion 39.0 pts. by weight of disulphide of potassium, 9.9 N, 31.2 carbonic anhydride, and 19.9 carbonic oxide.

The actual products of the combustion of gunpowder are, however, as already observed, much more complicated than the preceding theory would indicate; indeed, notwithstanding the near agreement of the composition of the best kinds of powder with that pointed out by theory, the equations above given cannot be taken as the real representation of the chemical change which takes place, inasmuch as the residue of the combustion is found to consist mainly of sulphate and carbonate of potassium, with only a small quantity of sulphide. When powder burns in contact with the air, it might be supposed that the sulphate of potassium is formed from the sulphide by atmospheric oxidation; but the same result is obtained in burning powder in a close vessel or even in a vacuum, whence it follows that the sulphate of potassium is a direct product of the combustion of the powder independently of atmospheric oxidation.

Gay-Lussac and Chevreul, by burning gunpowder in a copper tube, obtained a gaseous mixture containing in 100 pts. 45.4 pts. CO_2 , 37.5 N, 8.1 NO_2 , 0.6 carburetted hydrogen, and 8.3 of a peculiar gas containing carbon, hydrogen, and oxygen. In another experiment, they obtained 53 per cent. CO_2 , 42 N, and 5 CO. The solid residue was found to contain sulphate, carbonate, and the higher sulphides of potassium, as well as the protosulphide.

More elaborate investigations of the products of combustion of gunpowder have been made of late years by A. Vogel, jun. (Dingl. pol. J. cxxxvi. 156), by Bunsen and Schischkoff (Pogg. Ann. cii. 321; Wagner's Jahresb. 1857, p. 131; 1858, p. 158); by Linck (Ann. Ch. Pharm. cix. 53); and by Karolyi (Phil. Mag. [4] xxvi. 272). The experiments of Bunsen and Schischkoff were made with sporting powder; those of Linck with Wurtemberg war-powder; those of Karolyi with Austrian war-powder. The following table exhibits a comparative view of the results of these experiments:—

				Bunsen and Schischkoff.	Linck.	Karolyi.	
				Sporting powder.	War powder.	Small-arm powder.	Ordnance powder.
	Nitre			78.99	74.66	77.16	73.78
	Sulphur			9.84	12.49	8.63	12.80

Bunsen and Schischkoff find that the smoke of gunpowder has nearly the same composition as the solid residue of the combustion, consisting mainly of sulphate, carbonate, and hyposulphite of potassium.

The heat produced by the combustion of gunpowder has been variously estimated by different observers. Bunsen and Schischkoff found that one gramme of sporting powder evolved, in burning, a quantity of heat sufficient to raise the temperature of an equal weight of water 643.9°C . This number, however, must be diminished by the amount of heat due to the further combustion of the inflammable gases present by the air mechanically enclosed within the powder. This correction reduces the amount of heat due to the actual combustion of the powder to 619.5°C .; and this number divided by the sum of the specific heats of the products of combustion (estimated by B. and S. as $= 0.207$) gives 2993°C . for the temperature of the flame produced by the combustion of gunpowder. If the powder is burnt in a confined space, so that the gases cannot expand, the temperature of the flame will be considerably higher, equal in fact to the quotient obtained by dividing the heat of combustion by the specific heat of the products referred to a constant volume, that is to say, $\frac{619.5}{0.185} = 3340^{\circ}\text{C}$.

The maximum pressure exerted by the gases, at the first instant of evolution, on the inner surface of the gun, and on the projectile, is estimated by Bunsen and Schischkoff at 4374 atmospheres. Former experimenters had estimated it at much higher amounts, but the data on which their calculations were founded do not appear to be very trustworthy. The greatest mechanical effect or *theoretical working effect* of the powder examined by Bunsen and Schischkoff is estimated by them at 67,149 metre-kilogrammes* for a kilogramme of powder.

For descriptions of the machinery and processes used in the manufacture of gunpowder see *Richardson and Watts's Chemical Technology*, vol. i. pt. iv.—*Abel and Bloxam's Handbook of Chemistry*, London, 1854, p. 239.—*Ure's Dictionary of Arts, Manufactures, and Mines*, ii. 429.—*Regnault, Cours de Chimie élémentaire*, ii. 291.—*Pelouze et Frémy, Traité de Chimie générale*, 3me éd. ii. 293.

Analysis of Gunpowder.—1. *Determination of Moisture.*—A known weight of the powder is either placed for several days in a vacuum over oil of vitriol, or it is placed in a U-tube kept at a temperature of 60° or 70°C . and exposed to a current of dry air. In either case the loss of weight of the powder gives the quantity of moisture contained in it.

2. *Determination of the Nitre.*—10 grms. of the dry powder are digested in hot water, and the undissolved residue, consisting of sulphur and charcoal, is collected on a small filter previously dried and weighed, then washed, dried, together with the filter, at a moderate heat, and weighed. The total weight, diminished by that of the filter, gives the sum of the weights of the sulphur and carbon, which, deducted from the original weight of the powder, gives the nitre. The latter may also be determined directly by

* A metre-kilogramme is the force represented by the fall of a kilogramme weight through the height of 1 metre.

evaporating the aqueous solution, together with the wash-waters, and drying the residue in a small porcelain capsule at 149° C.

3. *Determination of the Sulphur and Charcoal.*—A weighed portion of the dry residue of charcoal and sulphur obtained as above is introduced into a small flask, and digested with a mixture of sulphide of carbon and ether, which dissolves the sulphur and leaves the charcoal. The latter is collected on a small tared filter, washed with the mixture of sulphide of carbon and ether, then dried and weighed. The weight of the sulphur is known by difference; or it may be determined directly by evaporating the solution, and weighing the residue.

Some analysts dissolve out the sulphur by means of a solution of sulphide or hyposulphite of sodium; but this method is objectionable, because these liquids likewise attack the charcoal, forming a peculiar acid called *ulmic acid*.

The charcoal in gunpowder is not pure carbon, but contains also hydrogen and oxygen, varying in quantity according to the degree to which the carbonisation has been carried. Its composition has a great influence on the quality of the powder, and must therefore be determined when a complete analysis is desired. The analysis of the charcoal is made by combustion with oxide of copper, as described under ANALYSIS, ORGANIC (i. 232).

The quantity of *sulphur* in gunpowder may also be determined by operating directly on the powder itself. For this purpose, 10 grms. of the dry powder are digested in a small quantity of hot water, nitric acid is added, the whole heated to boiling, and chloride of potassium added by small quantities. The sulphur then dissolves in the form of sulphuric acid, and may be precipitated from the filtrate by chloride of barium. The precipitate of sulphate of barium is collected and washed, with the precautions indicated at page 503, vol i., then dried and weighed, and the amount of sulphur thence determined.

Another method of determining the sulphur is to mix a known weight of the dry powder with an equal weight of nitre and 4 or 5 times the same weight of chloride of sodium, and throw the mixture by small portions into a red-hot platinum crucible. Deflagration then takes place slowly, without projection of the mixture. When it is ended, the fused mass is taken up with water, the liquid is supersaturated with hydrochloric acid, and the sulphuric acid is precipitated by chloride of barium.

It is sometimes required to determine merely the percentage of *nitre* contained in a sample of gunpowder. This is easily done by treating 50 grammes of the powder with 200 grammes of hot water, and filtering the liquid into a glass cylinder having a mark indicating the capacity of 500 cubic centimetres. The residue on the filter is washed with water till the filtered liquid just fills the cylinder up to the mark. The liquid is then cooled to 15° C., and a small quantity of water is added to make up for the contraction caused by cooling. It is then well stirred to render it homogeneous, and a small hydrometer is immersed in it, graduated in such a manner that the degree to which it is immersed indicates immediately the number of hundredth parts of nitrate of potassium contained in the 50 grammes of powder. By this method the proportion of nitro may be easily estimated within 0.3 per cent. (Regnault.)

GURHOFITE, or *Gurhofian*.—A variety of dolomite found at Phillipstown, New York. It has a semi-opaline appearance, and a fracture nearly like that of porcelain.

GUROLITE. See GYROLITE.

GUTTA PERCHA. A substance resembling caoutchouc, obtained from the *Isonarda Percha* (Hooker) or *Is. Gutta*, a large tree of the supotaceous order, growing in the peninsula of Malacca, Borneo, and many of the other islands of the Indian Archipelago, also, according to Bleekrode (Rép. Chim. app. i. 403) from *Sapota Muellieri*. It exudes from incisions in the bark, and is usually procured by the wasteful process of cutting down the trees, ringing the bark at distances of 12 or 18 inches apart, and placing a cocoa-nut shell, spathe of a palm, or some similar receptacle, under the trunk, to receive the milky sap which exudes from the incisions. The juice is afterwards inspissated by boiling.

The crude gutta percha imported into Europe is prepared for manufacturing purposes by rasping it in cold water, whereby it is freed from the greater part of the soluble salts, earthy matters, and extraneous organic substances which it contains, and washed with tepid water in a series of large basins. The residue is then heated for some time to 110° C. (230° F.) to reduce it to a single mass, and expel the last traces of water, which would otherwise remain between the particles of the gutta percha and diminish its coherence.

Another mode of purification is to dissolve the crude gutta percha in sulphide of carbon, filter the brown turbid solution under a bell-jar, and leave the limpid colourless filtrate to evaporate in the air in shallow porcelain dishes or on plates of glass. On

pouring cold water on the dry residue, the films separate from the glass or porcelain after a few minutes, and may be lifted off without breaking. (Payen.)

Purified gutta percha has a brownish red colour and a density of 0.979. It becomes electrical by friction, and is a very slow conductor of electricity. Hence it is much used for forming insulating supports in electrical apparatus, and for coating telegraph wires which are to be immersed in water. At the ordinary temperature of our climate, it possesses considerable tenacity, about equal to that of strong leather, and somewhat less flexibility. At about 48° C. (115° F.) it softens and becomes pasty, though still very tenacious. Between 42° and 60° C. (103° and 140° F.) it may easily be spread out into sheets or drawn into threads or tubes. Its suppleness and ductility diminish as the temperature lowers, and it does not possess, at any temperature, the elastic extensibility of caoutchouc. When softened by heat, it may be worked by pressure into any required shape, and will take the finest impressions of a mould; hence it is much used for ornamental mouldings of picture frames, &c.

Gutta percha is remarkably porous; a thin film of it obtained by leaving a drop of its solution in sulphide of carbon to evaporate spontaneously on a plate of glass, appears, when examined by the microscope, to be full of minute pores, like a sieve. This porous structure may be changed by traction into a fibrous structure, the gutta percha being capable of extending in this manner to double its original length; it then possesses little further extensibility, but will support without breaking a force equal to the double of that which produced the extension.

Gutta percha is insoluble in water, sparingly soluble in anhydrous alcohol and anhydrous ether. It dissolves in small quantity in boiling olive oil, and is deposited from the solution on cooling. Benzene, sulphide of carbon, chloroform, and oil of turpentine dissolve it easily with the aid of heat. It resists the action of alkaline solutions, of hydrochloric acid, and of hydrofluoric acid: bottles made of gutta percha form very convenient receptacles for hydrofluoric acid. It is carbonised by strong sulphuric acid, and converted into a yellow resin by nitric acid. By dry distillation it yields very inflammable oils.

According to Payen (Compt. rend. xxxv. 109), gutta percha purified by solution in sulphide of carbon, as above described, is a mixture of three proximate principles; viz. —1. A portion insoluble in alcohol, whether cold or boiling, and amounting to 75–82 per cent. of the whole. This is called by Payen pure gutta.—2. A crystalline substance called alban, insoluble in cold, but soluble in boiling alcohol; this has been already described (i. 64), it amounts to 19–14 per cent. of the gutta percha.—3. A yellow resinous substance called fluavil (ii. 669) soluble in cold alcohol, and amounting to 6–4 per cent. of the whole. According to Payen, these three substances are isomeric, their composition being expressed by the formula $C^{10}H^{14}$. Payen's pure gutta is white, opaque, elastic; softens and becomes adhesive at 50° C.; melts at about 100° ; dissolves in benzene when heated, in sulphide of carbon at ordinary temperatures, but is insoluble in alcohol and in ether.

From the experiments of Oudemans (Rép. Chim. app. i. 455), and of v. Baumhauer (J. pr. Chem. lxxviii. 277), it appears however that pure gutta is a hydrocarbon isomeric with oil of turpentine, $C^{10}H^{16}$, and that alban and fluavil are formed from it by oxidation, fluavil being $(C^{10}H^{16})^2O$ and alban $C^{10}H^{16}O$,—probably together with a whole series of other products of oxidation, including formic acid. This oxidation appears to take place during the extraction of the gutta percha from the trees, and if it could be prevented, there is no doubt that pure gutta would be at once obtained. (Bleekrode.)

Baumhauer prepares pure gutta by exhausting gutta percha with water and hydrochloric acid, and treating the residue with boiling ether (which dissolves everything excepting a few black flocks), leaving the filtrate to cool, pressing the substance which separates, and repeating the treatment till the ethereal liquid retains nothing in solution after cooling.

Pure gutta thus prepared is perfectly white when reduced to fine powder; cakes together and becomes transparent at 100° C., becoming somewhat turbid on cooling, and more so after some time; at 150° it begins to melt and is converted into a tenacious mass; at 180° an oily liquid begins to distil over; at 210° the mass becomes filled with vapour-bubbles, and at 280° it froths strongly. Gutta is strongly attacked by ozonised oxygen; also by strong hydrochloric acid, with which it appears to form two compounds containing chlorine. It is insoluble in cold ether, but becomes soluble after exposure to the air.

The view just given of the constitution of gutta percha is confirmed by the results of its dry distillation. Greville Williams (Chem. Soc. J. xv. 124) finds that gutta is decomposed by dry distillation, essentially in the same manner as caoutchouc, being resolved, for the most part, into the polymeric hydrocarbons, isoprene, C^5H^8 , and caoutchicin, $C^{10}H^{14}$, and heveone, which is probably also polymeric with the other two.

The caoutchouin forms about 20, the isoprene about 5 per cent. of the crude distillate. The distillate also contains a small quantity of water, which, instead of being alkaline as with caoutchouc, is strongly acid, and contains a volatile acid, apparently one of the lower members of the series $C^mH^{2m}O^2$. On neutralising the acid liquid with potash or soda, the odour of a volatile base becomes perceptible.

Alterations of Gutta Percha. Both the ordinary substance and the pure gutta obtained as above, experience, when exposed to the air, especially at a temperature of 25° to 30° C. (77° to 86° F.) and in thin sheets or threads, a peculiar alteration which takes place with various degrees of rapidity, and completely deprives the material of its flexibility, tenacity, and extensibility, thereby rendering it quite useless for industrial purposes; at the same time a peculiar pungent odour is evolved, which communicates itself to water or other liquids kept in vessels made of the gutta percha (Payen). This alteration is especially liable to occur in tropical climates, an instance of which was experienced in the construction of the East Indian telegraphs. Enormous quantities of gutta percha employed for this purpose became in a comparatively short time entirely useless, involving a loss of thousands of pounds. This altered gutta percha was submitted for examination to Dr. Hofmann (Chem. Soc. Qu. J. xiii. 87), who found that the change was due to oxidation. The altered gutta percha was a brown very brittle mass, from which cold alcohol extracted a brittle substance containing, on the average, 62.8 per cent. carbon, 9.3 hydrogen, and 27.9 oxygen. From the residue of this operation, boiling alcohol extracted a substance of similar physical character, containing on the average 67.7 per cent. carbon, 10.1 hydrogen, and 22.2 oxygen. The residue, insoluble both in cold and in boiling alcohol, was unchanged gutta percha, which yielded by analysis 88.1 per cent. carbon and 12.5 hydrogen. On the oxidation of gutta percha, see also Adriani (Chem. News, ii. 227, 289, 313; Jahresb. 1860, p. 496).

Respecting the manufacture and uses of gutta percha, see *Ure's Dictionary of Arts, Manufactures, and Mines*, i. 433; also Payen, *Précis de Chimie industrielle*, 4me. éd. (1859) i. 184.

GUYAQUILLITE. $C^{20}H^{40}O^2$.—A fossil resin, said to form an extensive deposit near Guayaquil in South America. It yields easily to the knife and may be rubbed to powder. Specific gravity 1.092. Colour pale yellow. Lustre not resinous, or imperfectly so. Slightly soluble in water and largely in alcohol, forming an intensely bitter yellow solution. Begins to melt at 157° F., but does not flow easily till heated to 212° F. Becomes viscid as it cools, and may be drawn out into fine threads. Dissolves in cold sulphuric acid, with dark reddish brown colour. A few drops of ammonia added to the alcoholic solution darken the colour and finally change it to a brownish red. Contains 76.665 per cent. C, 8.174 H, and 15.161 O. (Johnston, Phil. Mag. xiii. 329; Dana, ii. 468.)

GYMNITE. Syn. with DEWEYLITE (p. 312.)

GYPSUM. $Ca^2SO^4H^2O$, or $CaO.SO^3 + H^2O$. *Sulphate of lime. Alabaster. Selenite. Satin spar. Schaumkalk. Plaster of Paris.*—This mineral occurs both crystalline and massive. The crystals belong to the monoclinic system. Ratio of axes $a : b : c = 1.445 : 1 : 0.5976$. Inclination of clinodiagonal to principal axis = $81^{\circ} 26'$; $+P : +P$ in clinodiagonal principal section = $138^{\circ} 44'$; $-P : -P$ in the same = $143^{\circ} 28'$; $\infty P : \infty P$ in the same = $68^{\circ} 46'$. Ordinary combinations $\infty P. [\infty P\infty]. +P. -P$ (fig. 301, p. 155) and $\infty P. [\infty P\infty]. -P$ (fig. 302). Twins like figure 333 (p. 162). Cleavage very distinct, parallel to $[\infty P\infty]$. (Kopp's *Krystallographie*, p. 306.)

Hardness = 1.5. Specific gravity = 2.314—2.328. Lustre of $[\infty P\infty]$ pearly and shining; of the other faces sub-vitreous. Massive varieties often glistening, sometimes dull, earthy. Colour usually white, sometimes grey, flesh-red, honey-yellow, ochre-yellow, blue; impure varieties often black, brown, red or reddish-brown. Streak white. Transparent in various degrees down to perfect opacity. The transparent varieties are called *Selenite*; the fine massive varieties, *Alabaster*; the fibrous, *Satin spar*. *Schaumkalk* is a variety in small scales having a pearly lustre.

Gypsum contains 46.61 per cent. SO^3 , 32.56 CaO, and 20.93 water; or 54.56 SO^4 , 24.51 Ca, and 20.93 water. In the gypsum of the volcano of Albay, island of Luzon, De la Trobe found 8.43 per cent. silica.

Before the blowpipe gypsum becomes white, exfoliates, and falls to powder. At a very high temperature it melts with difficulty to a white enamel. The white powder obtained by heat hardens to a compact solid when moistened. Gypsum dissolves in 400—500 pts. water.

Gypsum often forms extensive beds in secondary countries, and is also found in tertiary and recent deposits, occasionally in crystalline rocks. It is also a product of volcanoes, occurring about fumaroles or where sulphur-gases are escaping, being formed from the sulphuric acid generated therefrom, and the lime afforded by the decomposing

lavas, lime being contained in augite and labradorite. Gypsum is also produced by the decomposition of pyrites when lime is present, and often about sulphur-springs where sulphydric acid is emitted, this gas changing, through reaction with vegetable matter, into sulphuric acid. Gypsum is also deposited on the evaporation of sea-water and brines.

Fine specimens of selenite are found in the salt-mines of Bex in Switzerland, at Hall in the Tyrol, in the sulphur mines of Sicily, in the gypsum-formation near Oçana in Spain, in the clay of Shotover Hill near Oxford; large lenticular crystals are found at Montmartre near Paris. Alabaster occurs at Castelino, 35 miles from Leghorn. Fibrous gypsum occurs in Cheshire and Derbyshire, in the red-sandstone near Moffat, in the Forth river, near Belfast, &c. Scaly foliated gypsum (*Schaumkalk*) occurs with selenite at Montmartre. Gypsum occurs in extensive beds in several states of North America, particularly in New York, Ohio, Illinois, Tennessee, and Arkansas, and is usually associated with salt-springs. Gypsum occurs altered to calcspar.

Plaster of Paris, or gypsum, heated and ground up, is used for making moulds, taking casts of statues, medals, &c., and for producing a hard finish on walls; also in the manufacture of artificial marble, as the scagliola tables of Leghorn, and in the glazing of porcelain. Alabaster is used for making statues and vases. Fibrous gypsum, when cut *en cabochon* and polished, forms an artificial gem resembling cat's-eye. (Dana, ii. 379.)

GYROLITE or **GUROLITE**. A mineral closely related to apophyllite. It occurs in spherical concretions having a lamellar radiate structure, white and pearly. Hardness = 3 to 4. Before the blowpipe and with acids it behaves like apophyllite. Analysis gave 50.70 per cent. SiO_2 , 1.48 Al_2O_3 , 33.24 CaO , 0.18 MgO and 14.18 water, agreeing approximately with the formula $3(2\text{CaO} \cdot 3\text{SiO}_2) \cdot 8\text{H}_2\text{O}$, or $3(\text{Ca}_2\text{SiO}_4 \cdot 2\text{SiO}_2) \cdot 8\text{H}_2\text{O}$. (Anderson, Phil. Mag. [4] i. 101.)

GYROPHORIC ACID. (Stenhouse, Phil. Trans. 1849, p. 393; Jahresh. f. Chem. 1849, p. 458.)—An acid obtained from two lichens, *Gyrophora pustulata* and *Lecanora tartarea*, which are collected abundantly in Norway for the manufacture of archil. To prepare the acid, the lichen is macerated with milk of lime; the strained liquid is treated with hydrochloric acid; and the resulting red-brown gelatinous precipitate, after washing and drying, is heated nearly to boiling with weak alcohol, to remove a green resin, then with animal charcoal and strong alcohol, which leaves undissolved a brown humus-like substance. The filtered solution deposits gyrophoric acid in crystals, which may be purified by repeated crystallisation from alcohol, with help of animal charcoal.

Gyrophoric acid forms small, soft, colourless crystals having neither taste nor smell. It is nearly insoluble in water, even at the boiling heat, very slightly soluble in ether and in cold alcohol, more soluble in boiling alcohol. It is a very weak acid; its solutions do not redden litmus, and the addition of the smallest quantity of potash or ammonia gives them an alkaline reaction. It is nearly insoluble in ammonia, dissolves in excess of potash or baryta-water, and is precipitated unaltered by acids.

By boiling with excess of potash or baryta-water, it is resolved into carbonic acid and orcin; but when boiled with a very small quantity of an alkali, it is converted into an acid of intermediate composition, soluble in water, having a distinct acid reaction, and differing from gyrophoric acid in crystalline form. Gyrophoric acid is reddened by chloride of lime. When exposed to the air in contact with excess of ammonia, it is slowly converted into a purple substance. Boiled for some time with strong alcohol, it yields (besides orcin and a resin) a product having the characters and composition of orsellate of ethyl, $\text{C}^{10}\text{H}^{12}\text{O}^4$ (q. v.).—With wood-spirit, it yields the corresponding methyl-ether.

Stenhouse assigns to gyrophoric acid the formula $\text{C}^{30}\text{H}^{18}\text{O}^{15}$. Gerhardt (*Traité*, iii. 818) regarded it as identical, either with lecanoric acid, $\text{C}^{16}\text{H}^{14}\text{O}^7$, or with evernic acid, $\text{C}^{17}\text{H}^{16}\text{O}^7$, to the latter of which it certainly approximates closely (analyses 60.81, 61.16, and 61.12 per cent. carbon, 4.90, 5.20 and 5.0 hydrogen; calculation for $\text{C}^{17}\text{H}^{16}\text{O}^7$, 61.44 C, 4.82 H, and 33.74 O).

GYROTROPE. A name applied to various contrivances for reversing the direction of an electric current, converting a continuous into an interrupted current, separating the two currents of an induction-coil, &c.

GYTGE. A peculiar mud, mixed with organic matter, found at the end of the Sandeford in Norway. After drying at 100°C . it contains 16.29 per cent. matter soluble in water and hydrochloric acid, 9.92 water and organic matter, and 73.80 sand and decomposed clay. (A. and H. Strecker, Ann. Ch. Pharm. xcv. 177.)

ADDENDA.

CONINE. The following new observations on this alkaloïd have been made by Th. Wertheim (Ann. Ch. Pharm. cxxiii. 167; Rép. Chim. pure, 1863, p. 45):

The conine was prepared from fresh hemlock seeds (p. 2), and rectified several times in a current of hydrogen. It was perfectly limpid and colourless, or very slightly coloured. It remained unaltered for months, and could even be distilled in an oil-bath in contact with the air. It boiled at 163.5° C. under a barometric pressure of 739 mm. Conine does not dissolve a trace of chloride of calcium, which may therefore be used to dry it.

Azoconhydrine. $C^8H^{16}N^2O^4$.—Nitrous anhydride passed into pure conine is absorbed in large quantity, and after the excess has been expelled by a current of carbonic anhydride at 30° or 40° C., a molecule of conine, $C^8H^{16}N$, is found to have absorbed exactly one molecule of nitrous anhydride. Water extracts nitric acid from the product; and if the remainder be washed several times with water, then with dilute carbonate of sodium, dilute hydrochloric acid, and again with water, it leaves a yellow oil, rather lighter than water, having an aromatic odour and burning taste, and without action on vegetable colours.

This substance is azoconhydrine. Its composition is most simply expressed by the formula $C^8H^{16}N^2O$, which is that of conine + H + N + O. The nitrous anhydride probably unites in the first instance directly with the conine, forming the compound $C^8H^{16}N.N^2O^2$, which is subsequently decomposed by the water, yielding nitric acid and azoconhydrine:

Ordinary commercial conine treated as above does not yield azoconhydrine, a violent decomposition taking place after a certain amount of nitrous gas has been absorbed. This effect perhaps arises from the presence of methyl-conine (p. 6).

The formula of azoconhydrine, $C^8H^{16}N^2O$, may be derived from that of conhydrine, $C^8H^{17}NO$, by the substitution of 1 at. N for 1 at. H; but its vapour-density, 22.25 (obs.), show that this formula must be quadrupled, making it $C^{32}H^{64}N^2O^4$, which for a condensation to 2 volumes, gives as the calculated density, the number 21.62.

Azoconhydrine is as poisonous as conine, but appears to act more slowly. It is insoluble in water, soluble in alcohol and ether, and dissolves without alteration in strong hydrochloric and sulphuric acids, whence it is precipitated unchanged by water. Ammonia and the fixed alkalis neither dissolve nor decompose it, even with the aid of heat. When heated above 200° C. it decomposes, giving off strongly alkaline vapours, which have the odour of conine.

Dry hydrochloric acid gas converts azoconhydrine into hydrochlorate of conine, eliminating at the same time a gas which contains 1 vol. nitrogen to 2 vols. nitric oxide:

The same gas passed into a solution of azoconhydrine in anhydrous ether, forms a magma of white shining crystals, apparently consisting of hydrochlorate of ethyl-conine, resulting from the intervention of the ether.

Conylene. C^8H^{14} .—This compound is produced by the action of phosphoric anhydride on azoconhydrine. When the latter substance is heated to 80° or 90° C., with excess of phosphoric anhydride, pounded glass being added to moderate the action, nitrogen gas is rapidly evolved, and conylene distils over in the form of a yellowish oil:

Conylene is a yellowish oil, having a pungent disagreeable odour, of specific gravity

0·7007 at 18° C., insoluble in water, soluble in alcohol and ether, boiling at 120° under a pressure of 738 mm. Vapour-density, obs. = 3·80; calc. (2 vols.) = 3·56.

Bromine unites energetically with conylene, forming a product containing more than 2 at. bromine. Dibromide of conylene, $C^6H^{14}Br_2$, is obtained by gradually adding alcoholic bromine to a well-cooled alcoholic solution of conylene till the mixture retains a faint yellow colour after agitation, precipitating with water, washing with dilute potash and then with water, dissolving in ether, drying the mixture with chloride of calcium, and expelling the ether by evaporation in vacuo. It is a liquid of specific gravity 1·5679 at 16·25° C., having a disagreeable odour, somewhat like that of mustard, insoluble in water, soluble in alcohol and ether. Treated with pulverised hydrate of potassium it yields a liquid which, after two rectifications in a current of hydrogen, is perfectly colourless, lighter than water, and has very nearly the composition of oxide of conylene, $C^6H^{14}O$.

Conhydrine, $C^6H^{11}NO$, is perhaps a compound of oxide of conylene with ammonia; and conine, $\left\{ \begin{smallmatrix} C^6H^{11} \\ H \end{smallmatrix} \right\} N$, might perhaps be produced by the action of ammonia on bromide of conylene.

CROTONYLENE. C^4H^6 . (E. Caventon, Ann. Ch. Pharm. cxxvii. 347).—A hydrocarbon, homologous with allylene, C^3H^4 , related to crotonic acid, $C^4H^6O_2$, in the same manner as ethylidene, C^2H^4 , to acetic acid, and to tetrylene, C^4H_8 , in the same manner as acetylene to ethylene. It is produced by the action of ethylate of sodium on bromotetrylene, the reaction being precisely analogous to that by which Sawitsch obtained allylene from bromotritrylene, (i. 1112):

Crotonylene is liquid below 15° C., but volatilises very quickly if not surrounded by ice. It has a very strong, slightly alliaceous odour, boils at about 18° C., and distils between 18° and 24°. Vapour-density, obs. = 1·936; calc. (2 vols.) = 1·868.

It unites very energetically with *bromine*. When bromine is dropt into crotonylene cooled by a freezing mixture, dibromide of crotonylene, $C^4H^6Br_2$, is obtained, as a liquid heavier than water, distilling between 148° and 158° C. with evolution of hydrobromic acid, and leaving a residue of charcoal.—This liquid left for some days in contact with excess of bromine is converted into the tetrabromide, $C^4H^6Br_4$, a crystalline compound isomeric with dibromide of dibromotetrylene, $C^4H^6Br_2 \cdot Br_2$, which it also much resembles; but the latter distils undecomposed between 148° and 158° C., at which temperature, as already observed, the bromide of crotonylene is partly decomposed; moreover dibromide of dibromotetrylene does not volatilise at ordinary temperatures, even when kept for months in an open dish; and the same is the case with the isomeric compound obtained by passing the vapours resulting from the decomposition of amylac alcohol-vapour at a red heat, into bromine; but dibromide of crotonylene volatilises completely under these circumstances in 10 or 12 days.

DILITURIC ACID. $C^4H^6N^2O^5$.—This acid, discovered by Schlieper (p. 330), has lately been more fully investigated by Baeyer (Ann. Ch. Pharm. cxxvii. 211), who obtains it by the action of nitric acid on hydurilic acid. Hydurilic acid dissolves in nitric acid of ordinary strength, with copious evolution of nitrous vapours, forming a yellow solution. As soon as the evolution of gas has ceased, and a sample of the liquid forms with ammonia, no longer a reddish but a white precipitate, the liquid is left to itself, and on cooling, solidifies to a mass of crystalline laminae, which when pressed and recrystallised from a small quantity of hot water, yield pure dilituric acid. The mother-liquor retains alloxan, together with a small quantity of dilituric acid, which may be obtained by precipitation with ammonia or ferrous sulphate. The reaction takes place in two stages, violuric acid being formed in the first instance, and afterwards converted into dilituric acid:

Schlieper obtained dilituric acid by boiling alloxantin with hydrochloric acid and treating the resulting crystals with nitric acid (p. 331). It was probably formed in this case by the action of the nitric acid on hydurate of ammonium resulting from the action of the hydrochloric acid on dialuric acid (p. 316), contained in the alloxantin. (See HYDURILIC ACID.)

Dilituric acid crystallises in colourless quadratic prisms and laminae, containing 6 at. water ($C^4H^6N^2O^5 \cdot 6H^2O$). The crystals effloresce when exposed to the air, and dissolve easily in hot, more slowly in cold water, forming a deep yellow solution. It is less soluble in alcohol, insoluble in ether. When heated it decomposes, with evolution of nitrous vapours, and leaves a brown red mass.

Diluturic acid is easily recognised by the deep yellow colour with which it dissolves in water, and more especially in dilute potash: also by forming a white precipitate with ammonium-salts, a white precipitate composed of needle-shaped crystals with ferrous sulphate, and a lemon-yellow precipitate with acetate of silver.

Diluturic acid exhibits the characters of a nitro-compound: when heated with hypochlorite of calcium, it yields considerable quantities of chloropicrin (i. 923); some of its salts explode violently when heated; and its amount of nitrogen cannot be determined by ignition with soda-lime.—When bromine is added to diluturic acid suspended in cold water, a very loosely combined compound is formed, which may be separated from the aqueous solution by ether, and is so unstable, that a few drops of benzene separate the whole of the diluturic acid from the ethereal solution in its original state, bromobenzene being probably formed at the same time. But when diluturic acid is heated to 100° C. with bromine and a small quantity of water in a sealed tube, it is resolved into nitric acid and bromalloxan, the compound NO²Br being probably formed in the first instance, and afterwards converted into nitric acid:

Diluturic acid.

Bromalloxan.

Hydriodic acid reduces diluturic acid to uramil:

This reaction and the preceding are analogous to those exhibited under similar circumstances by violuric acid (q. v.). In fact, these two acids differ only by 1 at. oxygen, and the formation of diluturic acid from violuric acid (p. 966) is simply the conversion of a nitroso-compound into a nitro-compound:

Violuric acid.

Diluturic acid.

Diluturic and violuric acids mixed in hot concentrated solution unite and form violantin, C⁸H⁴N⁴O⁸, a very unstable compound, which is partly resolved into its component acids when recrystallised from water.

Diluturates.—Diluturic acid is tribasic, but it is especially inclined to form salts containing only one atom of metal. Of these acid salts the sodium-salt is the most soluble, the others being sparingly soluble or insoluble. The diluturates have a white or yellow colour, and are remarkably stable, the acid not being separated from them by mineral acids.

Diluturate of Ammonium, C⁴H²(NH⁴)N²O⁸, is formed as a white crystalline precipitate on mixing diluturic acid with ammonia or an ammonium-salt; from very dilute solutions it separates in concentrically grouped prisms. It is very slightly soluble in cold, somewhat more in hot water, and crystallises therefrom in small crystals and shining laminae. It is not altered by ammonia or by nitric acid; in strong sulphuric acid it dissolves without decomposition, and is precipitated therefrom by water. Dilute potash dissolves it, with evolution of ammonia, forming a deep yellow liquid containing dipotassic dialurate; strong potash-solution colours it yellow without dissolving it. When heated it burns away with deflagration.

Diluturate of Barium separates on mixing diluturic acid with acetate of barium, in slender needles, which are decomposed by soluble sulphates, but not by free sulphuric acid. Chloride of barium converts this salt into a double salt, C⁴H²Ba²N²O¹⁰.Ba²Cl².4H²O, which may also be obtained in beautiful heavy crystals resembling twin-crystals of gypsum, on mixing a hot solution of diluturic acid with chloride of barium. The crystals give off their water at 140° C.

Diluturate of Calcium, C⁴H²Ca²N²O¹⁰, obtained by precipitating acetate of calcium with diluturic acid, forms slender white needles containing 4 at. water, half of which they give off at 140° C.

Diluturate of Copper, C⁴H²Cu²N²O¹⁰.12H²O, is obtained by mixing diluturic acid with a soluble copper-salt, as a white precipitate composed of slender needles with greenish iridescence. It gives off its water at 100° C. and explodes at a higher temperature.

Diluturates of Iron. The ferric salt, C⁴H²Fe²N²O¹⁴, or C⁴H²/₂N²O⁸, is precipitated on adding diluturic acid to a solution of ferric chloride, in small, light yellow needles, nearly insoluble in cold, sparingly soluble in hot water. Between 110° and 120° C. it gives off its water and assumes a brick-red colour, and at a stronger heat it explodes.

The ferrous salt, C⁸H⁴Fe²N²O¹⁰.16H²O, is formed on mixing diluturic acid with ferrous sulphate, as a white precipitate consisting of slender needles, and having a faint streak of green. It is very sparingly soluble in water, and is not decomposed by dilute sulphuric acid. At 120° C. it gives off 6 at. water, becoming dark brown, and at a higher temperature it deflagrates. It also gradually loses its water when left over sulphuric acid, but quickly recovers it on exposure to moist air.

Diluturate of Lead is a yellowish white precipitate.

Diluturates of Potassium.—The monopotassic salt, C⁴H²KN²O⁸, is obtained as a

white crystalline precipitate on adding hydrochloric acid to a solution of dilituric acid in potash. It is also formed on mixing dilituric acid with the solution of any potassium-salt, separating especially from dilute solutions in large cubes, which however do not appear to belong to the regular system. It is nearly insoluble in cold water, sparingly soluble in hot water, and contains no water of crystallisation.

The *dipotassic salt*, $C^4HK^2N^2O^5$, which was examined by Schlieper, separates in spherical groups of beautiful yellow needles on adding alcohol to the hot lemon-yellow solution of dilituric acid or of the ammonium-salt in potash-ley. It is insoluble in alcohol and in strong potash-ley; water decomposes it partially, abstracting potash and converting it into the monopotassic-salt. When heated to a certain temperature, it decomposes, as observed by Schlieper, with slight detonation, and is resolved into cyanate of potassium, carbonic anhydride, and probably cyanic acid:

It likewise explodes when moistened with strong sulphuric acid. The solution of this salt precipitates ferrous and cupric sulphates, but the precipitates consist, not of dimetallic salts, but of mixtures of the acid potassium-salt with an acid diliturate of iron or copper.

Diliturates of Silver.—The *monoargentic salt*, $C^4H^2AgN^2O^5.2H^2O$, is obtained by adding dilituric acid to nitrate of silver, and separates from somewhat dilute solutions in well-developed prisms.—When dilituric acid is added to a warm solution of acetate of silver, a yellow precipitate of triargentic salt is first formed: but this dissolves in excess of dilituric acid, and as the solution cools, the acid salt crystallises in colourless needles. It is sparingly soluble in cold, moderately soluble in hot water. When heated it turns yellow and decomposes with explosion.

The *triargentic salt*, $C^4Ag^2N^2O^5$, is produced on mixing dilituric acid with excess of a hot solution of acetate of silver, as a lemon-yellow precipitate composed of needles, anhydrous and sparingly soluble in water. It explodes somewhat violently when heated, but not by percussion.

Diliturate of Sodium, $C^4H^2NaN^2O^5$, is most easily prepared by mixing the hot concentrated solutions of dilituric acid and acetate of sodium, and crystallises on cooling in long, colourless, silky needles, forming an interlaced mass when dry. It may also be obtained by decomposing the barium-salt with sulphate of sodium. It dissolves easily in water, and effloresces when left over oil of vitriol. It appears to contain 4 at. water of crystallisation.

ERYTHROMANNITE (p. 504).—The following method of preparing this substance is given by V. de Luynes (Compt. rend. lvi. 803). Erythric acid (p. 502) washed and drained is mixed with a quantity of milk of lime somewhat less than sufficient to decompose it completely, and heated for about two hours to $150^{\circ}C$. in a closed iron vessel; the exclusion of the air during the reaction prevents the formation of a large quantity of resinous matter. The liquid, filtered to separate carbonate of calcium, and evaporated at a gentle heat, deposits orein in fine crystals; and the mother-liquors yield by further evaporation a crystalline mass of orein and erythromannite, from which the former may be dissolved out by ether.

Erythromannite exhibits in a high degree the phenomenon of *surfusion*, that is to say, it remains liquid when cooled a considerable number of degrees below its melting point. Heated with potash to $240^{\circ}C$. it is resolved into oxalic acid and hydrogen:

The aqueous solution of erythromannite in contact with platinum-black, absorbs oxygen so rapidly that the mass becomes incandescent; with a dilute solution, the action is less violent and yields an acid.

The iodide of tetryl formed by the action of hydriodic acid on erythromannite (p. 595) acts strongly on acetate of silver, yielding tetrylene and acetate of tetryl. The latter when decomposed by potash yields tetrylic alcohol, identical with that obtained from tetrylene, not with that produced by fermentation (De Luynes). (See TETRILIC ALCOHOL.)

ETHYL IODIDE OF (p. 533).—Messrs. Rieth and Beilstein (Ann. Ch. Pharm. cxxvi. 250) prepare this compound by introducing into a flask 10 pts. of amorphous phosphorus, 50 pts. alcohol of 90 per cent., and 100 pts. iodine, leaving the mixture to itself for 24 hours, and then distilling. The distillate thus obtained is but slightly contaminated with free iodine, and yields very nearly the theoretical quantity of iodide of ethyl.

ETHYL, PROTOSULPHIDE OF (p. 545).—This compound, heated with fuming nitric acid, dissolves, with evolution of red vapours, but without forming a trace of sulphuric acid; and the solution evaporated nearly to a syrup, solidifies on cooling

to a crystalline mass, consisting of diethylsulphone $C^2H^4SO^2$ (analogous to sulphobenzide $C^{12}H^{10}SO^2$). This compound crystallises easily from water or alcohol, in thin, colourless, tabular crystals several inches long; melts at $70^\circ C.$; boils at 248° ; offers great resistance to the action of oxidising substances. It may be distilled unaltered from fuming nitric acid. Nascent hydrogen reduces it to protosulphide of ethyl.

With nitric acid of specific gravity 1.2, a different action takes place, the sulphide dissolving easily at ordinary temperatures, without much evolution of gas, and losing its penetrating odour. The product formed appears to be analogous in composition to nitrate of tellurethyl. The solution gently heated with *ferricyanide of potassium* and free alkali, yields on cooling crystals which appear to consist of diethylsulphone.—The same solution reduces *chromate of potassium*, the liquid on cooling depositing rhombic tables, the composition of which has not yet been determined.—*Ferric chloride* added to the nitric acid solution produces an abundant separation of oily drops which solidify in the crystalline form on cooling, and probably consist of dichloride of sulphethyl ($C^2H^4SCl^2$), analogous to dichloride of selenethyl. (A. v. Oefele, Ann. Ch. Pharm. cxxvii. 370.)

ETHYLENE, IODOCHLORIDE OF. C^2H^4ClI .—This compound, described at p. 579, as obtained by the action of chloride of iodine on iodide of ethylene, is likewise produced by the action of chloride of iodine on ethylene-gas, namely by passing this gas through an aqueous solution of chloride of iodine, washing the red oil which falls to the bottom with caustic potash, and distilling. That which passes over above $145^\circ C.$ is iodochloride of ethylene.

This compound has a density of 2.151. Heated with alcoholic potash, it yields iodide of potassium, and gives off a gas burning with a green-edged flame, probably chlorethylene, C^2H^3Cl .

Tritylene obtained from glycerin yields in like manner iodochloride of tritylene. (Maxwell Simpson, Proc. Roy. Soc. xii. 278; Rép. Chim. pure, 1863, p. 500.)

EUGETIC ACID. $C^{11}H^{12}O^4$. (Scheuch, Ann. Ch. Pharm. cxxv. 14.)—An acid obtained by the action of carbonic anhydride on eugenate of sodium:

Sodium is dissolved in eugenic acid contained in a retort through which a current of carbonic anhydride is passing, the action being assisted towards the end by a gentle heat. The cooled mass dissolved in warm water and heated with hydrochloric acid, yields an oil which is a mixture of eugenic and eugetic acids. It is agitated several times with solution of carbonate of ammonium, and evaporated with addition of carbonate of ammonium; hydrochloric acid is then added, the liquid shaken up with ether, the ethereal solution evaporated, and the crystalline residue recrystallised from boiling water. The product is not very abundant.

Eugetic acid crystallises from its hot aqueous solution in long colourless prisms. It melts at $124^\circ C.$, is sparingly soluble in cold water, very soluble in alcohol and ether. Its solutions have an acid reaction. The aqueous solution is coloured blue by ferric chloride. The acid is resolved by heat into eugenic acid and carbonic anhydride.

Erica vulgaris (s. Calluna, i. 722).	—	Etherin and Etherol	508
Ericaceæ	—	Etherinamone	—
Ericinol	500	Etheriplatonic acid	—
Ericinone	—	Etherol (s. Etherin).	—
Ericolin	—	Etherone	—
Erinite	501	Ethers	—
Eriophorum vaginatum	—	Ethers containing Monatomic Alcohol-radicles:	—
Eritannic acid	—	1. Oxides	510
Erlanite	—	2. Sulphides, Selenides, Tellurides	511
Ersbyite	—		

	PAGE		PAGE
Ethers—containing Monatomic Alcohol-radicles:		Ethyl, Oxide of—Ethyates:	
8. Oxygen-salts:		Ethylate of Octyl	542
a. Containing Monatomic Acid-radicles	512	Ethylate of Potassium	—
b. Containing Diatomic Acid-radicles	514	Ethylate of Sodium	543
c. Containing Triatomic Acid-radicles	516	Ethylate of Tetryl	—
4. Haloid Salts of Monatomic Alcohol-radicles	—	Ethyl, Phosphides of (s. Phosphorus-bases).	—
Ethers containing Diatomic Alcohol-radicles; <i>Glycol-ethers</i> :		Ethyl, Plumbides of (s. Plumbethyls).	—
1. Oxides	517	Ethyl, Selenhydrate of	—
2. Oxygen-salts	518	Ethyl, Selenide of	544
3. Haloid-salts	519	Ethyl, Stannides of (s. Stannethyls).	—
Ethers containing Triatomic Alcohol-radicles	—	Ethyl, Sulphides of:—	
Ethers containing Tetraatomic Alcohol-radicles	521	Protosulphide	545 and 967
Ethers containing Hexatomic Alcohol-radicles	—	Compounds of Ethylic Sulphide with Metallic Chlorides: <i>Mercury and platinum-compounds</i>	—
Polyethylenic, Polyglyceric ethers, &c.	522	Chlorinated Derivatives of Ethylic Sulphide:	
Ethers, Acetic	523	Di- and Tri-chlorethyllic Sulphides	—
Ethers, Bromhydric or Hydrobromic	—	Tetra- and Per-chlorethyllic Sulphides	546
Ethide, Boric (see Ethyl, Boride of, p. 526).	—	Disulphide of Ethyl	—
Ethionic acid	—	Tri- and Penta-sulphides	547
Ethionic Anhydride	—	Ethyl, Sulphydrate of	—
Ethyl	524	Sulphethylates, or Mercaptides	548
Ethyl-amyl	525	Zeise's Indifferent Sulphuretted Oil	549
Ethyl-tetryl	—	Ethyl, Telluride of, or Tellurethyl	550
Ethyl, Antimonides of (s. Antimony-radicles, Organic, i. 339).	—	Salts of Tellurethyl	—
Ethyl, Arsenides of (s. Arsenic-radicles, Organic, i. 397).	—	Ethylacetamide	552
Ethyl, Boride of: <i>Borethyl</i>	—	Ethyl-diacetamide	—
Ammonio-borethyl	526	Ethylamines and Ethylammoniums	—
Oxide of Borethyl	527	Ethylamine	553
Dioxethylo-borethyl and Dioxhydro-borethyl	—	Salts of Ethylamine	556
Ethyl, Bromide of	528	Substitution-products of Ethylamine:	
Ethyl, Chloride of	—	Dichlorethylamine	558
Chlorinated Derivatives of Chloride of Ethyl	530	Dibromethylamine	—
Monochlorinated Chloride of Ethyl	531	Di-iodethylamine	—
Di-, Tri-, Tetra-, and Per-chlorinated Chloride of Ethyl	532	Diethylamine	—
Heavy Hydrochloric ether	—	Triethylamine	559
Ethyl, Chloroplatinate of	—	Triethyl-carbotriamine, or Triethylcyanodiamine	560
Ethyl, Chlorosulphate of	—	Diethyl-anylamine	—
Ethyl, Cyanide of	—	Tetrethylammonium	561
Ethyl, Fluoride of	533	Triethylamylammonium	563
Ethyl, Hydrate of (s. Alcohol, i. 72).	—	Triethyl-oxethyl-acetyl-ammonium	—
Ethyl, Hydride of	—	Ethylammonium (s. Ethylamines).	—
Ethyl, Iodide of	533 and 967	Ethylamyl (s. Ethyl, p. 526).	—
Ethyl, Nitrides of (s. Ethylamines).	—	Ethylamylcitric acid	564
Ethyl, Oxide of: <i>Ethylic ether</i>	536	Ethylamyllic ether (i. 205).	—
Chlorinated and Sulphuretted Derivatives of Ethylic ether:		Ethylaniline (s. Phenylamines).	—
Monochlorethyllic ether	540	Ethyl-bases (s. Ethylamines, Ethylarsines, -phosphines, &c.	—
Dichlorethyllic ether	—	Ethyl-benzylamine (s. Benzethylamine, i. 576).	—
Sulphethyllic ether	541	Ethyl-bromaniline (s. Phenylamine, Derivatives of).	—
Chlorosulphethyllic ether	—	Ethyl-butylic ether (s. Ethyl, Oxide of p. 543).	—
Perchlorethyllic ether	—	Ethyl-cacodyl (s. Arsendiethyl, i. 397).	—
Perchlorobromethyllic ether	—	Ethyl-carbamic acid (s. Carbamic acid, i. 751).	—
Double Ethers containing Ethyl:		Ethyl-carbamides	—
<i>Ethylates</i> :—		Ethyl-chloraniline (s. Phenylamine, Derivatives of).	—
Ethylate of Amyl (i. 205).	—	Ethyl-codeine (s. Codeine i. 1068).	—
Ethylate of Cetyl (i. 842).	—	Ethyl-conine (s. Conine, ii. 5).	—
Ethylate of Benzylene (i. 578).	—	Ethyl-cyanamide (s. Cyanethylamide).	—
Ethylates of Ethylene (ii. 579).	—	Ethyl-cyananiline (s. Phenylamine, Derivatives of).	—
Ethylate of Methyl	542	Ethyl-diacetamide (p. 552).	—

	PAGE		PAGE
Ethyl-dithionc acid (s. Sulphurous ethers).		Ethylene-phenylamines (s. Phenylamine).	
Ethylene		Ethylene-phosphines (s. Phosphorus-bases).	
Ethylene, Acetates of:	565	Ethylene-succinic acid (p. 582).	
Monoacetate	566	Ethylene-sulphuric acid (p. 582).	
Monethylenic Diacetate	567	Ethylene-sulphurous acids (s. Sulphurous ethers).	
Polyethylenic Diacetates	—	Ethylene-tetramines and -triamines (p. 588).	
Ethylene, Acetobutyrate of	568	Ethylene-ureas (s. Ethylene-carbamides (p. 595)).	
Ethylene, Aceto-valerate of	—	Ethylidene	598
Ethylene, Acetoxychloride of	—	Bromide, Chloride, and Oxychloride of Ethylidene	599
Ethylene, Acetoxiodide of	—	Chlorethylate of Ethylidene	600
Ethylene, Benzoate of	—	Ethyl-formamide (s. Formamide).	
Ethylene, Bromide of	569	Ethyl-formyl	—
Brominated Derivatives of Bromide of Ethylene	570	Ethyl-glycocine (s. Glycocine, p. 905).	
Ethylene, Butyrate of	571	Ethyl-glycollic acid (s. Glycollic ethers, p. 916).	
Ethylene, Butyroxychloride of	—	Ethyl-hemipinic acid (s. Hemipinic ethers).	
Ethylene, Chloride of	—	Ethylia (s. Ethylamine).	
Chlorinated Derivatives of Chloride of Ethylene	573	Ethylides or Ethides	—
Ethylene, Chloriodide of	574	Ethyl-lactic acid (s. Lactic ethers).	
Ethylene, Cyanide of	—	Ethyl-malic acid (s. Malic ethers).	
Ethylene, Dibromide, Dichloride, and Di-iodide of (s. Ethylene, Bromide, Chloride, and Iodide of).	—	Ethyl-meconic acid (s. Meconic ethers).	
Ethylene, Ethylates of	—	Ethyl-mellic acid (s. Mellic ethers).	
Ethylene, Hydrates of, or Ethylenic Alcohols	—	Ethyl-mercaptan (s. Ethyl, Sulphydrate of, p. 547).	
Monoethylenic Alcohol: <i>Glycol</i>	—	Ethyl-methylamines (s. Methylamines).	
Ethylenates of Sodium	576	Ethyl-methyl-coninium (s. Conine, p. 109).	
Polyethylenic alcohols	—	Ethyl-methylic ether (s. Ethyl, Oxide of, p. 542).	
Ethylene, Hydroxybromide of	577	Ethyl-morphine (s. Morphine).	
Ethylene, Hydroxychloride of	—	Ethyl-mucic acid (s. Mucic ethers).	
Ethylene, Hydroxyiodide of	578	Ethyl-nicotine (s. Nicotine).	
Ethylene, Iodide of	—	Ethyl-nitraniline (s. Nitraniline, under Phenylamines).	
Ethylene, Iodated	579	Ethyl-nitrophenidine (s. Phenic ethers).	
Ethylene, Iodochloride of	579 and 968	Ethyl-octylic ether (s. Ethyl, Oxide of, p. 542).	
Ethylene, Oxide of	579	Ethyl-oxacetic acid (s. Glycollic ethers, p. 916).	
Dioxethylenes	580	Ethyl-oxalic acid (s. Oxalic ethers).	
Compound of Ethylenic Oxide with Aldehyde	—	Ethyl-oxamic acid (s. Oxamic ethers).	
Ethylene, Oxybromide of	—	Ethyl-oxamide (s. Oxamide).	
Ethylene, Oxysulphide of	—	Ethyl-paratartaric acid (s. Paratartaric acid).	
Dioxysulphide of Ethylene	581	Ethyl-phenylamines (s. Phenylamines).	
Ethylene, Oxysulphydrate of	—	Ethyl-phosphines (s. Phosphorus-bases).	
Diethylenic Oxysulphydrate	—	Ethyl-phosphoric and -phosphorous acids (s. Phosphoric and Phosphorous ethers).	
Ethylene, Stearate of	582	Ethyl-picoline (s. Picoline).	
Ethylene, Succinate of	—	Ethyl-piperidine (s. Piperidine).	
Ethylene, Sulphate (acid) of	582	Ethyl-pteritanic acid (s. Pteritanic acid).	
Ethylene, Sulphides of	—	Ethyl-pyridine (s. Pyridine).	
Ethylene, Sulphites of	583	Ethyl-quinine (s. Quinine).	
Ethylene, Sulphobromide of	—	Ethyl-selenhydric acid (s. Ethyl, Selenhydrate of, p. 543).	
Ethylene, Sulphochlorides of	—	Ethyl-sinamine (s. Sinamine).	
Ethylene, Sulphydrates of	585	Ethyl-stibines (s. Antimony-radicles, Organic, i. 841).	
ethylene-bases	—	Ethyl-strychnine (s. Strychnine).	
Diamines	—	Ethyl-sulphydic acid (s. Ethyl, Sulphydrates of, p. 547).	
Ethylene-diamines containing monoatomic and Diatomic Alcohol-radicles	587	Ethyl-sulphocarbonic and -sulphophosphoric acids (s. Sulphocarbonic and Sulphophosphoric ethers).	
Ethylene-triamines	588		
Ethyolated Ethylene-triamines	590		
Ethylene-tetramines	591		
Ethyolated Tetrammoniums	—		
Monatomic Bases produced by the action of Dibromide of Ethylene on Ammonia and the Monamines	593		
Oxethylenamines or Ethylene-hydoramines	—		
ethylene-carbamides	595		
ethylene-dichloride of Platinum	—		
ethylene-hydoramines (s. Ethylene-bases, p. 594)	—		

	PAGE		PAGE
Ferrocobaltine	638	Fluoride of Ammonium	670
Ferrocyanides } (s. Cyanides of Iron,		Fluoride of Antimony (i. 822).	
Ferroprussiates } p. 222).		Fluoride of Arsenic (i. 817).	
Fibrin	—	Fluoride of Benzoyl	671
Preparation	—	Fluoride of Barium (i. 504).	
Formation from Albumin	639	Fluoride of Boron (i. 632).	
Properties and Composition	—	Fluorides of Cadmium, Calcium, Cerium,	
Decompositions	640	Cobalt, Copper, &c. (see the several	
Sources and Physiological relations	642	metals).	
Fibrin, Vegetable	643	Fluoride of Ethyl (ii. 533).	
Fibroferrite	644	Fluoride of Hydrogen (ii. 669).	
Fibroin	—	Fluoride of Phosphorus (s. Phosphorus	
Fibrolite	645	Fluoride of).	
Fichtelite	—	Fluoride of Silicon (s. Silicon, Fluoride	
Ficaria	—	of).	
Ficarin	—	Fluorides, Metallic	—
Ficinite (s. Vivianite).	—	Fluorides, Organic	672
Ficus	—	Fluorine	—
Feldite	646	Fluorine, Detection and Estimation of:	
Figure-stone (s. Agalmatolite, i. 60).	—	1. Reactions	673
Filicic acid	—	2. Quantitative estimation	—
Filimellic acid	647	Estimation in Solutions	674
Filimelisi-sulphuric acid	—	in insoluble com-	
Filipelosic acid	—	pounds	675
Chlorofilipelosic acid	—	of free Hydrofluoric	
Filix	—	acid in presence of	
Filixolinic and Filosmylic acids	—	Fluorides	—
Filtration	—	3. Separation of Fluorine from other	
Florite	651	Elements	—
Fireblende	—	4. Atomic weight of Fluorine	676
Fire-clay	—	Fluor spar	677
Fire-damp	654	Fluosilicanilide	679
Fire-opal (s. Opal).	—	Fluosilicates } (s. Fluorides, p. 671;	
Fireworks (s. Pyrotechny).	—	Fluotantalates } also Silicon, Tantalum,	
Firewood (s. Wood).	—	Fluotitanates } Titanium).	
Fischerite	—	Flux	—
Fish-oil (s. Oils).	—	Fly-powder	680
Fixed air	—	Fodder	—
Fixity	—	Foliated Tellurium (s. Nagyagite).	
Flake-white	—	Food (s. Nutrition).	—
Flame	—	Formamide	681
Flavin	655	Naphthyl-formamide	—
Flavindin	—	Phenyl-formamide	682
Flavine	656	Formanilide	—
Flax	—	Formenamine	—
Composition of the Ash of the Stem	657	Formene, trinitrated (s. Nitroform).	
and Seed	—	Formic acid	—
Composition of Flax-soils	658	Occurrence	—
Steep-waters	659	Formation	683
Hot-water steeping	660	Preparation	685
Flesh	661	Properties	687
Flesh-juice	665	Decompositions	—
Broth—Liebig's broth for invalids	667	Formates	688
Flexible Sandstone	—	Formic Ethers	693
Flexible Silver ore (s. Sternbergite).	—	Formonmethyhal (s. Methylal).	
Flint	—	Formonaphthalide (s. Naphthylforma-	
Flinty Slate (s. Slate).	—	mide, p. 681).	
Floatstone	668	Formonetin	695
Flos ferri	—	Formula, Rational	—
Flour	—	Formyl	705
Flowers, Colours of	—	Formylia, Formylamine	—
Fluavil	669	Formylene	—
Fluocerine	—	Formyl-diphenyl-diamine (s. Phenyla-	
Fluolite	—	mines).	—
Fluoboric acid (s. Boron, Fluoride of, i.	633).	Forsterite	—
Fluocerine	—	Posresinic acid	—
Fluocerite	—	Fournetite	—
Fluochlore	—	Fowlerite	—
Fluolite	—	Foyait	—
Fluor (s. Fluor spar).	—	Fracture of Minerals	706
Fluorhydric or Hydrofluoric acid	—	Fragaria	—
Fluoride of Aluminium (i. 157).	—	Fraidonite	—
		Francolite	—

	PAGE		PAGE
Frangulin	706	G	
Nitrofrangulic acid	707	Gabbro	756
Frankincense	—	Gabbronite (s. Scapolite).	—
Franklinite	—	Gadolinic acid	—
Fraxetin	—	Gadolinite	757
Fraxin	708	Gaduin	—
Fraxinine	709	Gagates	—
Fraxinite	—	Gahnite	—
Fraxinus	—	Galactin	—
Freibergite	710	Galactin	—
Freislebenite	—	Galactite	758
French Berries	—	Galam-butter	—
French Polish	—	Galanga	—
Fritillaria imperialis	—	Galapetite (s. Halloysite).	—
Fritt	—	Galbanum	—
Fruit	—	Galena	759
Fucus (s. Sea-weed).	—	Gallipot	—
Fucosamide	717	Gallitannic acid	—
Fucosine	—	Gallium	—
Fucusol	718	Gall (s. Bile).	—
Fuel	—	Gallamic acid	—
Composition of Coal	719	Gallerythronic acid	—
Lignite	721	Gallhumic acid	—
Wood	—	Gallic acid	—
Peat, Turf	—	Gallates	761
Relative calorific powers of various	—	Gallicenite (s. Rutile).	—
kinds of Fuel	723	Gall-nuts	762
Thermal effect of Fuel	724	Gallotannic acid	—
Fuller's Earth	730	Gallotannates	767
Fulminates	—	Galls (s. Gall-nuts).	—
Fulminate of Copper	732	Gallstones	769
Fulminate of Hydrogen	—	Gallulmic acid (s. Gallic acid)	—
Fulminate of Mercury	—	Galvanism (s. Electricity).	—
Fulminates of Silver	738	Galvanometer	—
Fulminates of Zinc	737	Galvanoplasty	—
Fulminic acid (p. 732).	—	Galvanoscope	—
Fulminuric acid	738	Gambir (s. Catechu).	—
Fulminurates	739	Gamboge	770
Fulminuric ether	741	Gamsigradite	771
Fumaramide	—	Gangue	—
Fumaric acid	—	Ganomatite	—
Fumarates	743	Garanceux	—
Fumaric anhydride	746	Garancin	—
Fumaric Ether	—	Garbenstilbite (s. Stilbite).	—
Fumarimide	—	Garcinia	—
Fumarine	747	Gardenia	—
Fumaryl, Chloride of	—	Garnet	—
Fumigation	—	Gas	773
Fuming Liquor of Boyle	—	Gas Burners and Furnaces	783
Cadet	—	Bunsen's Burner	—
Libavius	—	Griffin's Gas-furnaces for Evapora- tion, and for Fusion of Silicates, &c.	—
Fungic acid	—	Griffin's Blast Gas-furnace	785
Funkite	—	Gore's Gas-furnace	789
Furfuramide	—	Gases, Absorption of:	—
Furfurine	—	I. By Liquids	790
Furfurine-salts	748	II. By Solids	804
Ethyl-furfurine	750	Gases, Collection and Preservation of	805
Amyl-furfurine	—	Collection in exhausted vessels	—
Furfural	—	Collection by displacement of air	806
Thiofurfol	752	Collection in liquids:	—
Seleniofurfol	753	Water and mercury troughs	—
Fuscite (s. Scapolite).	—	Cooper's mercurial receiver	—
Fusel oil	—	Gas-holders and Gasometers	807
Defuselation of Alcohol	754	Bunsen's Mercurial Gasometer	808
Fusible metal	805	Preservation of Gases in sealed tubes	—
Fusion (s. Heat).	—	Gases, Combination of, by Volume	809
Fustic	—	Gases, Diffusion of	812
Fustin	—	Separation of Gases by Diffusion: <i>Atmo- spheric</i>	815
Fusyl	—	Theory of Diffusion	817
Disulphide of Fusyl	—

Gases, Effusion of	818	Glucium	846
Gases, Liquefaction and Solidification of (s. Heat).	—	Glaucodote	846
Gases, Osmose of	—	Glaucolite (s. Scapolite).	—
Gases, Relations of, to Pressure and Temperature	819	Glaucomelanic acid	—
Gases, Specific Gravity of (s. Specific Gravity).	—	Glaconite	—
Gases, Specific Heat of (s. Heat).	—	Glaucophane (s. Wichtyn).	—
Gases, Transpiration of	820	Glaucopierine	—
Gasterase	821	Glaucosiderite (s. Vivianite).	—
Gastric Juice	—	Glechoma	—
Gaultheria	825	Gliadin, s. Gluten	—
Gaultheric acid (s. Methyl-salicylic acid).	—	Glinkite	847
Gaultherilene	826	Globularia	—
Gay-Lussite	—	Globulin	—
Gedrite	—	Glockerite	—
Gehlenite	—	Glonoin (s. Nitroglycerin).	—
Geic acid (s. Ulmic acid).	—	Glossecolite	—
Gelatin	—	Glottalite	848
Gelatin, Vegetable (s. Gluten).	—	Glucic acid	—
Gelidium	—	Glucinum	849
Gelose	—	Compounds of Glucinum	—
Gems	829	Glucinum, Alloys of	851
Gentian	—	Glucinum, Bromide of	—
Gentianic acid	830	Glucinum, Chloride of	—
Gentianin	—	Glucinum, Detection and Estimation of:	—
Geoceraïn	—	1. Reactions	—
Geoceric acid	—	2. Quantitative Estimation and Separation	—
Geocerinone	831	3. Atomic Weight	—
Geocronite	—	Glucinum, Fluoride of	852
Geode	—	Glucinum, Iodide of	—
Geology, Chemistry of	—	Glucinum, Oxide of: <i>Glucina</i>	—
Geomyricin } (s. Geoceric acid).	—	Glucinum, Oxygen-salts of	853
Georetic acid }	—	Glucinum, Phosphide of	—
Germination of Plants	836	Glucinum, Selenide of	854
Gersdorffite (s. Nickel-glance).	838	Glucinum, Sulphide of	—
Gerserite (s. Opal).	—	Glucosan	—
Gibbsite	—	Acetyl-glucosan	—
Giesseckite	—	Benzo-glucosan	—
Gigantolite	—	Butyro-glucosan	—
Gilbertite	—	Ethyl-glucosan	855
Gilding (s. Gold).	—	Glucose	—
Gillingite (s. Hisingerite).	—	Dextroglucose	—
Gin	—	Occurrence	—
Ginger	—	Formation	—
Ginseng	—	Preparation	857
Giobertite (s. Magnesite).	—	Properties	858
Girasol	—	Decompositions	859
Giamondin (s. Abrasite).	—	Combinations:	—
Githagin (s. Saponin).	—	With Water	862
Glaadin (s. Gluten).	—	With Metallic oxides	—
Glairin (s. Baregin, 1.500).	—	With Bromide and Chloride of Sodium	863
Glance	—	Lævoglucose and Inverted Sugar	—
Glaserite	—	Lævulosan	864
Glass	—	Glucose, Detection and Estimation of	—
Composition of various kinds of glass:	—	Glucose Ferment	865
Bottle and Window-glass	840	Glucosides	—
Plate glass. Bohemian glass	841	Glucosacitic acid	872
Crystal glass. Flint glass	—	Glucososuccinic acid	—
Mentz Flux or Pierre de Strass	—	Glucososulphuric acid	—
Aventurin glass. Ruby-glass	842	Glucosotartaric acid	—
Enamel	843	Glue	873
Decomposition of glass	—	Gluten	—
Devitrified glass. Reaumur's Porcelain	844	Glyceramine	875
Glaubapatite	845	Diglyceryl-dihydrobromamine	—
Glauber salt (s. Sulphates).	—	Diglyceryl-dihydrochloramine	876
Glauberite	—	Glyceric acid	—
Glaucone	—	Glycerates	—
Glaucoic acid	—	Glycerides	877
Glaucone	—	Constitution	—
	—	Occurrence and Formation	879

Glycerides:		Glycocyamidine	906
Glycerides containing Monatomic		Glycocyamine	—
Alcohol-radicles	882	Glycogen	—
Ethylin	883	Glychoychohic acid (s. Hyo-glycocholic acid)	—
Ethyl-chlorhydrin	—	Glycol, Amylenic (s. Amylene, Hydrates of, i. 208).—Glycol, Ethylenic (s. Ethylene, Hydrates of, p. 574).	—
Diethylin	—	Glycolaldehyde	908
Diethyl-chlorhydrin	—	Glycolic ethers	—
Ethyl-chlorobromhydrin	—	Glycollamide	—
Triethylin	884	Glycollic acid	909
Amylin	—	Glycollates	910
Amylchlor-, -brom-, and -iodhydrin	—	Derivatives of Glycollic acid:	
Diamylin	—	Acetoglycollic acid (p. 917).	
Ethylamylin	—	Benzoglycollic acid (i. 548).	
Polyglycerides	—	Bromoglycollic acid	912
Glycerin		Diglycollic acid	—
Formation and Preparation	887	Diglycolethylenic acid	914
Properties	—	Glycolic ethers	—
Uses	888	Methyl-glycollic acid	916
Impurities and Adulterations	—	Ethyl glycollic acid	—
Decompositions	889	Glycollate of Ethyl	917
Nitroglycerin	890	Amyl-glycollic acid	—
Glycerocitric acid	891	Phenyl glycollic acid	918
Glycero-oxalic acid	—	Cresyl-glycollic acid	—
Glycerophosphoric acid	—	Glycollide	—
Glycero-sulphuric acid	892	Glycols	919
Glycerotartaric acid	893	Glycosine	—
Glyceryl	—	Glycyrretin	—
Glyceryl, Bromhydrates and Bromide of (s. Bromhydrins, i. 667).	—	Glycyrrhizin	920
Glyceryl, Chlorhydrates and Chloride of (s. Chlorhydrins, i. 898).	—	Glyoxal	—
Glyceryl, Hydrates of	894	Glyoxaline	921
Diglycerin or Pyroglycerin	—	Glyoxylic acid	—
Chlorhydro-diethyl-pyroglycerin	—	Gmelinite	924
Triethyl-pyroglycerin	—	Gnaphalium	—
Triglycerin	—	Gneiss	—
Tetretethyl-triglycerin	895	Gökumite (s. Idocrase).	—
Diglycide, Pyroglycide, or Metaglycerin	—	Gold	—
Glyceryl, Iodhydrates and Iodide of (s. Iodhydrins).	—	Occurrence	—
Glyceryl, Oxide of	—	Extraction	925
Glyceryl, Oxygen-salts of (s. Acetins, Benzoin, Butyrins, &c.).	—	Properties	926
Glyceryl, Sulphhydrates of	—	Compounds	—
Glycide	—	Gold, Alloys of	—
Glycidic ethers	—	Gold, Bromide of	927
Amylglycide	897	Gold, Chlorides of	—
Ethyl-glycide	—	Chloraurates	928
Monobromhydroglycide or Epi-bromhydrin	—	Gold, Detection and Estimation of:	
Monochlorhydroglycide or Epi-chlorhydrin	898	1. Reactions	—
Mono-iodhydroglycide or Epi-iodhydrin	—	2. Quantitative Estimation and Separation	—
Dibromhydroglycide or Epidibromhydrin	899	3. Atomic Weight	929
Dichlorhydroglycide or Epidichlorhydrin	—	Gold, Iodides of	—
Chlorobromhydroglycide or Epi-chlorobromhydrin	—	Gold, Mannheim	930
Glycidyl	—	Gold, Metallurgy of (p. 925).	—
Glycocholic acid	—	Gold, Mosaic	—
Glycocholates	901	Gold, Oxides of:	
Paraglycocholic acid	—	Aurous Oxide	—
Glycocine or Glyocol	902	Auric oxide: <i>Aurates</i>	—
Metallic compounds of Glycocine	903	Gold, Oxygen-salts of	—
Compounds of Glycocine with Acids and Salts	904	Sodio-aurous and -auri-sulphites	931
Ethyl-glycocine	905	Baryto-aurous Hyposulphite	—
Dimethyl-glycocine	—	Gold, Phosphide of	—
Di- and Tri-glycollamic acids	—	Gold, Sulphides of	—
		Gold, Telluride of	—
		Gold-amalgam (p. 927).	—
		Gold-assay	932
		Gold-beater's skin	933
		Gold-beating	—
		Gold-purple: <i>Purple of Cassius</i>	—
		Golden Marcasite	939
